## AGRICULTURAL RESEARCH ADMINISTRATION

ADMINISTRATOR—E. C. Auchter

### OFFICE OF EXPERIMENT STATIONS

CHIEF—James T. Jardine

ASSISTANT CHIEF—R. W. Trullinger

## THE AGRICULTURAL EXPERIMENT STATIONS

ALABAMA— <i>Auburn</i> : M. J. Funchess. <sup>1</sup>	NEBRASKA— <i>Lincoln</i> : W. W. Burr. <sup>1</sup>
ALASKA— <i>College</i> : L. T. Oldroyd. <sup>1</sup>	NEVADA— <i>Reno</i> : S. B. Doten. <sup>1</sup>
ARIZONA— <i>Tucson</i> : P. S. Burgess. <sup>1</sup>	NEW HAMPSHIRE— <i>Durham</i> : M. G. Eastman. <sup>1</sup>
ARKANSAS— <i>Fayetteville</i> : C. O. Brannen. <sup>1</sup>	NEW JERSEY— <i>New Brunswick</i> : W. H. Martin. <sup>1</sup>
CALIFORNIA— <i>Berkeley</i> : C. B. Hutchison. <sup>1</sup>	NEW MEXICO— <i>State College</i> : Fabian Garcia. <sup>1</sup>
COLORADO— <i>Fort Collins</i> : H. J. Henney. <sup>1</sup>	NEW YORK—
CONNECTICUT—	State Station: <i>Geneva</i> : A. J. Heinicke. <sup>1</sup>
[New Haven] Station: <i>New Haven</i> : W. L. Slate. <sup>1</sup>	Cornell Station: <i>Ithaca</i> : C. E. F. Guterma. <sup>1</sup>
Storrs Station: <i>Storrs</i> : E. G. Woodward. <sup>1</sup>	NORTH CAROLINA— <i>State College Station, Raleigh</i> : L. D. Bayer. <sup>1</sup>
DELAWARE— <i>Newark</i> : G. L. Schuster. <sup>1</sup>	NORTH DAKOTA— <i>State College Station, Fargo</i> : H. I. Walster. <sup>1</sup>
FLORIDA— <i>Gainesville</i> : H. Mowry. <sup>1</sup>	OHIO— <i>Wooster</i> : Edmund Secrest. <sup>1</sup>
GEORGIA—	OKLAHOMA— <i>Stillwater</i> : W. L. Blizzard. <sup>1</sup>
Experiment: <i>H. P. Stuckey</i> . <sup>1</sup>	OREGON— <i>Corvallis</i> : W. A. Schoenfeld. <sup>1</sup>
Coastal Plain Station: <i>Tifton</i> : G. H. King. <sup>1</sup>	PENNSYLVANIA— <i>State College</i> : F. F. Lininger. <sup>1</sup>
HAWAII— <i>Honolulu</i> : J. H. Beaumont. <sup>1</sup>	PUERTO RICO—
IDAHO— <i>Moscow</i> : E. J. Iddings. <sup>1</sup>	Federal Station: <i>Mayaguez</i> : K. A. Bartlett. <sup>1</sup>
ILLINOIS— <i>Urbana</i> : H. P. Rusk. <sup>1</sup>	Insular Station: <i>Rio Piedras</i> : Arturo Roque. <sup>1</sup>
INDIANA— <i>La Fayette</i> : H. J. Reed. <sup>1</sup>	RHODE ISLAND— <i>Kingston</i> : M. H. Campbell. <sup>1</sup>
IOWA— <i>Ames</i> : R. E. Buchanan. <sup>1</sup>	SOUTH CAROLINA— <i>Clemson</i> : H. P. Cooper. <sup>1</sup>
KANSAS— <i>Manhattan</i> : L. E. Call. <sup>1</sup>	SOUTH DAKOTA— <i>Brookings</i> : I. B. Johnson. <sup>1</sup>
KENTUCKY— <i>Lexington</i> : T. P. Cooper. <sup>1</sup>	TENNESSEE— <i>Knoxville</i> : C. A. Mooers. <sup>1</sup>
LOUISIANA— <i>University Station, Baton Rouge</i> : W. G. Taggart. <sup>1</sup>	TEXAS— <i>College Station</i> : A. B. Conner. <sup>1</sup>
MAINE— <i>Orono</i> : F. Griffee. <sup>1</sup>	UTAH— <i>Logan</i> : R. H. Walker. <sup>1</sup>
MARYLAND— <i>College Park</i> : W. B. Kemp. <sup>1</sup>	VERMONT— <i>Burlington</i> : J. E. Carrigan. <sup>1</sup>
MASSACHUSETTS— <i>Amherst</i> : F. J. Slevers. <sup>1</sup>	VIRGINIA—
MICHIGAN— <i>East Lansing</i> : V. R. Gardner. <sup>1</sup>	<i>Blacksburg</i> : A. W. Drinkard, Jr. <sup>1</sup>
MINNESOTA— <i>University Farm, St. Paul</i> : C. H. Bailey. <sup>1</sup>	Truck Station: <i>Norfolk</i> : H. H. Zimmerman. <sup>1</sup>
MISSISSIPPI— <i>State College</i> : C. Dorman. <sup>1</sup>	WASHINGTON—
MISSOURI—	College Station: <i>Pullman</i> : E. C. Johnson. <sup>1</sup>
College Station: <i>Columbia</i> : M. F. Miller. <sup>1</sup>	Western Station: <i>Puyallup</i> : J. W. Kalkus. <sup>1</sup>
Fruit Station: <i>Mountain Grove</i> : P. H. Shepard. <sup>1</sup>	WEST VIRGINIA— <i>Morgantown</i> : C. R. Orton. <sup>1</sup>
Poultry Station: <i>Mountain Grove</i> : T. W. Noland. <sup>1</sup>	WISCONSIN— <i>Madison</i> : E. B. Fred. <sup>1</sup>
MONTANA— <i>Bozeman</i> : C. McKee. <sup>1</sup>	WYOMING— <i>Laramie</i> : J. A. Hill. <sup>1</sup>

<sup>1</sup> Director.

<sup>2</sup> Acting Director.

<sup>3</sup> Superintendent.

# EXPERIMENT STATION RECORD

EDITOR: HOWARD LAWTON KNIGHT

## EDITORIAL DEPARTMENTS

Agricultural and Biological Chemistry—H. C. WATERMAN, GEORGIAN ADAMS.  
 Agricultural Meteorology—F. V. RAND.  
 Soils and Fertilizers—H. C. KNOBLAUCH, H. C. WATERMAN.  
 Agricultural Botany, Diseases of Plants—H. P. BARSS, F. V. RAND.  
 Genetics—G. HAINES, H. M. STEECE, J. W. WELLINGTON.  
 Field Crops—H. M. STEECE.  
 Horticulture and Forestry—J. W. WELLINGTON.  
 Economic Zoology and Entomology—W. A. HOOKER, F. ANDRE.  
 Animal Husbandry, Dairying and Dairy Farming—G. HAINES.  
 Veterinary Medicine—W. A. HOOKER.  
 Agricultural Engineering—H. C. WATERMAN.  
 Agricultural Economics—F. G. HARDEN, B. YOUNGBLOOD.  
 Rural Sociology—B. YOUNGBLOOD, F. G. HARDEN.  
 Agricultural and Home Economics Education—F. G. HARDEN.  
 Foods and Human Nutrition, Home Management and Equipment—SYBIL L. SMITH, GEORGIAN ADAMS.  
 Textiles and Clothing—GEORGIAN ADAMS, H. M. STEECE.  
 Indexes—MARTHA C. GUNDLACH.  
 Bibliographies—CORAL FELDkamp.  
 Cooperation with *Biological Abstracts*—F. V. RAND.

## THE FIFTY-SIXTH CONVENTION OF THE ASSOCIATION OF LAND-GRANT COLLEGES AND UNIVERSITIES

The central theme of the 1942 convention of the Association of Land-Grant Colleges and Universities was the wartime responsibilities of these institutions—how they may aid and adjustments required. Not since the memorable session of 1917 had a convention been held under comparable circumstances, and inevitably these circumstances profoundly affected its location, its attendance, its program, and its reactions.

In a spirit of continued cooperation with efforts to avoid increasing congestion in the Nation's Capital, Chicago was selected as the place of meeting for the second consecutive year. The usual date was advanced in a readjustment due to a necessary shifting of hotels from the Stevens to the Drake following the preemption of the original quarters by the War Department. The general sessions took place from October 28 to 30, 1942, with preconvention assemblies of various constituent groups and committees scattered over the 5 days preceding.

On the whole the attendance was representative of the various institutions and interests, but for obvious reasons delegations tended to be curtailed to a minimum. Among those kept in Washington by the pressure of daily business was the Secretary of Agriculture, who had been scheduled to discuss the major significance and outstanding accomplishments of the Second Inter-American Conference of Agriculture (E. S. R., 87, p. 757). A brief message from him entitled Working Together for Victory was read by Dr. M. L. Wilson, Director of Extension Work. In this message Secretary Wickard pointed out that "the land-grant colleges and universities, which performed such notable services in the last war, are proving their ability to serve equally well in this one." He stated that "we in the Department are looking, as we always have looked, to the land-grant colleges and the Extension Service to help every farm family carry the wartime policies into action." "In fact," he added, "your group is the only one with the experience and the trained personnel for making the findings of research available to farm families."

The convention was opened with the address of the president of the association, President James D. Hoskins, of Tennessee, who took for his subject **A Unified Command and Democracy in Agriculture**. In this address the background of the acts establishing the land-grant institutions and the Department was reviewed. In his opinion "an identical philosophy of aid to agriculture inspired both acts and founded a national policy of cooperation between these two agencies, which has been maintained down the years." Acknowledging that "it is generally recognized that the exigencies of war require centralization of administration of certain powers and war programs to a degree unprecedented in peace," and that "our greatest task at the present time is to adjust our resident instruction, research, and extension activities toward winning this war," he nevertheless advocated "the restoration of the democratic relationship between the United States Department of Agriculture and the land-grant colleges and other departments and agencies of the Federal Government all along the line—as swiftly as possible in the post-war world." In conclusion he maintained that "in the democratic policy or pattern provided for in the Land-Grant College Act and the act creating the United States Department of Agriculture, and the cooperative relationship between them during the past 80 years, the land-grant colleges have made a great contribution to the development of the Nation's agriculture and industry. Their usefulness has continually increased. This relationship sets a pattern for all educational programs sponsored jointly by the Federal Government and the States. This relationship is essentially the democratic process in the development of educational programs for the masses of the people and is the basis of an enduring democracy and of democratic institutions."

As would be expected, much consideration was given by the convention and its constituent groups to the question of necessary immediate and post-war adjustments. Among the addresses scheduled for the general sessions were **The Utilization of the Facilities of the Land-Grant Colleges and Universities**, by President Edward C. Elliott of Purdue University; **Adjustments That Should Be Made in the Engineering Curricula for the War and Post-War Periods**, by Dr. W. E. Wickenden, president of the Case School of Applied Science; **Adjustments That Should Be Made in the Land-Grant Curricula Exclusive of Engineering**, by President W. C. Coffey of Minnesota; and **Agricultural Problems in the War and Post-War Periods**, by Dr. W. I. Myers, of Cornell University. Of these addresses, further mention may be made of that of President Coffey, in which he pointed out that "first, we must make haste slowly in shifting courses or in planning our research programs. . . . Second, we must be realistic and at the same time opportunistic. By that I mean that we must be able

and willing to shift and make curriculum adjustments when and only when the need is clear and has been definitely established. . . . Third, we must, in making adjustments, escape the danger that is involved in . . . dropping old and tested types of education. . . . Society can ill afford to tear down for the duration all of the tested disciplines upon which has been built the strength of our democracy and to substitute therefor a narrowly practical curriculum stressing only military measures to meet the present emergency."

Another topic of prominence was that of fostering increased relations with Latin America. This discussion was opened by Dean E. J. Kyle, of Texas, in an address before the general session entitled *The Mission of the Land-Grant Colleges in Promoting Our Good-Neighbor Policies Among the Latin-American Republics*, and subsequently further developed by him before the section of agriculture under the subject of *Our Relations to the Agricultural Economy of the Latin-American Countries and What It Means to Proper World Stabilization at the Close of World War II*. One session of the subsection of resident teaching was given over to a discussion of problems of cooperation, and a paper by Dr. R. H. Allee, Chief of the Division of Latin-American Agriculture of the U. S. D. A. Office of Foreign Agricultural Relations, was presented before the agricultural extension subsection on the subject *How Can the Extension Service Assist in Carrying Out the Recommendations of the Inter-American Conference on Agriculture at Mexico City?*

Dean Kyle presented brief notes as to the status of a considerable number of Latin-American educational and research institutions scattered from Mexico to Argentina as visited by him during the late summer and fall of 1941 under the auspices of the Coordinator of Inter-American Affairs. In general he found vast natural resources but an urgent need for trained specialists for their development. "I am thoroughly convinced," he declared, "that the United States has its best opportunity to promote complete and lasting understanding and friendship with our neighbors to the south by cooperating with them on a strictly practical basis in the development of their courses of study in agriculture, engineering, and in veterinary medicine, and in aiding them to better equip their physical plants and to strengthen their faculties."

Additional information was given by Dr. E. N. Bressman, head of the newly established Inter-American Institute of Agricultural Sciences (E. S. R., 87, p. 758) and by Dr. R. E. Moore, Assistant Director of the Office of Foreign Agricultural Relations, who, in a paper on *Agriculture in the Program of Inter-American Cooperation*, discussed the broad program which the United States Government has been developing through many agencies working under the gen-

eral supervision of the Interdepartmental Committee on Cooperation With the Other American Republics and specifically with those phases operated by the Department of Agriculture as regards the establishment of cooperative agricultural experiment stations, the inauguration of extension education, and the training of citizens of the several republics for eventually assuming the leadership in both the research and extension work. Already, he pointed out, "cooperative agricultural experiment stations are being inaugurated in Ecuador, El Salvador, Nicaragua, and Peru, to enable people of those countries to apply their own resources and ingenuity to the satisfaction of their economic needs. Every effort is being made to adapt these efforts to local conditions, but the work will be integrated in such a way that common goals may be achieved. Disease-resistant and high-yielding strains of rubber and other plants are being introduced. Many improvements in cultivation should result. Both the countries in which the stations are located and the United States are contributing certain portions of the equipment and personnel required. It is hoped that ultimately the direction of these stations will be in the hands of the people of the country themselves."

As usual all matters of association business were considered and decided by its executive body behind closed doors. The trend in recent years to apply similar methods of procedure to matters before the sections and subsections was continued and extended, so that much that went on is not available for comment. It is hoped, however, to present additional details of some of the research aspects in the February issue of the *Record*.

Announcement was made of the election as president for the coming year of President Edmund E. Day, of Cornell University. Dean and Director C. B. Hutchison, of California, was reelected vice president, and Dean and Director T. P. Cooper, of Kentucky, secretary-treasurer. President J. J. Tigert, of Florida, was reelected to the executive committee, and Dean O. J. Ferguson, of Nebraska, was succeeded on this committee by Dean M. L. Enger, of Illinois. A list of section officers and committee appointments may be found on page 143 of this issue.

# RECENT WORK IN AGRICULTURAL SCIENCE

## AGRICULTURAL AND BIOLOGICAL CHEMISTRY

[Chemical investigations by the Missouri Station] (*Missouri Sta. Bul.* 444 (1942), pp. 46, 47).—These include work on the polarimetric determination of lactose in milk, by E. R. Garrison; and on the use of petrographic microscope in studying the different types of lactose crystals in sandy ice cream, by W. H. E. Reid, C. W. Decker, and W. S. Arbuckle.

[Chemical investigations by the Nebraska Station] (*Nebraska Sta. Rpt.* [1941], pp. 41-43, figs. 2).—Baking characteristics of flour are reported upon by R. M. Sandstedt and K. Fortmann, and starch and amylase in flour, by Sandstedt, E. Kneen, and C. M. Hollenbeck.

Factors to be considered in quantitative polarography, I. M. KOLTHOFF. (Univ. Minn.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, pp. 195-200, figs. 5).—This paper is mainly concerned with those factors that are of primary importance when dealing with mixtures of electroreducible substances. In general, oxygen should be removed from the solution before electrolysis is started, as by passing nitrogen or hydrogen through the solution in the cell for from 10 to 20 min. or, in neutral or alkaline media, by adding solid sodium sulfite. In order to get reproducible results with the same capillary and the same solution, the pressure on the dropping mercury should be kept constant. The value of  $k$  in the relation  $i_d = kC$  ( $i_d$  being the true diffusion current and  $C$  the concentration) is considerably affected by a change of the solvent. In water-alcohol mixtures  $k$  is much smaller than in water. The diffusion currents of most substances increase by from 1.3 to 2.0 percent per degree increase in temperature, owing chiefly to the increase in the diffusion coefficient with increasing temperature. In order to find the true diffusion current the migration current has to be eliminated. This is done by making the concentration of the indifferent electrolyte about 50 times greater than that of the reduced ion. If the migration current is not eliminated, there is no longer proportionality between  $i_d$  and the concentration. For reasons discussed in some detail, the author prefers an outside reference electrode (the saturated calomel half-cell) to the use of a pool of pure mercury in the cell as an internal reference electrode. Numerous other matters of technic are taken up, together with their theoretical bases.

Some applications of the polarograph in soil investigations, R. W. CUMMINGS and J. F. REED. (Cornell Univ. coop. Ln. State Univ.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 167-170, figs. 4).—The authors briefly discuss the polarographic method as applied (1) to the determination of copper and zinc in plant ash, and (2) to the study of metal organic complexes as illustrated by the behavior of the ferric-ferrous-oxalate system. They believe that the polarographic method may prove serviceable in the study of some of the more complex oxidation-reduction changes occurring in soils.

Embedding specimens in methacrylate resins: A selected list of references with annotations, G. R. FESSENDEN and C. E. SANO (U. S. Dept. Agr., *Bur. Agr. Chem. and Engin.*, 1942, ACE-174, pp. [1]+9).—These references are divided into three sections—(1) those relating to processing data and to physical and chemical characteristics of methacrylate resins, (2) those describing speci-

men-embedding technic, and (3) those dealing with proposed use of these resins in microscopic preparations. Annotations have been included to facilitate finding the particular information sought. Some of the papers noted in section 1 discuss optical properties, scratch resistance, and other properties directly related to specimen mounting and use in microscopic work. Several of the papers listed as section 3 note shrinkage of the mounting medium with subsequent bubble formation in the mounts and the fading of certain stains.

**A cutter for spectroscopic electrodes**, E. S. HODGE. (Ky. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, p. 260, fig. 1).—The device described consists of two telescoping sleeves, of which the outer fits over the carbon to be cut, the inner sleeve, of an outside diameter the same as that of the carbon, fitting a drill which is to form the crater. The outer or centering sleeve is attached to the inner, and the inner sleeve to the drill, by means of setscrews.

**Dissolved oxygen recordings with the dropping mercury electrode**, R. S. INGOLS. (N. J. Expt. Stas.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, pp. 256–258, figs. 4).—The variations in the dissolved oxygen produce changes in the current flow which are amplified and recorded upon a thread galvanometer for a 24-hr. period. The curves showing the dissolved oxygen in activated sludge-sewage mixtures in the laboratory under different conditions demonstrated that the shape of the vessel can largely determine the efficiency of the gas used for aeration. The effect upon the dissolved oxygen of the addition of different quantities of the same food to activated sludge indicated that when more food is added there is no effect upon the dissolved oxygen unless or until the enzyme capacity is large enough to handle the increased load. The electrodes were placed in the aeration tank of an activated sludge-sewage treatment plant, and the dissolved oxygen levels at several points in the tank were recorded continuously for 24-hr. intervals. The first section of an aeration tank showed no dissolved oxygen during the day. The dissolved oxygen increased during the night. There was a relatively large volume of dissolved oxygen in the final section of the aeration tank with only slight variations over the 24-hr. period.

**Column for stripping solvents from extracted oils**, F. H. SMITH. (N. C. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, p. 255, fig. 1).—A glass apparatus for laboratory use is described. The solvent recovery from five samples is reported as having varied from 85 to 93 percent.

**Extraction of metals from aqueous solutions with dithizone, lead**, L. P. BIEFELD and T. M. PATRICK. (Purdue Univ.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, pp. 275–278, figs. 4).—The results of a series of studies on the effect of pH, diverse anions, and amount of reagent used in lead determinations with dithizone are reported. It was found that favorable pH ranges for extraction vary considerably with different masking anions, whereas only limited change occurs with variation in amount of excess reagent.

**Clay and colloid content determination of soils using a rapid photoelectric procedure**, M. L. JACKSON. (Wis. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 50–60, figs. 3).—The coarse and fine clay contents of 38 soils, representing a considerable number of great soil groups and localities, were determined by means of a rapid photoelectric turbidity procedure and by the conventional pipette and mechanical separation procedures for control and comparison. Dispersion was effected by treatment of the soils with  $H_2O_2$ , addition of  $NaPO_3$  solution, and shaking. The turbidity measurements were made with the Evelyn photoelectric colorimeter, with a 6,600 a. u. wavelength light filter, in the selected test tubes ordinarily used with this instrument. Turbidity was defined as log

$_{10}G_0/G$ ,  $G_0$  and  $G$  being the galvanometer readings of the suspension medium (water) and the suspension, respectively. Turbidity was found to be proportional to concentration for low concentrations of a given suspension. The procedure consisted of two centrifugings of a suitably diluted aliquot of soil suspension for periods computed by the Stokes formula and reading the turbidity at 10 cm. for clay ( $<2\mu$ ) and at 3 cm. for fine clay ( $<0.2\mu$ ). The turbidity due to coarse clay ( $2\mu$ - $0.2\mu$ ) was computed as the difference between these measurements. All turbidity readings were reduced to a uniform basis of unit dilution per gram of soil.

Turbidity measurements for coarse clay correlated closely with the percentage of coarse clay found by control methods. The correlation coefficient was  $+0.97$ . Turbidity measurements for fine clay correlated less closely with the percentages of fine clay, but when the soils were placed into two groups, by separating one group of poorly aerated soils low in free iron oxides from the others, the correlation was satisfactory. The percentages of fine clay from the turbidity and control methods had a correlation coefficient of  $+0.98$ .

**Semiquantitative estimation of montmorillonite in clays**, S. B. HENDRICKS and L. T. ALEXANDER. (U. S. D. A.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 95-99, figs. 2).—Competitive saturation of montmorillonites and micaceous materials by the calcium and ammonium ions, the piperidine and hydrogen ions, and the ceric and hydrogen ions is reported upon as a basis for estimations. The  $Ce^{++} - II^+$  distribution was found to be the most useful of the three for estimation of montmorillonites. In equivalent concentrations the micaceous materials preferentially take up  $II^+$ , while the montmorillonites take up much more of the  $Ce^{++}$ . A knowledge of the quantities of both these ions held, together with the total exchange capacity, permits an estimate of the amount of montmorillonite present in mixtures.

**Determination of  $K_2O$  in commercial fertilizers, using 95 and 80 per cent alcohol and acid-alcohol**, O. W. FORD and C. W. HUGHES. (Ind. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, pp. 217-218, fig. 1).—The authors find a definitely larger potassium value to be obtained with 95 percent in place of 80 percent alcohol in the determination of potassium in fertilizers by the Official method. This difference for fertilizers of from 12 to 40 units of plant food ranged from 0.13 to 0.19 percent  $K_2O$ . For potassium chloride samples there was an average difference of 0.23 percent in favor of the use of 95 percent alcohol.

**Phospholipids in dairy products.—I, Determination of choline in milk fat**, J. C. CRANE and B. E. HORRALL. (Ind. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 8, pp. 651-658).—A microtechnic, based on a modification of the Roman method for the determination of choline, was found to be applicable to the analysis of extracted milk fat for choline, thus providing a method for the determination of choline-bearing phospholipids in dairy products.

**A colorimetric method for estimating the quality of butter.—A preliminary report**, G. KNAYSIL and E. S. GUTHRIE. (Cornell Univ.). (*Jour. Dairy Sci.*, 25 (1942), No. 7, pp. 589-593).—The described test, which is a measure of the degree of hydrolysis of butterfat, consists in dissolving 1 cc. of the melted milk fat in chemically pure xylol saturated with the base of neutral red and comparing the color with standards containing known quantities of oleic acid. It is found useful for quickly detecting bad samples and the majority of fair or good samples of butter and should prove a valuable adjunct to organoleptic judging.

**A new colorimetric method for the determination of free fatty acids in milk fat**, V. N. KRUKOVSKY and G. KNAYSIL. (Cornell Univ.). (*Jour. Dairy Sci.*, 25 (1942), No. 8, pp. 659-661).—A more detailed description of the method noted above, with supporting data.

**Evaluating starches for textile purposes**, W. T. SCHREIBER and W. L. STAFFORD. (U. S. D. A. and Ala. Polytech. Inst.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, pp. 227-231, figs. 7).—Procedures for evaluating starches for use on fabrics include methods for judging the starch mixtures from a processing or plant operating viewpoint and methods for evaluating the quality of starched fabrics. The former may be used for measuring the stickiness of starch mixtures during ironing and the penetration of such mixtures, the latter to measure the transparency of starch films and to determine the smoothness, stiffness, and resistance to crushing of starched fabrics. These methods may also be used to advantage in evaluating other sizing or finishing agents. Apparatus for each of these tests is described and illustrated by photograph.

**Ultraviolet absorption of vitamin A in various solvents**, F. P. ZSCHEILE and R. L. HENRY. (Ind. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, pp. 422-425, figs. 2).—Absorption values, obtained by a procedure described as to instruments, source of irradiation, slit widths employed, derivation of  $E_{1\text{ cm.}}^{1\%}$ , and purification of reagents, are presented by graph for vitamin A in diethyl ether and various alcohols and of vitamin A palmitate in ethanol from 2,240 to 3,760 a. u. Similar data are presented for solutions in several hydrocarbon solvents. The numerical  $E_{1\text{ cm.}}^{1\%}$  values for all preparations in the solvents studied, at wave lengths 3,260 and 3,280 a. u., are tabulated. The absorption curves showed that for most solvents a definite inflection appeared in the region of 3,150 a. u., this being more pronounced for one sample of vitamin A than for the other samples examined. With one exception, the maximum of absorption was found at wave lengths shorter than 3,280 a. u., usually at 3,260 a. u. These findings, it is noted, are slightly different from the wave length of 3,280 a. u. usually given for the maximum. The curves of all preparations examined in the region of lower wave lengths had a second maximum. These results and others cited indicated that small differences exist among the most carefully prepared samples of vitamin A and that the solvent has a definite effect upon the maximum absorption value.

**A simple, rapid method for determination of leaf carotene**, O. F. CURTIS, JR. (Cornell Univ.). (*Plant Physiol.*, 17 (1942), No. 1, pp. 133-136, fig. 1).—A fresh leaf sample, dipped in boiling water for 1 min to prevent subsequent oxidation, is blotted to remove excess water and extracted with petroleum ether containing about 2 percent of methyl alcohol by grinding with quartz sand in a mortar. The extract is decanted, and the extraction is repeated with small successive portions of the solvent until no more pigment is removable. Separation of the pigments is accomplished by a chromatographic adsorption technic, using soluble starch as the adsorbent. The leaf extract is poured on the prepared column, suction is applied, and the chromatogram is developed with petroleum ether. Carotene, carotenoids, and colorless fat-soluble substances pass through the column almost completely, leaving the chlorophyll and xanthophylls in the column. The solution obtained is used without purification for quantitative measurement of the carotene by means of the photronic colorimeter. With this method the colored impurities are of no concern. It is pointed out that the carotenoid fraction of many leaves consists only of  $\beta$ -carotene; other carotenes if present rarely comprise more than 10 percent of the fraction. The method is accurate and rapid, and by the use of several adsorption columns connected with an aspirator through the same suction flask several determinations may be conducted at one time. Critical attention to the preparation of the

adsorbent is not required, and the adsorption column may be regenerated with ether to serve for at least five separations.

**Some assays of provitamin A carotenoids**, G. MACKINNEY, S. ARONOFF, and B. T. ROENSTEIN. (Univ. Calif.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, pp. 391-395, figs. 3).—"An endeavor is made to present the problem of provitamin A carotenoid determination in plant materials in broad perspective. Results on carrots, spinach, tomatoes, apricots, peaches, and prunes are discussed, particularly with reference to preservation practices. The problem is essentially that of  $\beta$ -carotene determination, because  $\alpha$ -carotene is at best a minor contributor and cryptoxanthin is important only in special instances. Each material presents a different problem, sometimes of extraction, but more frequently in effective removal of interfering pigments without vitamin activity. The answer then is found in selection of suitable adsorbents with the proper solvent, and separation is made on small Tswett columns over which  $\beta$ -carotene or cryptoxanthin may be passed without adsorption, but where other pigments are effectively adsorbed. Because data on vitamins are so frequently interpreted in terms of human needs, and much effort is being devoted to vitamin surveys at the behest of State nutrition committees, the significance of the various findings is briefly evaluated in terms of bio-assay and nutrition."

**Resynthesis of biotin from a degradation product**, D. B. MELVILLE, K. HOFMANN, and V. DU VIGNEAUD. (Cornell Univ.). (*Science*, 94 (1941), No. 2439, pp. 308-309).—The diaminocarboxylic acid obtained as a degradation product of biotin through treatment with  $\text{Ba}(\text{OH})_2$  was converted back to biotin through a reaction employed for the synthesis of urea derivatives, namely, through treatment with phosgene. The resynthesized biotin, obtained as a crystalline product from the reaction mixture in 98 percent yield, was shown to be identical in melting point, optical activity, and biological potency with the natural product, indicating that little or no racemization took place during the  $\text{Ba}(\text{OH})_2$  treatment of the biotin. The synthesis of biotin from the diamino compound afforded additional and conclusive proof for the cyclic urea structure in biotin.

**The extraction of biotin from tissues**, R. C. THOMPSON, R. E. EAKIN, and R. J. WILLIAMS (*Science*, 94 (1941), No. 2451, pp. 589-590).—Six methods of extraction were applied in tests involving the use of liver, brain, and muscle tissues; egg yolk (plain and dialyzed); egg white saturated with biotin; and cells of *Pseudomonas fluorescens* and *Clostridium butylicum*. Biotin yields from these materials, subjected to the different treatments including hot and cold water extraction, autolysis, acid hydrolysis, enzyme digestion for 24 and 48 hr., and alkaline hydrolysis, indicated that the surest method for extracting biotin consisted in drastic acid hydrolysis (6 N acid at 120° C. for 2-5 hr. or at 15 lb. pressure for 1 hr.). Alkaline hydrolysis was unsuitable, since it brought about a gradual destruction of the vitamin. Prolonged heating with acid also caused some destruction. Beef and rat liver were found to have a biotin content of about 3.5  $\gamma$  per gram of dry tissue, this value being many times higher than values previously reported.

**A color reaction for dehydroascorbic acid useful in the determination of vitamin C**, J. H. ROE and C. A. RUETHER (*Science*, 95 (1942), No. 2455, p. 77).—The reaction described involves the reaction of 1 cc. of a dilute acetic acid solution of dehydroascorbic acid with 1 cc. of a saturated solution of 2,4-dinitrophenylhydrazine in 85 percent  $\text{H}_3\text{PO}_4$ . After 5 min. 8 cc. of concentrated  $\text{H}_2\text{SO}_4$  is added. A red color develops, and the reddish colored product shows maximum absorption at 500-550  $m\mu$  and 350-380  $m\mu$ . The proportionality of the color obtained in the reaction is in good agreement with Beer's law, and the reaction has been used, therefore, in a simple and rapid colorimetric method for the deter-

mination of ascorbic acid. Possible interfering substances are pentoses, glucose, and fructose, but only in concentrations much greater than those usually obtained in acid extracts of plant and animal tissues. Furthermore, the absorption curves of the xylose, glucose, and fructose derivatives of 2,4-dinitrophenylhydrazine and also of this reagent itself show practically complete transmission in the wave lengths at which the red color obtained from dehydroascorbic acid is compared. The reaction, therefore, is considered specific for the determination of ascorbic acid.

**Fruit as sugar savers in candy making.** W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 11, pp. 324-325, 349).—Dried fruits, it is pointed out, contain from 50 to 65 percent of sugar and are, therefore, excellent substitutes for sugar in certain kinds of candy to which they are adapted. Several formulas found satisfactory on a small scale are given for uncooked, dried fruit candies made with some sugar; fruit rolls made from dried fruit and a little honey, orange concentrate, or invert or other heavy sirup as a binder; and fruit jelly candies made from fruit pulp or juice, sugar, invert or glucose sirup, and fruit pectin as the jellying agent.

**Chemical composition of Arkansas-grown American grapes.** H. REYNOLDS and J. E. VAILE (*Arkansas Sta. Bul.* 420 (1942), pp. 53, figs. 3).—Total solids, sugar, acid, ash, alkalinity of ash, tannin, total astringents, and pH were determined and juice color descriptions recorded for juices extracted by hot-pressing 62 varieties of American grapes grown at the main station vineyard during 1938-41. Data showing the relative composition and color of hot- and cold-pressed juices from a number of varieties are included. Additional data from the analysis of Concord grapes dealing with the effect on juice composition of holding grapes before pressing, size of sample, uneven ripening, thinning and dormant pruning, comparative composition of the juice and whole fruit, and comparative composition of fruit from the main station vineyard with that from other vineyards in northwestern Arkansas are also reported. Samples for analysis were taken at the earliest date when edible and sufficiently colored to meet the standards for U. S. No. 1 table grapes (eastern type).

**The chloroacetic acids as preservatives for apple juice.** F. W. FABIAN and E. F. BLOOM. (Mich. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 10, pp. 292-296).—In experiments described it was found that unclarified apple juice had from 40 to 50 times more micro-organisms present than clarified juice, and that after about 7 days neither the unclarified nor the clarified juice was salable as fresh apple juice, the former because of alcoholic fermentation and the latter because of acetic acid fermentation. Mono-, di-, and trichloroacetic acids in this order exhibited decreasing preserving actions in tests with the two types of apple juice. In comparative trials benzoic acid and monochloroacetic acid had about the same preserving action under practical conditions, though the growth of micro-organisms was inhibited to a somewhat greater extent by the benzoic acid. Both chemicals were more effective against yeasts than against acid-producing bacteria. "Monochloroacetic acid apparently has no superior preserving qualities over sodium benzoate and has the disadvantage of being an adulterant and its use prohibited by law."

**Results of a demonstration sale of fruit juice blends.** H. G. BEATTIE and C. S. PEDERSON. (N. Y. State Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 8, pp. 227, 240, 251, 253).—A summary of consumer questionnaires indicated favorable response to the five fruit beverages prepared in the fruit juice laboratory at the New York State Station and offered for sale to a limited group consisting of people experienced in judging fruits and fruit flavors. The juices included apple juice, apple-raspberry juice, cherry cocktail prepared

as previously directed (E. S. R., 79, p. 583; 85, p. 848), a cherry-apple juice, and a plum-apple juice. Directions are given for the preparation of the two latter juices, both of which are clarified products. The cherry-apple blend was made in much the same way as the cherry cocktail except that apple juice was used as the diluent instead of water.

**Cider-apple jelly**, S. G. DAVIS, C. R. FELLERS, and A. S. LEVINE. (Mass. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 9, pp. 260-261, 283, fig. 1).—This paper presents production details of an investigation to develop a satisfactory cider-apple jelly. "A cider-apple jelly of highly desirable taste, flavor, and color was prepared by adding sweet Baldwin cider, concentrated to one-third its original volume, to the heat-extracted apple juice from an equivalent weight of apples. The amount of dry sugar added was about 60 percent of the weight of the apple stock used. The remainder of the sugar was naturally present in the added cider. The mixture of the concentrated cider, extracted apple juice, and sugar was concentrated by boiling to a soluble solids content of 68 percent by the usual jelly manufacture procedure." Details of the formula and procedure for obtaining this jelly are presented.

**The effect of certain substances and pretreatments on the retention of color and sulphur dioxide by dried cut fruits**, E. M. MRAK, C. D. FISHER, and B. BORNSTEIN. (Univ. Calif. et al.). (*Food Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 10, pp. 297-299, fig. 1).—Since poor retention of color in dried apricots has been associated in part at least with poor  $\text{SO}_2$  retention, a sodium citrate (5 percent) dip, applied before or after cutting but before sulfurizing, was tested and found to favor  $\text{SO}_2$  retention during drying. The fruit in some but not all cases retained a better color for a longer time than any of the samples dipped in other solutions (water, trisodium phosphate, sodium bicarbonate, calcium hydroxide, tartrate, or citric acid) or sprayed with the sodium citrate or given no treatment.  $\text{SO}_2$  retention apparently did not account entirely for color retention, since not all samples retained good color and since loss of  $\text{SO}_2$  during storage (50-percent loss in 6 mo.) was not accompanied by color loss. A 30-sec. dip of whole fruit in 5-percent sodium citrate solution favored color retention, but a 5-min. immersion period apparently caused excessive leaching, since color retention was poor.

**Souring of dried dates by sugar-tolerant yeasts**, C. R. FELLERS and J. A. CLAGUE. (Mass. State Col.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 11, pp. 326-327, 347, figs. 2).—Sour dates, characterized by being soft, dark-colored, and matted together, and having a peculiar aromatic odor and poor flavor, were obtained for examination from lots imported from Iraq and Algeria. Saprophytic molds, yeasts, and sporulating bacteria, but far more yeasts than bacteria, were found present. Six types of sugar-tolerant yeasts, representative of the many types encountered, were isolated, characterized, and shown, through reinoculation into sound, pasteurized dates of high moisture content, to produce typical souring. The Khadrawy variety was more prone to souring than the Halawy or Sayer varieties. Although yeasts, mainly *Torula* and *Willia*, were largely responsible for the souring, *Acetobacter* were often present as secondary invaders. The yeasts did not produce souring in dates if the moisture was below 25 percent; 23 percent is suggested as a safe moisture maximum for market dates. The pasteurization of dates effectively destroyed all the date-souring yeasts.

**Rapidly refreshing dehydrated vegetables**, J. SUGIHARA and W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 8, pp. 233-240, fig. 1).—Vegetables dehydrated with and without preliminary blanching were cooked for 10-, 15-, 20-, 30-, and 40-min. intervals, the drained weights

being recorded for each time interval to determine the rate of resorption of water. The results showed that blanching aided the rate of regain of water and that, with the possible exception of the leafy vegetables, the limiting factor for complete cooking was the rate of absorption of water. Most of the vegetables blanched long enough to cook completely could be cooked in 15 min. without presoaking. In all cases the blanched, refreshed products were equal or superior to the unblanched in color, odor, and flavor. In unblanched vegetables soaked overnight the production of a tender product upon cooking was inhibited, due apparently to enzymatic activity.

**Public health compliance by manufacturers of paper for packaging perishable foods, J. R. SANBORN.** (N. Y. State Expt. Sta.). (*Jour. Milk Technol.*, 5 (1942), No. 2, pp. 88-93).—An investigation in 1937-38 of the bacteriological condition of paperboard used for milk containers showed that most of the 22 mills investigated were able to meet with fair consistency a standard of less than 500 colonies per gram, while several of the largest producers met a standard of less than 250 colonies. An investigation in 1941-42 of 4 of the 7 or 8 mills continuing to make milk-container board showed a maximum count of 140; in 2 of the mills 81 and 90 percent of the tests, respectively, gave counts between 0 and 10. Studies of the experiences of these and other mills showed that the growth of micro-organisms in pulp, paper, and paperboard could be effectively controlled by locating the origin of contamination and focal points of growth and by persistently applying efficient remedies and control, from raw stock, through the various processes, including the final step of calendering. References cited concern mixers found suitable for disintegration of paperboard, microbiological methods satisfactory for determining the bacteriological content, interpretation of the counts, and standards for the paper products.

## AGRICULTURAL METEOROLOGY

**Temperature contrasts in the United States, S. S. VISHNER** (*Sci. Mo.*, 55 (1942), No. 3, pp. 239-244, figs. 8).—Wide contrasts with respect to several significant temperature conditions in the United States are shown by the accompanying maps, based on data for 40 yr. (1890-1938), and most of them using records from about 5,000 stations. Data are shown on the maps for the average January temperature ranges, average annual minimum temperatures, lowest temperatures, average depth of frost penetration, average length of the frost-free period, average July temperature, highest temperatures experienced during the normal summer, and the highest shade temperatures officially recorded. Seven major influences noted for the pronounced regional contrasts in temperature are latitude, length of day and night, altitude, the ocean, inland water bodies (especially the Great Lakes), atmospheric humidity and soil moisture, and normal wind direction.

**Effects of the Great Lakes on the annual march of air temperature in their vicinity, J. LEIGHLY.** (Univ. Calif.). (*Mich. Acad. Sci., Arts, and Letters, Papers*, 27 (1941), pp. 377-414, figs. 17).—In this discussion, and particularly in the accompanying maps, the author reports an investigation of the thermal influences of the Laurentian Great Lakes on the annual cycle of air temperatures over the lands about them. Being concerned mainly with the general problem of the role of these lakes in the heat economy of the atmosphere above and about them, it has necessarily dealt with the most general qualities of the annual march of temperature. However, attention is also called to climatic elements of some immediate practical importance that would yield to the cartographic procedure used, such, e. g., as the average maximum and minimum

temperatures at the extremes of the annual march, maximum and minimum temperatures at times that are critical in relation to certain crops and on days to which some particular interest may attach, and on precipitation. In all such climatic phenomena it should be possible to dissect out the effects of the lakes and to make more precise the rather indefinite impressions that are now the only available basis for statements concerning their climatic influence.

**Rainfall evaluation as an aid to irrigation interval control, J. A. SWEZEY** (*Hawaii. Planters' Rec. [Hawaii. Sugar Planters' Sta.], 46 (1942), No. 2, pp. 75-100, figs. 11*).—The evaluation of normal amounts of rainfall as supplementary irrigations on Hawaiian sugarcane lands has for years been attained by individual judgment, and thus influenced largely by personal considerations. More recently studies of soil moisture and cane growth relationships have indicated that a program of regular, routine soil-moisture observations could be expected to provide information relative to the elapsed time between successive irrigations which would furnish the cane plant with water at the most efficient frequencies on a basis of the commercial product. In September 1939 at Waipio a rain of 1.54 in. in a 24-hr. period fell on 32 experimental plats which had a considerable variation in their initial soil moisture contents. An opportunity was thus afforded to analyze the effects of this rain toward replenishing soil moistures under the varied conditions existent. From this analysis a set of curves, one for each 0.1-in. increment of rainfall, was derived which would correct an irrigation interval for such rainfall as might occur at any time between scheduled irrigations. The elapsing interval and the correction for rainfall were expressed in day-degrees, so as to take advantage of this method of gaging intervals, the correction to be deducted from the elapsed interval. These corrections were further tested and adjusted in the field for 2 more years and a method of rain evaluation said to be both workable and practical is offered which combines scientific theory, recognition of the character and influence of conditions observed in the field, and a reasonable degree of conservatism.

The derivation of the adjustments for use at Waipio are described in detail, and rules are presented for operating a day-degree-measured irrigation interval with the aid of the adjustment table. In the course of deriving the adjustments, a revised concept of the term "permanent wilting percentage" is discussed, and the significance of the "wilting range" in affecting the method of applying the interval adjustments is presented. Eight other adjustment tables are included which it is believed should provide for evaluating rainfall on soil types differing from that at Waipio. Experimentation to determine the local optimum interval is suggested as an adjunct to successful use of the table most suited to a given soil type.

**Centuries-long tree indices of precipitation in the Southwest, I, II, E. SCHULMAN.** (*Univ. Ariz.*). (*Amer. Met. Soc. Bul.*, 23 (1942), Nos. 4, pp. 148-161, figs. 11; 5, pp. 204-217, figs. 6).—Tree-ring series, if proved to be climatic records, have much potential value, but significant dendrochronological work must recognize the importance of selection of specimens and cross-dating of records. Douglas fir was found to be one of the best recorders of precipitation, and this species and ponderosa pine form the basis of the present study. Synchronous fluctuation in annual growth is illustrated in many selected trees in the southwestern United States. Curves of mean annual growth are given for five areas, covering 300-560 yr. Growth curves are shown to represent to a marked degree the recorded year-to-year fluctuations in winter precipitation for five representative areas of the Southwest. The precipitation spectrum of wet and dry years appeared nearly identical at nearby and at high- and low-level stations. In the Southwest, trees under the climatic stress of precipitation deficit may disagree in ring

chronology with others a few yards away but not under climatic stress, yet may closely parallel trees on difficult sites 400 miles away. Summer precipitation in this area, roughly 50 percent of the annual total, has little influence in general on variations in ring thickness in Douglas fir and ponderosa pine, and no general effects of annual temperature variations were found in the ring records. Tree growth in the Gila River headwaters provided a centuries-long and closely approximate index of runoff. Comparisons of chronologies across 400 miles north-south and 250 miles east-west emphasized that even in regions of generally similar climate there is a changing areal domain under the influence of drought in different years—a persistent feature of the three centuries of data. A method is suggested for quantitatively delineating a homogeneous dendrochronological area, interpretable as a climatic unit. The average duration of excess (wet) or deficient (dry) growth in the Southwest is about 8-9 yr., on the basis of the last three centuries of data. Since 1640 about 4 percent of the years there are characterized by extreme winter droughts with growth less than half the normal, and about 15 percent of the years show growth less than three-fourths of normal. In some areas the absence and in others the presence of the sunspot cycle in tree growth leads to the suggestion of a possible relation to climatic latitude.

**Climatic types of California, according to the decimal scheme of world climates, W. GORCZYNSKI** (*Amer. Met. Soc. Bul.*, 23 (1942), No. 4, pp. 161-165, fig. 1).—As shown in the accompanying chart the author distinguishes 5 large climatic groups divided into 10 types. The limits of each type are given, and the occurrence of each type and group in California and the peninsula of Baja California and throughout the world are tabulated, together with the world areas having the best climatic type. An example for computing the aridity factor is presented.

**Monthly Weather Review, [May-June 1942]** (*Mo. Weather Rev.* [U. S.], 70 (1942), Nos. 5, pp. 93-115, pls. 10; 6, pp. 117-151, pls. 10, figs. 14).—In addition to meteorological, climatological, solar radiation, and sunspot data, these numbers contain the following contributions: No. 5, Oxygen Deficiency in Antarctic Air, by E. E. Lockhart and A. Court (pp. 93-96); and No. 6, The Heavy Rains Over Southeast Texas, November 22-25, 1940, by J. H. Ferguson (pp. 117-133).

**Central Snow Conference** (*Cent. Snow Conf. Proc.*, 1 (1941), pp. VII+214, figs. 95).—The following papers are of interest to agricultural meteorology: The Role of Snow, Ice, and Frost in the Hydrologic Cycle, by R. E. Horton (pp. 5-21); The Melting of Snow, by J. E. Church (pp. 21-31) (Nev. Expt. Sta.); Some Factors in Relating the Melting of Snow to Its Causes, by W. T. Wilson (pp. 33-41); Preliminary Study of Radiation Penetration Through Snow, by I. F. Hand and R. E. Lundquist (pp. 42-44); The Influence of Snow Cover on Air Temperature, by H. Landsberg, G. P. Cressman, and H. K. Saylor (pp. 45-49); Upper Limits of Snow Melting, by P. Light (pp. 49-51); Relationships of Winter Weather to Farmland Wildlife in the Midwest, by D. L. Allen (pp. 95-102); Snow and Game in Northern Michigan, by I. H. Bartlett (pp. 102-105); Snow and Ice Conditions Affecting Forest Game, by H. F. Olson (pp. 105-107) (U. S. D. A.); The Effect of Openings in a Young Lodgepole Pine Forest on the Storage and Melting of Snow, by C. H. Niederhof and E. G. Dunford (pp. 108-109) (U. S. D. A.); Snow in Its Relation to Silviculture, by J. N. Spaeth (pp. 109-112) (Univ. Ill.); The Influence of Snow Cover on Fruit Production, by N. L. Partridge (pp. 113-115) (Mich. Sta.); Observations on Snow Cover as Affecting Farm Crops, by P. O. Ripley (pp. 116-123a); Snow Utilization in Prairie Agriculture, by G. D. Matthews (pp. 127-133); Economic Significance of Snowfall and Snow Retention on Western Watersheds, by W. W. McLaughlin (pp. 134-135) (U. S. D. A.); Snow Ridging to Conserve Moisture, by T. E. Long (pp. 136-137) (N. Dak. Agr. Col.); Seasonal

Fluctuations of Precipitation Intensity Frequency Values in the Ohio Valley, by R. E. Allen (pp. 138-151) (U. S. D. A.); Snowfall—Maps of Canada, by A. J. Connor (pp. 153-159a); Snow Measurement in Pennsylvania, by L. F. Conover (pp. 160-165); and Some Characteristics of Winter and Non-Winter Floods in the St. Lawrence River Drainage Basin, by W. G. Hoyt (pp. 176-190). Most of the articles are followed by discussions.

## SOILS—FERTILIZERS

**Federal-State cooperation in soil-plant research, E. C. AUCHTER.** (U. S. D. A.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 3-7).—This is a general discussion dealing with advantages of closer relationships among soil scientists and between them and scientists in other fields, this viewpoint being illustrated by a number of examples of successful cooperation between Federal and State research institutions.

[**Soil investigations by the Arkansas Station**] (*Arkansas Sta. Bull.* 417 (1942), pp. 5-6, 17-18, fig. 1).—Results of investigations of soil and water losses under different types of cropping methods are reported by R. P. Bartholomew and D. G. Carter. Experiments with phosphates in various areas of the State indicate that application of phosphates will result in increased yields on upland soils.

[**Soil investigations by the Missouri Station**] (*Missouri Sta. Bul.* 444 (1942), pp. 76-79, 80, 81-88, figs. 2).—Progress of crop rotation and fertilizer experiments are reported by W. A. Albrecht and G. E. and N. C. Smith; value of timothy hay as sheep feed in response to the soil treatment, by A. G. Hogan, Albrecht, and G. Norwood; land classification of Missouri, by H. H. Krusekopf; permanent pastures, by C. E. Marshall, Albrecht, N. C. Smith, and R. A. Struchtemeyer; the determination and mapping of Missouri soil types—soil survey, by Krusekopf, W. D. Shrader, and E. M. Springer; the best systems of soil management for the most important soil types in Missouri, by G. E. and N. C. Smith; the utilization of cornstalks and straw in soil building, by Albrecht and G. E. Smith; finely ground limestone for agricultural purposes, by Albrecht; effects of different soil treatments, long continued, upon bacterial activity in the soil, by Albrecht and D. R. Browning; a study of the nature of soil structure and its influences upon soil tillage, by C. M. Woodruff; the properties of colloidal material in Missouri soils, by Marshall, Albrecht, E. R. Graham, and C. E. Ferguson; soil erosion, by Krusekopf and Woodruff; and nitrogen fixation in soils by legumes, by Albrecht, Graham, and Ferguson.

[**Soil investigations by the Nebraska Station**] (*Nebraska Sta. Rpt.* [1941], pp. 6-12, figs. 4).—Progress of work on soil erosion control and soil moisture conservation is reported upon by F. L. Duley and J. C. Russel (coop. U. S. D. A.); results of various tests with different commercial fertilizers, by M. D. Weldon and J. W. Fitts; soil profile studies, by H. F. Rhoades and H. W. Smith; factors affecting the permeability of soils to water, by Rhoades and Fitts; and nitrate studies and soil organic matter, both by Weldon.

[**Soil investigations by the Texas Station**]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 23, 105-107, 122-124).—Experiments are noted on nitrification, by G. S. Fraps and A. J. Sterges; and soil and water conservation. Investigations at the Tyler Substation, by J. B. Pope and [J. C.] Archer, and at the Temple Substation, by W. J. Peevy.

**Soil Survey of Iowa.**—Reports 80-82 (*Iowa Sta. Soil Survey Rpts.* 80 (1941), pp. 56, figs. 14, map 1; 81 (1941), pp. 84, figs. 28, map 1; 82 (1942), pp. 51, figs. 15, map 1).—The three reports here noted continue the series (*E. S. R.*, 84, p. 298), recording survey data obtained in Decatur County, by R. W. Simonson.

and in Marion and Ida Counties, by Simonson and T. H. Benton, and which supplement the Federal soil surveys (E. S. R., 82, pp. 18, 154, 591).

**Soil survey of Albany and Schenectady Counties, New York,** C. LOUNSBURY ET AL. (Coop. [N. Y.] Cornell Expt. Sta.). (U. S. Dept. Agr., Bur. Plant Indus. [Soil Survey Rpt.], Ser. 1936, No. 16, pp. 79, figs. 2, map 1)

**Illinois loess—variations in its properties and distribution: A pedologic interpretation,** G. D. SMITH (*Illinois Sta. Bul.* 490 (1942), pp. 137-184, figs. 15).—Primary attention was given in this progress report to the distribution of the loess deposits and to the relation between the character of these deposits and the distance from their source.

It is concluded that (1) differences in the texture of the loess bear, within limits, a linear relation to the logarithm of the distance from the river bluffs. (2) The rate of the thinning of the loess with the distance from its source is a linear function of the logarithm of the distance. (3) The carbonate content of the loess decreases as the loess becomes thinner. The relation between the carbonate content and the loess thickness is expressed by the equation  $Y = a - \frac{b}{X}$ , when  $Y$  equals the percentage of carbonates,  $X$  equals the thickness of the loess,  $a$  equals the carbonate content of the loess at the time of deposition, and  $b$  equals the loss of carbonates by leaching during the period of deposition. (4) The carbonate loss due to leaching during the deposition of the first quarter of the Peorian loess was approximately half as great as the leaching loss in the entire period subsequent to the loess deposition, showing that there was a very slow deposition of the loess. (5) The differences in the profiles of the grassland soils found in loess deposits of varying thicknesses are attributed to the differences in the age of that portion of the loess in which the solum is developed and to a possible influence of the substratum either through direct mixing with the loess by animals or through the return of bases or other nutrient elements to the surface by the grasses. (6) Many of the Prairie soils are not in equilibrium with their environment, the direction of their development being toward the condition of the Planosols.

**Soil structure effects in the growth of sugar beets,** L. D. BAYER and R. B. FARNSWORTH. (Ohio Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 45-48, figs. 3).—On the heavy clay soils of northwestern Ohio from blocking and thinning time to harvest losses of nearly 50 percent were experienced on plats where the noncapillary porosity was as low as 2 percent by volume. Soils with poor aeration produce short, stubby beets with many auxiliary roots. Well-aerated soils produce long, tapering beets. Soils with noncapillary porosities exceeding from 7 to 10 percent produce good tonnages of beets with high sugar contents. Increased aeration may be effected by turning under sod crops or manure, by surface applications of organic materials, or by ridging. The presence of organic matter in the surface of the soil not only causes a higher content of noncapillary pores but also preserves this favorable structural condition throughout the season. Maximum beneficial effects of fertilizers on this soil cannot be expected unless the structure of the soil is so improved as to permit adequate aeration for the growing beet.

**Comparison of absorbent materials employed in the electrical resistance method of making a continuous measurement of soil moisture under field conditions,** G. J. BOUYOUKOS and A. H. MICK. (Mich. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 77-79, fig. 1).—Substances considered as possible substitutes for plaster of paris were cement, concrete, marble dusts, dental casting compounds, and lime plasters. Laboratory examination of these materials, however, showed that compared to plaster of paris their rate of moisture

absorption and, therefore, the establishment of an equilibrium between block moisture and soil moisture was relatively slow. The concrete block, for example, required 80 min. to become saturated when completely immersed in water as against 25 sec. required by plaster of paris. An examination of plaster of paris blocks buried and in use for three continuous seasons has shown that the tendency to soften is not of great practical importance. It appears that because of its physical structure, its solubility characteristics, and its cheapness and ease of handling, plaster of paris is at the present time the most satisfactory absorbent material for the resistance method of measuring soil moisture.

**A field comparison of the electrothermal and gypsum block electrical resistance methods with the tensiometer method for estimating soil moisture in situ.** R. W. CUMMINGS and R. F. CHANDLER, JR. (Cornell Univ.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 80-85, figs. 7).—Four tensiometers, six thermocouples, and six of each of the other moisture indicator units were installed at the 3-, 6-, 15-, and 30-in. depths below the surface of a sod plat on a Dunkirk silty clay loam soil. Natural-structure cores of the soil were used to obtain detector current- (electrothermal) moisture content and electrical resistance-moisture content curves in the laboratory. Electrothermal data showed extreme variability between units and did not, in this investigation, give a satisfactory measure of soil moisture conditions in the field. Laboratory studies made on isolated soil blocks by this method, on the other hand, gave universally satisfactory results. The difficulty of obtaining and maintaining adequate contact between soil and heating unit under field conditions seemed to be the principal source of difficulty. Gypsum blocks gave a rather satisfactory picture of the trend of soil moisture conditions. The possibility of calibrating the resistance of the gypsum blocks in terms of soil moisture tension and thus following actual tensions through drier ranges than can be measured by tensiometers is demonstrated. Variability in resistance readings from blocks placed under similar conditions seems to be due to inherent variability in the block itself and to the fact that the electrical current conductance path is partially outside the block. The possibility of redesigning the blocks so as to reduce these effects and thereby increase precision is suggested.

**Movement of water through soils in relation to the nature of the pores.** W. R. NELSON and L. D. BAVER. (Ohio Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 69-76, figs. 7).—The first objective of the work here recorded was to ascertain what actually happens in the drainage of pores, the second to show the relation of pore size to percolation rate.

Experimental investigations and theoretical analyses show that the permeability of the soil is related (1) to the volume of the pores drained at the flex point, (2) to the tension of the flex, (3) to the size distribution of the pores up to the flex point, and (4) to the continuity of the soil pore space. Additional investigations are necessary to clarify many of the doubtful points in soil-pore space relationships.

**Effect of mulches and surface conditions on the water relations and erosion of Muskingum soils.** H. L. BORST and R. WOODBURN. (Coop. Ohio Expt. Sta.). (*U. S. Dept. Agr., Tech. Bul.* 825 (1942), pp. 16, figs. 8).—Straw incorporated into the soil at rates of 1, 2, and 4 tons per acre effected little or no reduction in runoff or soil loss when artificial rain was applied at about 2¼ in. per hour. The application of artificial rain to soil sealed by either natural or artificial rain resulted in a high percentage of runoff and heavy erosion.

Shallow cultivation to break the crust increased infiltration and reduced erosion. Application of a straw mulch at the rate of 2 tons per acre to a sealed soil (crusted surface) increased infiltration only slightly more than cultivation but afforded a nearly complete control of erosion. Application of a straw mulch at the same rate to a soil with the surface crust broken resulted in a high rate of infiltration and a very low soil loss. The straw mulch protected the soil surface from the impact of raindrops and from the formation of an impervious layer on the soil, caused largely by their dispersing action. The mulches also reduced the velocity of overland flow. The effect of the straw mulch on infiltration seemed to be in proportion to the amount of surface covered. In controlling erosion, 1 ton per acre was nearly as effective as 2 tons. Cornstalks applied at a rate of about 2 tons per acre, laid across the slope, were nearly as effective in controlling both soil and water losses as was straw at 1 ton per acre. The tests show that the surface condition has a pronounced effect on water intake.

**Variability of eroded material,** C. S. SLATER and E. A. CARLETON. (U. S. D. A. coop. N. Y. State Expt. Sta.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 4, pp. 209-219).—For information on the extent to which eroded material differs in quality and texture from its original soil, a series of soil losses and the corresponding plat soils have been analyzed texturally and for their organic-matter content. Under conditions favorable to infiltration, texture of eroded material has been coarser than that of the corresponding soil, but under conditions of greater impermeability eroded material has been finer. These differences tend to disappear as erosion increases, and the composition of the eroded material approaches the composition of the soil. Irrespective of texture, eroded material has been shown to be somewhat higher in organic-matter content than the eroding soil, especially where small runoffs are incurred. This anomaly has been shown to be the result of organic debris that is removed preferentially by the eroding process. If the effect of organic debris is discounted, colloidal material removed by erosion has essentially the same organic-matter content as the colloidal material of the eroding soil.

**Lysimeter studies: The translocation of cations in the profile of a Gray-Brown Podzolic soil,** J. S. JOFFE. (N. J. Expt. Stas.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 187-190).—Calcium and magnesium movements showed a seasonal character, the elements concentrating during the period August through October, with the highest translocation rate in March. The movement of potassium through the A<sub>1</sub> horizon did not show this definite seasonal trend, but low and high rates appeared to alternate monthly. There was some evidence of an August maximum. The sesquioxides showed a behavior similar to that of the calcium and magnesium. Data concerning sodium were obtained during but 1 yr., as compared with 9 years' figures for the elements previously named. Most of the sodium came from the precipitation, but some appeared to be released from sodium feldspars. The quantity of manganese found appeared to decrease with increase in that of the alkaline earth bases.

**Base exchange capacity determination as influenced by nature of cation employed and formation of basic exchange salts,** C. A. BOWER and E. TRUOG. (Wis. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 86-89, fig. 1).—The exchange capacities of the clay fractions of Miami silt loam and of a montmorillonite sample were determined by means of the cations of a monovalent group consisting of hydrogen, sodium, potassium, and ammonium, and of a polyvalent group consisting of barium, strontium, calcium, magnesium, beryllium, copper, manganese, zinc, ferric iron, lanthanum, and thorium. Results obtained with ammonium, calcium, and magnesium were also determined for a variety

of other clays. Exchange capacity values, determined by means of polyvalent cations, were significantly higher than those determined by means of monovalent cations. Results obtained with monovalent cations were in good agreement. Those obtained with polyvalent cations were values increasing with decreases in the strength of the bases which the respective cations form. The data obtained show that the weak base-forming, polyvalent cations form basic salts with the relatively weak clay acid to a degree depending upon the strength of base which the cation in question forms, and thereby give high exchange capacity values. It is believed that the results obtained may have considerable significance in connection with the determination of base exchange capacity and also the availability and toxicity of certain nutrient elements.

Soil reaction as a basis for certain land management practices: A symposium. (Coop. U. S. D. A. et al.). (*Fla. Univ. Agr. Ext. Misc. Pub. 30* (1942), pp. 36, figs. 6).—The contents of this publication consist of a foreword by R. V. Allison and discussions of Factors Affecting the Soil Sampling Procedure, by G. M. Volk and M. Peech (pp. 4-12); Routine Field Sampling and Notes, by A. White, E. L. Ayers, and R. E. Norris (pp. 13-16); Methods of Determination of Soil pH, by R. A. Carrigan (pp. 17-31); and of A Method of Reporting Results to the County Agent and to the Grower, by E. F. Debusk and L. H. Rogers (pp. 32-33), followed by a general discussion of the topics noted by H. G. Clayton, W. E. Stokes, A. F. Camp, and R. P. Thornton.

Nitrogen fixation by *Azotobacter* as influenced by molybdenum and vanadium, C. K. HORNER, D. BURK, F. E. ALLISON, and M. S. SHERMAN. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 4, pp. 173-193, figs. 6).—Several strains of *Azotobacter* were grown in nonaerated solution cultures to determine the effect of vanadium and molybdenum on nitrogen fixation. Additions of optimum molybdenum resulted in a tenfold to thirtyfold increase in nitrogen fixation with eight strains of *A. chroococcum* and one strain of *A. vinelandii*. Nitrogen fixation was increased twofold with two strains of *A. agile* and three of *A. vinelandii* because of the presence of molybdenum. The presence of molybdenum usually resulted in slight increases in the nitrogen content of the cells. The effective concentration range for molybdenum and vanadium was found to vary from 0.00001 or 0.0001 p. p. m., which gave a detectable effect with *A. chroococcum*, to about 1 p. p. m., which gave maximum growth in 6 days. With younger cultures the range was appreciably narrower, 0.005-0.01 p. p. m. giving maximum growth for 1-day cultures. The concentration range for vanadium was approximately the same as for molybdenum, but the maximum effect was only from 50 to 80 percent of that produced by molybdenum. The effect of other elements to molybdenum response was similar to that obtained by other workers in establishing that both iron and molybdenum must be present in optimum concentrations for maximum growth and fixation. Manganese was found to have no appreciable effect on *Azotobacter* in the presence or absence of molybdenum.

Colony variation in actinomycetes under constant environmental conditions, K. L. JONES (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 255-258).—Colonies of five strains of soil actinomycetes were grown from single conidia on media of known composition under controlled environmental conditions. New series of plates were inoculated every 3 weeks for 1.5 yr. Variations were numerous but proved mostly temporary. The only permanent variations (six) were saltation mutations. There has been, so far, no difficulty in maintaining relatively constant strains. The activity lost from prolonged culture on laboratory media was restored by transferring to sterilized soil. There was no evidence that colony characteristics could not be considered trustworthy criteria in the delineation of these "species" of actinomycetes.

**Studies on plant food availability in alkaline-calcareous soils: Seedling tests and soil analysis.** W. T. MCGEORGE (*Arizona Sta. Tech. Bul. 94 (1942), pp. [2]+375-418, figs. 12*).—A comparison of the quantitative removal of phosphate, potassium, and calcium from alkaline-calcareous soils by various crops showed a good relative agreement for rye, barley, wheat, and tomatoes and a fair relative agreement for rye with cowpeas, corn, and hegari. There was a good correlation between the availability of phosphate, calcium, and potassium as measured by the carbonic acid method and the availability values obtained from the Neubauer (E. S. R., 53, p. 319) test. Factors found to be related to or to influence the absorption of these three ions were (1) phosphate absorption increases with decrease in pH, decrease in water-soluble calcium, carbonic acid-soluble calcium, and calcium carbonate; (2) potassium absorption increases with decrease in pH value; (3) calcium absorption increases with decrease in pH value; (4) phosphate Neubauer values correlate with the carbonic acid-soluble phosphate and with the calcium Neubauer values; (5) potassium Neubauer values correlate with increase in calcium Neubauer values, carbonic acid-soluble potassium, and replaceable potassium; and (6) calcium Neubauer values correlate with carbonic acid-soluble calcium and calcium carbonate but inversely with replaceable calcium. In varying the weight of soil in each 100-plant Neubauer culture there was observed a steady increase in phosphate value or milligram PO<sub>4</sub> per 100 plants up to from 80 to 100 gm. of soil, above which the value was closely constant. For potassium the Neubauer potassium value was closely constant above 100 gm. of soil. For calcium the Neubauer value curve showed less constancy, reaching maximum values at from 40 to 90 gm. soil, beyond which it decreased. When both number of plants and weight of soil are varied in the Neubauer test, the value on the basis of 100 plants decreases as the number of plants and weight of soil are increased. The curves obtained, both for phosphate and for potassium, on plotting values obtained by maintaining the number of plants constant at 100 and increasing the weight of soil per culture, showed practically horizontal curves above from 80 to 100 gm. of soil; the absorption was at a maximum and practically constant above this. It is believed that some point below 100 where the values are steadily increasing, possibly 50 gm. of soil, would give more satisfactory values.

✓ **The chemical composition of some pasture and hay plants as affected by soils and fertilizers.** B. A. BROWN and E. A. HOLLOWELL. ([Conn.] Storrs Expt. Sta. and U. S. D. A.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 131-139).—Reviewing work not only of the [Connecticut] Storrs Experiment Station but also, with respect to some of the hay plants, of a number of other stations, the author shows the variations with locality and with other factors in the composition of grasses and legumes. Phosphorus was the element most frequently present in extremely small quantities. Causes either of acidity or of alkalinity of the soil may make the soil phosphate difficultly available to the hay plants, but the total phosphate of the soil may often be low enough to permit remarkable effects of phosphatic fertilization on grassland. The lasting qualities of such treatments are emphasized. It has been demonstrated that an application of 16 percent superphosphate at 500 lb. per acre on the run-out pastures of northeastern United States will increase the quantity and quality of the herbage for at least 14 yr. When superphosphate is the source of phosphorus, there is usually an increase in the calcium content of the grasses or legumes. In most of the humid areas calcium is the next most important limiting element. Evidence of the adequacy of the available potassium supply in soils for forage plants is much more conflicting than it is for phosphorus and calcium. The tables contain many examples of wide differences in the potassium content of plants

due to variations in soils or fertilization. There is some evidence that the land run out by grazing is much less in need of potassium than are adjacent areas depleted by removing the hay. However, on light soils or on soils under tillage for many generations the successful growing of forage plants, particularly legumes, depends upon conserving and returning manure to the land or on applying potassic fertilizers. Minor element deficiencies appear to have been more common among legumes than grasses.

The composition of corn, oats, and wheat as influenced by soil, soil treatment, seasonal conditions, and growth, F. M. STUBBLEFIELD and E. E. DETURK. (Ill. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 120-124, figs. 4).—It was found, in part, that percentages of the various elements tended to vary inversely with yields, while removal per acre varied directly with yields, except that potassium, reflecting the soil supply, increased in percentage on the plats supplied with crop residues, lime, rock phosphate, and potassium, coincident with larger yield. Weather conditions had a marked effect, crops grown on the same plat in succeeding years sometimes varying as much in chemical composition as crops grown on different plats. The maintenance of reasonably high producing capacity of soil thus tends to stabilize crop composition. Nitrogen and phosphorus are found primarily in the grain of the cereal crops, potassium and calcium in the straw, and magnesium and sulfur approximately equally distributed.

Relation of soil composition to plant and animal deficiencies (*Texas Sta. Rpt. 1941*, pp. 23-24).—Deficiencies in forage samples are reported upon by J. F. Fudge and G. S. Fraps. .

Response of young corn plants to inorganic phosphates differing in solubility.—I, The effect of phosphorus absorption from rock phosphate on the composition and dry weight of corn at three growing stages, S. R. DICKMAN and E. E. DETURK. (Ill. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 213-219, figs. 3).—Variations in the amount of coarse rock phosphate in a sub-irrigated substrate of quartz particles resulted in corresponding variations in the phosphorus composition of the plants at each of three samplings. The percentage of phosphorus in plants which utilized fine rock phosphate, however, was higher at the first sampling and lower at the second and third samplings than in those plants which utilized coarse rock phosphate. The greatest root increases during the first period were made by plants which utilized rock phosphate as the sole source of phosphorus, but at later stages the roots of plants which received continuous soluble phosphate made the greatest increases. A phosphorus limitation factor is obtained by dividing the dry weight increase per milligram of phosphorus absorbed by the soluble phosphate plants into the corresponding values of the rock phosphate plants, and serves as a relative index of the phosphorus level in the plant. Values greater than one indicate that phosphorus was deficient, while values less than one demonstrate that phosphorus was absorbed in excess of the ability of the plant to utilize it for dry weight production. In rock phosphated plants the phosphorus limitation factor was highest at the first sampling and then decreased regularly. This indicates an adjustment of the metabolism of the plant to the low phosphorus uptake. In those plants which utilized rock phosphate, the proportional decrease in phosphorus content during the second period was greatest in those which contained the highest percentage of phosphorus at the first sampling. This trend was reversed during the final period, and a critical percentage of phosphorus (0.137) at the second sampling was found, above which plants increased in phosphorus content during the final period, and below which they decreased. No quantity of rock phosphate was found capable of producing plants containing as high a

percentage of phosphorus as that of the plants which received 20 p. p. m. of soluble phosphate in the nutrient solution. Plants which grew on the highest rock phosphate treatment approached 0.17 percent phosphorus as the maximum, about half of that found in plants which received soluble phosphate and about half that found ordinarily in field-grown corn.

It is considered erroneous to judge responses to phosphates on the basis of dry weights or plant measurements only; phosphorus uptake must be determined and the percentage of phosphorus in the tissues considered before any general conclusions regarding phosphorus fertility can be drawn.

**Phosphate fixation in soils**—a critical review, A. R. MINGLEY. (Univ. Vt.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 24-30).—The author analyzes and compares experimental results and findings of numerous investigators, drawing conclusions of which the following are a part:

Though there is experimental support for the view that phosphate ions may be fixed by replacing hydroxyl ions in the crystal lattice of bentonite and to a greater degree because of the presence of more replaceable hydroxyl groups, those of kaolinite, the author points out that it is difficult to distinguish such adsorption from chemical precipitation, especially in face of the fact that the crystal structure of kaolinite is known to be altered by its fixation of phosphate. The hydroxyl ion is quite effective in replacing or liberating adsorbed phosphate, but in some instances it is likely that the fixing complex was partly dissolved due to increased alkalinity. Liberation of fixed phosphate by the citrate ion also may be due to its dissolving effect since citric acid quite readily dissolves iron phosphate, and although silicates applied to phosphate-deficient soils have appeared to increase phosphate availability, the evidence thus far reviewed indicates that the silicate may dissolve rather than actually replace the native phosphate in soils. The author does not concur in the view that soluble iron and aluminum in acid soils are the main agents which render phosphate slowly soluble and difficultly available to plants for the reasons (1) that free iron and aluminum ions are not, except in very acid or alkaline soils, present in the soil solution in quantities such as to account for the speed at which fixation takes place, and (2) that freshly precipitated iron and aluminum phosphates are known to be quite readily available to plants. Slightly soluble and difficultly available phosphates may more probably be formed by union of the phosphate with undissolved hydrated oxides of iron and aluminum. Lack of phosphate availability in alkaline calcareous soils seems to be due to a carbonate-phosphate complex rather than simple tricalcium phosphate. Fluorophosphate or fluorapatite may also form under such conditions, because fluorine is apt to be present in underground waters of calcareous soils, and it reacts quite readily with tricalcium phosphate when alkaline to form fluorophosphate. Since superphosphate also contains active fluorine, care should be exercised in producing nonacid-forming fertilizers because fluorophosphate also forms under these conditions.

**Availability of fixed potassium as influenced by freezing and thawing**, L. O. FINE, T. A. BAILEY, and E. TRUOG. (Wis. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 183-186).—Net releases of as much as 150 lb. of potassium per acre (2,000,000 lb.) resulted from freezing and thawing treatment in about two-thirds of the soils studied. In some instances a fixation of potassium resulted, however, and in others no change was detected. The addition of lime tended to inhibit the release of fixed potassium upon freezing. Increasing the nonexchangeable potassium content of a Chlico soil by a potassium fixation treatment caused a release of potassium upon freezing slightly greater than when the soil was not so treated. When subjected to the freezing treatment,

most of the clay minerals allowed the release of considerable proportions of the nonexchangeable potassium which they held as a result of fixation treatments, a fact considered to indicate that some of the soil minerals of high base-exchange capacity may be active in the release of nonexchangeable potassium in soils upon freezing. Illite, however, appeared to retain its nonexchangeable potassium despite the freezing treatment. The clay of Miami garden soil, containing much nonexchangeable potassium and consisting perhaps largely of illite, also tended to retain its nonexchangeable potassium when subjected to the freezing treatment. Carrington soil, of which the clay fraction appeared to consist of approximately 40 percent illite, showed the same tendency. Illite may be a mineral of which the exchangeable potassium becomes nonexchangeable during freezing.

The absorption of potassium in soils in non-replaceable forms, L. K. Wood and E. E. DeTurk. (Ill. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 5 (1940), pp. 152-161, figs. 3).—Dipotassium phosphate and potassium chloride were added at rates ranging from 0 to 9,775 p. p. m. to each of six Illinois soil types representing widely different stages in soil development. The extent and nature of the fixation of the added potassium was determined after 8-, 16-, 25-, and 52-week periods of moist contact at room temperature. Replaceable potassium was determined by leaching with ammonium acetate, with or without previous removal of the water-soluble potassium compounds by leaching with 60 percent methanol. Of potassium fixed by the soil, that held in an acid-soluble combination was extracted by boiling with normal nitric acid solution and the acid-insoluble fraction determined by difference. The potassium was precipitated as the cobaltinitrite (E. S. R., 81, p. 326) and titrated by a hexanitratammonium cerate method not yet published.

The three forms were found to be in a slowly shifting equilibrium with each other, equilibrium being reached after from 16 weeks to 1 yr., depending on the soil used and the amount of potassium added. Shifts in the equilibrium apparently occurred by the law of mass action, as increasing additions of soluble potassium caused increasing shifts to fixed forms. The native replaceable and acid-soluble potassium ranged from large to very small amounts in passing from young dark-colored soils to those in late stages of development. The capacity to fix potassium in acid-soluble form after additions decreased with increasing stage of development. The gains in acid-insoluble potassium following additions were more nearly uniform but not consistent. The more mature soils tended to reach equilibrium more quickly than the young soils. There was a tendency of the fixation to go beyond the equilibrium point, usually at 16 weeks, then to rebound to equilibrium. Previous fertilizer treatments in the field, including potassium applications for many years, had little effect on the reactions involved. The associated anion exerted a pronounced effect on the water-soluble-replaceable equilibrium, and it also affected the ratio of acid-soluble to acid-insoluble potassium. These relations were greatly modified by the nature of the soil, and the results gave some clues as to the nature of the reactions involved in potassium fixation.

It is pointed out that the fact that potassium fixation as it is found in Illinois soils is an equilibrium reaction is of great importance in the potash economy of soils. This investigation has made it evident that in many soils fixation is not an objectionable phenomenon from the farmer's standpoint, but rather that it is a means of conservation of added potassium by holding it in forms which are relatively insoluble, but which, being in equilibrium with the replaceable form, return to that form as it is depleted by growing crops. Other Illinois soils in

which potassium fixation is undoubtedly detrimental to crop utilization of potash fertilizers are known, however.

**Calcium- and sulfate-ion concentrations in a soil receiving excess gypsum, as influenced by several factors,** I. E. VANONI and J. P. CONRAD. (Univ. Calif.). (*Soil Sci.*, 53 (1942), No. 2, pp. 125-133, figs. 2).—The authors treated 2-kg. portions of soil, containing an excess of gypsum, with 1 l. each of distilled water alone, of three concentrations of  $\text{CaCl}_2$ , and of five concentrations of  $\text{K}_2\text{SO}_4$ . Each of the nine solutions was also allowed to remain in contact with an excess of gypsum alone. The effect of changing ionic strength on the solubility of gypsum was approximated by making 2:1 extracts from soils to which KCl solutions had been added. A comparison of the extracts of equivalent total anionic concentrations contained when calcium chloride, potassium sulfate, or potassium chloride was added indicated an approximately constant ion concentration product for gypsum in solutions of equal ionic strength and showed the effect of increasing ionic strength on the solubility of gypsum. To simulate the effect of biologically produced acids on the solubility of gypsum in soils, because of the calcium and other ions brought into solution, various concentrations of HCl were added to lots of soil containing an excess of gypsum. The effect of varying water content on a soil system containing a given amount of calcium chloride and an excess of gypsum was explored over a wide range of soil-water ratios.

The concentrations of Ca and  $\text{SO}_4$  ions found were, within reasonable limits, explicable in terms of solubility-product and ionic-strength phenomena.

**Boron in some Hawaiian soils and crops,** T. TANADA and L. A. DEAN. (Hawaii Expt. Sta.). (*Hawaii. Planters' Rec. [Hawaii. Sugar Planters' Sta.]*, 46 (1942), No. 2, pp. 65-74, fig. 1).—Distribution of total and water-soluble boron, the availability of water-soluble boron, and the fixation of boron in Hawaiian soils are considered in this article. Information is also given on the boron content of various agricultural crops.

Both the total and the water-soluble boron were found to be highest in surface soils—4 to 56 and 0.4 to 3.2 p. p. m., respectively. Old eroded soils from regions of heavy rainfall had the most total boron, but generally the soils with high total boron had a low water-soluble boron content. A normal crop of sugarcane was found to remove from the soil less than 0.5 lb. of boron per acre.

**Are there possibilities in subsoil fertilization?** R. J. BORDEN (*Hawaii. Planters' Rec. [Hawaii. Sugar Planters' Sta.]*, 46 (1942), No. 2, pp. 59-64).—Results of Mitscherlich tests are given for soil samples collected from areas where cooperative field tests were conducted. Samples were taken from each of two depths, i. e., from 0 to 12 in. designated as surface soil and from 12 to 24 in. as subsoil. Acknowledging the limitations of the method used, the author points out that without nitrogen or  $\text{P}_2\text{O}_5$  or  $\text{K}_2\text{O}$  there was only one instance where the subsoils yielded as well as the surface soils, but that well-fertilized subsoils were made to produce yields which were not significantly different from similarly fertilized surface soils.

**Using crop residues for soil defense,** F. L. DULEY and J. C. RUSSEL. (Coop. Nebr. Expt. Sta.). (*U. S. Dept. Agr., Misc. Pub.* 494 (1942), pp. 16, figs. 27).—An illustrated publication on the utilization of crop residues as a means of conserving soil and water. Crop residues are defined to include materials such as stubble, straw or stalks from various crops, or even old weed growth. Adjustments and modifications of farm equipment to carry out the program for effective utilization of crop residues are described in detail. Data on the effect of the various treatments on soil and water losses and crop yields, soil moisture, and soil structure are given.

**Filter-cake compost,** J. P. MARTIN (*Hawaii. Planters' Rec. [Hawaii. Sugar Planters' Sta.]*, 46 (1942), No. 2, pp. 53-58, figs. 3).—Data are presented from

investigations to determine the rate of decomposition of filter cake under field and laboratory conditions and the nutritive value of filter cake compost. Filter cake is defined as a byproduct of sugar production and is the filtered residue obtained from clarifying raw cane juices.

### AGRICULTURAL BOTANY

[Botanical studies by the Missouri Station] (*Missouri Sta. Bul.* 444 (1942), pp. 51, 81, fig. 1).—Brief reports of progress are given on work by D. I. Allen on the physiological causes of relative adaptations among soybean varieties, with special reference to mineral nutrition; and on photoperiod effects on lespedeza by G. E. Smith.

[Botanical studies by the Texas Station]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 20–21, 21–23, 115–116).—Brief reports, by V. L. Cory, H. B. Parks, A. H. Alex, and C. E. Minarik, are included on studies of the adaptability of native plants, with special reference to those suspected of possible use for stabilization of blowing sand areas; plant survey of the State with special reference to economic usage; tests of canaigre and other plants for tannin; native vegetation in relation to the livestock industry, and miscellaneous physiological studies of rice.

**Bibliography of the botany of New York State, 1751–1940, II, H. D. HOUSE** (*N. Y. State Mus. Bul.* 329 (1942), pp. 175–233).—It was found necessary to publish additional titles (E. S. R., 86, p. 751), along with indexes to biographical citations, species, localities, and subjects mentioned, and an author index covering both parts. These matters are here presented.

**A botanical survey of the upper Columbia River region, Washington, H. T. ROGERS** (*Wash. State Col. Res. Studies*, 10 (1942), No. 2, pp. 99–140, fig. 1).—Following introductory remarks and general discussions of the topography, geology, and vegetation of the area, an annotated catalog arranged by plant families is presented.

**Proceedings of the Eighth American Scientific Congress** (8. *Amer. Sci. Cong., Washington, 1940, Proc., vol. 3*, pp. 125–132, 135–192, 199–206, 223–242, 251–274, 277–278, 279–283, 287–294, pls. 15, figs. 6).—The following papers are of interest to agricultural botany: The Life Forms and Flora of the North American Desert, by F. Shreve (pp. 125–132); Plant Tissue Cultures—A New Technique in Experimental Science, by P. R. White (pp. 135–142); Central and South American Potatoes for the Improvement of European and North American Stocks, by E. K. Balls (pp. 143–147); New Discoveries of Myriangiales in the Americas [10 new species of *Elsinoc* described], by A. A. Bitancourt and A. E. Jenkins (pp. 149–172) (U. S. D. A. et al.); Induced Evolution in Plants Through Chromosome Changes, by A. F. Blakeslee (p. 173); Los frutos de las especies silvestres de *Arachis* [The Fruits of Wild Species of *Arachis*], by A. Burkart (pp. 175–178); Pesquisas taxonômicas sobre os gêneros *Pseudananas* e *Ananas* [Taxonomic Study of the Genera *Pseudananas* and *Ananas*], by F. C. Camargo (pp. 179–192); Genetic Interpretations of Cultural Variations in the Fungi, by B. O. Dodge (pp. 199–206); Experimental Induction of Heritable and Other Alterations in the Fungus *Neurospora tetrasperma* (pp. 223–229), and The South American Genetic Groups of the Genus *Nicotiana* and Their Distribution (pp. 231–238), both by T. H. Goodspeed (Univ. Calif.); What the Study of the Green Plant Has Taught Us Concerning a Mechanism of Photosynthesis, by O. L. Inman (pp. 239–242); Cotton Breeding in Relation to Taxonomy, by T. H. Kearney (pp. 251–255) (U. S. D. A.); The Cultivation of Hevea Rubber in Tropical America, by W. E. Klippert (pp. 257–262); Mangosteen Cultivation, by W. R. Lindsay (pp. 263–265); The Origin of Maize, by P. C. Mangelsdorf (pp. 267–274); Vitamins as Growth Substances for Plants, by W. J. Robbins (pp. 277–278); The Presence

of *Azotobacter agilis* in North and South America, by S. Soriano (pp. 279-283); and Temperature Reaction, Mutation, and Geographical Distribution in Plant Groups, by O. E. White (pp. 287-294).

**Reclaiming agar for bacteriological use**, A. F. ROE (*Science*, 96 (1942), No. 2479, p. 23).—It is claimed that by the procedure briefly outlined a product may be obtained that is actually superior to the common commercial crude agar. When a sufficient quantity of waste agar for immediate processing is not available it may be dried and stored.

**Reclamation of used agar**, H. I. THALER. (U. S. D. A.). (*Science*, 96 (1942), No. 2479, pp. 23-24, fig. 1).—Using the method described, it is estimated that 75-80 percent of the waste agar is recovered, including the initial loss adherent to flasks in pouring. The product has been tested in other laboratories with over 30 different micro-organisms and the results have been reported as uniformly satisfactory.

**Bacterial activity in dilute nutrient solutions**, C. E. ZOBELL and C. W. GRANT. (Univ. Calif.). (*Science*, 96 (1942), No. 2486, p. 189).—As a result of studies summarized in this preliminary note, it is believed that under proper conditions concentrations of utilizable organic matter considerably smaller than 0.1 mg./l. will provide for bacterial multiplication. Solid surfaces seemed to facilitate assimilation of dilute nutrients.

**The productions of two antibacterial substances, fumigacin and clavacin**, S. A. WAKSMAN, E. S. HORNING, and E. L. SPENCER. (N. J. Expt. Stas.). (*Science*, 96 (1942), No. 2487, pp. 202-203).—In a study of the presence of antagonistic fungi in nature, more than 160 cultures with such properties were isolated from soils, manures, and composts and separated into nine groups on the basis of their taxonomic and physiologic relationships. Among them, two species producing active substances were studied in detail: Fumigacin, isolated from *Aspergillus fumigatus*, proved especially active against gram-positive bacteria, and clavacin, isolated from *A. clavatus*, was particularly active against gram-negative bacteria. Their properties are briefly described. Unlike most substances of this type, clavacin possesses high bactericidal as well as bacteriostatic activity.

**The separation and characterization of carotenoid pigments produced from mineral oil by bacteria**, H. F. HAAS, L. D. BUSHNELL, and W. J. PETERSON. (Kans. Expt. Sta.). (*Science*, 95 (1942), No. 2477, pp. 631-632).—A new adsorption technic was developed for the separation of petroleum-soluble carotenoids from mineral oil. Four carotenoids were separated as products of bacterial metabolism with mineral oil as the sole C source, and two of them possessed vitamin A potency. No xanthophylls were present, but one pigment was definitely shown to be astacin, a carotenoid found primarily in crustacea and not hitherto associated with bacterial metabolism.

**Relation of maximum growth temperature to resistance to heat**, C. LAM-ANNA. (Oreg. State Col.). *Jour. Bact.*, 44 (1942), No. 1, pp. 29-35).—Studying species of *Clostridium* and *Bacillus*, this paper presents experimental evidence suggesting a relation between the maximum growth temperature of a bacterial species and its capacity (including spores) to survive heat injury. Within the genus *Bacillus* three groups were separable with respect to spore resistance and relation to maximum growth temperature. The inexact correspondence of maximum growth temperature to thermal resistance of spores is believed to mean that factors in addition to those determining maximum temperature of growth are involved in thermal resistance. There are 20 references.

**Bactericidal action of ultraviolet radiation on air-borne organisms**, H. C. RENTSCHLER and R. NAGY (*Jour. Bact.*, 44 (1942), No. 1, pp. 85-94, figs. 5).—Through use of a specially devised tower arrangement, the sensitivity to ultra-

violet irradiation of air-borne bacteria and of similar organisms on the surface of agar was shown to be the same. Studies described also indicate that bacteria may be so injured by heat, Grenz rays, or X-rays that the surviving individuals are less resistant to such irradiation. This result is incompatible with the "single photon hit" theory. All bacteria in a pure strain of a culture are not identical, and the term  $k$  in the exponential equation generally used for expressing the survival ratio for different exposures to ultraviolet radiation is not as constant as commonly assumed. The air centrifuge, as used in determining the bacterial contamination of air moving through a duct at low humidity, is selective in taking the bacteria from the air. This appears to explain the reason for the general statements that air-borne bacteria at low humidity are more vulnerable to ultraviolet radiation than when on the surface of agar, and that at low relative humidity the bactericidal action is greater than for high humidity.

**Some problems in fungus phylogeny**, E. A. BESSEY. (Mich. State Col.). (*Mycologia*, 34 (1942), No. 4, pp. 355-379, figs. 5).—An address critically analyzing the subject, with 34 references.

**Two cases of unusual development of fruit bodies**, C. M. CHRISTENSEN. (Minn. Expt. Sta.). (*Mycologia*, 34 (1942), No. 4, pp. 400-402, figs. 3).—A note recording nongestrophic development of the agarics *Russula* sp. and *Daedalia confragosa*.

**The mycorrhiza of *Zeuxine strateumatica***, J. N. PORTER (*Mycologia*, 34 (1942), No. 4, pp. 380-390, figs. 6).—*Rhizoctonia mucoroides* is shown to be the mycorrhizal associate of the orchid *Z. strateumatica* in Florida. Details of the study are presented.

**Relationship of dissociation of cellular proteins by auxins to growth**, H. T. NORTEN. (Univ. Wyo.). (*Bot. Gaz.*, 103 (1942), No. 4, pp. 668-683, fig. 1).—Using the centrifuge method of determining protoplasmic viscosity, and principally on cortex cells of bean petioles and stems, unilateral applications of growth substances were found initially to condition negative curvatures, in which cases the viscosity was lower in cells on the faster than on the slower growing sides and also lower than in controls. When subsequent positive curvatures resulted, the viscosity was decreased about equally on the treated and untreated sides, except for petioles treated with the lanolin paste at 100 mg. of indole-3-n-propionic acid per gram, where the viscosity was lower on the untreated sides. Applications of this acid or of  $\alpha$ -naphthaleneacetic acid to the tops of decapitated plants resulted in a decrease in the structural viscosity of protoplasm in cells below the cut surfaces. These decreases were conditioned in part at least by dissociations of cellular proteins, i. e., by the splitting of proteins into molecules one-half, one-fourth, one-eighth, etc., that of the original ones. Biochemical and thermodynamical evidence introduced suggests that such dissociations condition increased protoplasmic swelling pressure, respiration, and polysaccharide hydrolysis, as well as altering development. There are 81 references.

**Interrelation of organic materials in the growth substance response**, S. C. BAUSOR (*Bot. Gaz.*, 103 (1942), No. 4, pp. 710-724, figs. 4).—Intact tomato seedlings and cuttings in a mineral nutrient kept in darkness during treatment produced only a small response to growth substances in 6 days and limited to slight enlargement of cells and increase in size of nuclei and nucleoli. The reaction was almost completely inhibited when the leaves were removed. Intact and defoliated cuttings cultured in sucrose, maltose, levulose, glucose, and lactose (but not mannitol) in darkness produced the complete response as in plants in the light. In cuttings left in darkness for 1-6 days before treatment, those in a sucrose nutrient showed no differences due to pretreatment, but those in the mineral nutrient alone showed progressively less response through the third

day and none at all beyond that time. Cuttings treated with lanolin paste for 3 days while in the mineral solution were then transferred to the sucrose medium. Six days later, when harvested, the treated regions had proliferated and produced root primordia. This response was not so great, however, as in cuttings cultured in sucrose but not treated until the time the minus-sucrose plants were put into the sugar solution. Bean cuttings in a mineral nutrient in the dark also showed decreased response to the growth substance and complete response when cultured in sucrose. Galactose proved toxic to both tomato and bean cuttings. Tomato cuttings in a minus-N medium responded as vigorously to the growth substances as did those without N. The most obvious cytological change in response to the growth substances in both plants was the great increase in size of nucleolus. Under carbohydrate deficiency the nucleolus diminished in size and finally disappeared. No changes occurred in the nucleoli of plants cultured in a sugar medium in the absence of growth substances. There are 34 references.

**Auxin storage as related to endosperm type in maize**, G. S. AVERY, JR., J. BERGER, and B. SHALUCHA (*Bot. Gaz.*, 103 (1942), No. 4, pp. 806-808).—From the experimental results presented it is believed clear that kernels of sweet corn are much richer in auxin than those with brittle, waxy, floury, or flinty endosperm. So far as could be determined, these are the first assays demonstrating markedly different auxin storage in ontogenetically identical tissues from different varieties of the same species.

**A reversible growth inhibition of isolated tomato roots**, J. BONNER (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 8, pp. 321-324).—Isolated roots of three different tomato clones were inhibited in growth by addition of sulfanilamide, sulfapyridine, or sulfathiazole to the nutrient medium. This effect was in whole or in part abolished by further addition of *p*-amino benzoic acid. Isolated roots of the clones used normally contain this acid or a substance with similar physiological activity.

**Colchicine stimulation of seed germination in *Petunia axillaris***, L. BOND. (*Univ. Wis.*). (*Jour. Hered.*, 33 (1942), No. 5, pp. 200-201, fig. 1).—Treatment induced an increase in the number of seed germinating and a reduction in germination time. The optimum concentration (0.04 percent) for germination proved high enough to induce polyploidy. Seedling growth was seriously retarded only by concentrations of 0.1 percent or stronger, the concentrations most widely used in seed treatment. In view of these results, it seems that seed treatment by weaker solutions should yield satisfactory results in the practical production of large numbers of polyploid plants.

**Occurrence of vitamins in fungi**, C. C. CARPENTER and E. W. FRIEDLANDER (*Science*, 95 (1942), No. 2477, p. 625).—From results of the authors' studies and of investigations by others, it is deemed quite evident that the production of thiamin and riboflavin, and probably of other vitamins, is a normal function of the fungus group.

**Vitamin synthesis by a yeast converted from a heterotrophic to an autotrophic habit**, L. H. LEONIAN and V. G. LILLY. (W. Va. Expt. Sta.). (*Science*, 95 (1942), No. 2478, p. 658).—The authors succeeded in inducing 10 strains of *Saccharomyces cerevisiae*, generally considered heterotrophic for a number of vitamins, to grow without an outside supply of thiamin, pyridoxin, inositol, and pantothenic acid, and a rich growth without even biotin was induced in at least one strain. This building-up process of autotrophic habit was accomplished by prolonged incubation, use of a large amount of inoculum in initial stages, and successive transfers to solutions from which one of the essential vitamins had been omitted.

**Physiological activity of ascorbic acid in plant life**, E. F. KOHMAN and D. R. PORTER (*Science*, 95 (1942), No. 2476, pp. 608-609).—From experiments with potted young tomato plants it is concluded that the losses in ascorbic acid noted in fruits and vegetables in storage are not due entirely to oxidation by atmospheric O<sub>2</sub>, but to its being used in some physiological process, the activity of which is diminished by severing the plant from the root system.

**Synthesis of ascorbic acid in excised tomato roots**, M. E. REID and W. J. ROBBINS (*Science*, 95 (1942), No. 2477, pp. 632-633).—The results reported suggest that vitamin C may play a much more important role in the economy of the plant than has previously been attributed to it.

**A proteolytic enzyme in the latex of the weed *Euphorbia lathyris* (caper spurge)**, W. J. ELLIS and F. G. LENNOX (*Austral. Jour. Sci.*, 4 (1942), No. 6, pp. 187-188).

**Apparatus for the production of artificial frost injury in the branches of living trees**, R. A. STUDHALTER and W. S. GLOCK (*Science*, 96 (1942), No. 2485, p. 165, fig. 1).—Spontaneous late frost injuries have been used in the past to determine the presence of multiple growth rings in 1 yr. in the branches of living trees. To facilitate such studies, an apparatus was devised for producing artificial frost injury under controlled conditions which is said to have certain advantages over types previously developed and to have a temperature range of 0° to -45° C. over intervals up to 7 hr. Described and illustrated in detail, it consists essentially of a lid, dry-ice chamber, and treatment chamber, all of wood insulated by cork on the interior and by aluminum paint on the exterior.

**Effect of chemical treatments in prolonging dormancy of tung buds**, H. M. SELL, W. REUTHER, E. G. FISHER, and F. S. LAGASSE. (U. S. D. A.). (*Bot. Gaz.*, 103 (1942), No. 4, pp. 788-793, figs. 2).—One of the most important problems of the tung industry is the injury to the flowers by late spring frosts. This study concerned the effects in prolonging dormancy of certain organic compounds ( $\alpha$ -naphthaleneacetic acid and its K salt, indole-3-acetic acid, and  $\alpha$ -naphthaleneacetamide in various carriers). The data obtained indicated a pronounced effect of the treatments in delaying bud development. It is possible that some practical application of these preliminary results may develop from future studies.

**The rooting of flowers in sterile culture**, C. D. LA RUE (*Bul. Torrey Bot. Club*, 69 (1942), No. 5, pp. 332-341, figs. 5).—Tests for regeneration were made on nutrient agar for flowers of 12 species of monocotyledons in 9 genera of 3 families, and of 80 species in 74 genera of 34 families of dicotyledons. Roots were produced on flowers of various members of both groups, and the results are detailed. It is concluded that the apparent lack of regeneration in flowers is due to their short life, their position which does not allow them contact with moist substrata, and their lack of food supply. The conditions needed for their regeneration were supplied by placing them in sterile culture on nutrient agar. Besides supplying moisture and food, the culture conditions prolonged the life of the flowers to an extraordinary degree and allowed them time for regeneration. There are 19 references.

**Studies on the embryo of *Hordeum sativum***.—II, **The growth of the embryo in culture**, J. MERRY (*Bul. Torrey Bot. Club*, 69 (1942), No. 5, pp. 360-372, figs. 6).—In continuation (E. S. R., 86, p. 606), it was found that when embryos 7-8 days old were cultured on a nutrient agar medium no changes were apparent, when cultured at 9 days all the cells enlarged and no cell division occurred, at 10-11 days some cell division took place but eventually all the cells stopped dividing and enlarged, and at 12 days or older the cells in certain regions continued to divide as long as the plants were grown, while the cells in other

regions enlarged at once or divided for a short time and then enlarged. No cell division and only slight cell enlargement was noted in the scutellum of cultured embryos. The size of the stem meristem was about the same in all plants from embryos 12 days old or more. Leaf primordia were formed more rapidly, and the coleoptile and leaves were larger in plants from older embryos. The ratio of size of coleoptile, leaves, and roots of cultured plants to size of these parts in normal embryos increased rapidly with age of embryo for early ages but soon decreased with an increase in embryo age. The vascular bundles became lignified sooner and to a greater extent in plants from older embryos. The primary root was longest in plants from embryos 14-16 days old and was successively shorter in plants from progressively older embryos. Only as many seminal roots as were already differentiated in the embryo grew in culture, other roots formed being adventitious on the stem. There are 16 references.

**Behavior of woody desert legumes at the wilting percentage of the soil,** R. F. DAUBENMIRE and H. E. CHARTER. (Univ. Idaho). (*Bot. Gaz.*, 103 (1492), No. 4, pp. 762-770, figs. 3).—The wilting percentage of the soil had essentially the same significance in the water relations of *Prosopis velutina*, *Acacia farnesiana*, and *Lysiloma thornberi* as in wheat. In contrast to wheat, attainment of the wilting percentage in these legumes was not marked by a wilting of the leaf blades but brought about an essentially concomitant increase in abscission rate, deviation from normal diurnal positions of pinnales, cessation of shoot elongation, and sharp decrease in transpiration rate. It appeared that the growth and transpiration rates of the legumes continued at about normal levels as long as the soil contained water in excess of the wilting percentage. Wherever the legume roots had access to growth water, their transpiration rates appeared to be closely related to the strength of illumination and to be unrelated to variations in the evaporative power of the air, so long as the latter was not likewise controlled principally by insolation.

**Withdrawal of water from the fruit by the leaves of cotton,** V. A. NOVIKOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 32 (1941), No. 4, pp. 288-290).—Results of the four tests reported appear to indicate that water is drawn from the bolls on wilting of the plant and that the main part of it is absorbed by the leaves. The bolls of Egyptian cotton, containing more water than American varieties, suffered less from dehydration. The fact that upland cotton has a tendency toward forming the abscission layer in the peduncle is explained partly on the basis of a high water loss from the bolls when the leaves are in need of it.

**Theory of porometers used in the study of stomatal movements in leaves,** H. L. PENMAN (*Roy. Soc. [London], Proc., Ser. B*, 130 (1942), No. 861, pp. 416-434, figs. 4).—The mathematical theory of porometers for studying stomatal movements in leaves is given for viscous and diffusive flow of gases. It is shown that under certain circumstances the theory applies to both kinds of gas movements, and a correction is made for those cases in which the basic assumptions for diffusion are not realized. From determinations of the total leaf resistance to gaseous flow the conductance of the stomata can be found if the mesophyll resistance is known. The importance of this quantity is discussed and demonstrated, methods of measuring it are suggested, and possible checks on the reliability of the results are described. As an illustration, the theory is applied to some new data on two pelargonium leaves, the treatment giving results that were internally consistent and deduced assimilation rates being of the same order of magnitude as those observed in practice.

**Identification of selenium indicator species of *Astragalus* by germination tests.** S. F. TRELEASE (*Science*, 95 (1942), No. 2478, pp. 656-657).—The simple germination test described, based on the observation that a Se indicator species tolerates and is even stimulated by a high concentration of  $\text{Na}_2\text{SeO}_3$ , whereas a nonindicator species is severely poisoned by a low concentration, was found to agree with the results of field data and growth experiments of longer duration. The study included 25 *Astragalus* species.

**Rubber analysis of plants in South Carolina.** J. H. MITCHELL, M. A. RICE, and D. B. RODERICK. (Clemson Agr. Col.). (*Science*, 95 (1942), No. 2477, pp. 624-625).—Chemical analyses as to rubber content are presented for 34 species.

**Carbohydrate nutrition of *Rhizopus suinus*.** C. J. CORUM (*Bot. Gaz.* 103 (1942), No. 4, pp. 740-750, fig. 1).—Extraction of dextrose, levulose, galactose, and sucrose with acetone, alcohol, and ether resulted in increased mycelial production. Extraction of dextrose with alcohol and ether also resulted in increased mycelial production but the increase was not so great as by the preceding method. Recrystallization of dextrose from 80 percent alcohol resulted in about the same growth increase as from the acetone-alcohol-ether treatment. Presence of vitamin  $\text{B}_1$  in reagent-grade dextrose was shown by the thiochrome oxidation method. Removal of traces of this vitamin from sugars during extraction was possibly the cause of the growth phenomena obtained. The dextrose extract contained a substance which, when concentrated by evaporation and added to the medium, promoted vegetative growth of *R. suinus*. Under the extraction conditions, removal of vitamin  $\text{B}_1$  would be more extensive than removal of the ash, the influence of this vitamin removal being more effective in increasing the fungus growth than removal of the small amount of ash in decreasing its growth. However, when the extract was concentrated the influence of the ash on mycelial production was much greater than that of the vitamin, with the resulting increase in growth. There are 14 references.

**Carbohydrate metabolism in wheats under conditions of insufficient soil moisture.** K. G. MIROSHNICHENKO (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 32 (1941), No. 1, pp. 81-84).—The carbohydrate metabolism under deficient moisture was followed throughout the growth cycle of a drought-resistant and a drought-susceptible variety of wheat. At whatever developmental phase the drought was brought to bear, the yields were adversely affected.

**Some effects of nitrogen on young apple trees.** B. F. LUTMAN (*Vermont Sta. Bul.* 488 (1942), pp. 35, pls. 4, figs. 15).—Young McIntosh and Northern Spy apple trees were fertilized with either relatively large or small amounts of sodium nitrate in an attempt to determine possible relations between N applications and foliage susceptibility to scab. Shoots in the high-N trees lengthened much more rapidly than did those on low-N trees during the first 6 yr. of growth, but less so later. This increased growth was accompanied by the formation of a larger pith, thus making the shoots on high-N trees soft and fleshy and more readily open to scab infection. Leaves from both sets of trees were very stable as to size of cells, nuclei, and chloroplasts, although those grown on the high-N trees were thicker and larger. No differences were noted in cuticle thickness. Chemical analyses showed higher percentages of organic N in leaves of the high-N trees. Little pruning had been done and the foliage of the well-fed trees was relatively large and dense, and during three summers humidity averaged higher and temperature lower in their foliage than in that of the low-fed trees. Periods of high humidity and low temperature were accompanied by scab outbreaks which were much more severe on the well-fed than on the less well-fed trees. Leaves on the higher-N trees were apt to remain green all summer, whereas they

were likely to turn a yellow-green in early August on the low-N trees. Chloroplasts in the leaves of the high-N trees remained large and active, whereas those from leaves of the low-N trees tended to disintegrate in the upper palisade layers. Small globules, staining intensely, filled the cells of the upper row of palisade cells as the chloroplasts and nuclei disappeared, and were especially noticeable in the less well-fed trees. These bodies began to appear almost as soon as the leaves were grown. The one or more sterols (nature undetermined) extracted from the yellowing leaves appeared to be byproducts of plastid activity and may possibly injure the leaf cells. These globules when located in the upper layer of palisade cells may be of advantage, since they interpose a yellow layer which diffuses and filters out some of the sunlight's ultraviolet rays, enabling underlying cells the better to survive and function.

**Studies in tropical fruits.**—XII, The respiration of bananas during storage at 53° F. and ripening at controlled temperatures, E. R. LEONARD and C. W. WARDLAW (*Ann. Bot. [London], n. ser., 5 (1941), No. 19, pp. 379-423, figs. 26*).—The respiration of individual banana fruits of standard commercial grades during storage at 53° F. and ripening at controlled temperatures (65° and 68°) was investigated by methods yielding data on respiration rates, internal concentrations of CO<sub>2</sub> and O<sub>2</sub>, and the CO<sub>2</sub> content of the tissues. Detailed results are presented and discussed in relation to the findings of other investigators for other fruits, such as apples and pears, and consideration is also given to the significance of the readjustments of internal concentrations of CO<sub>2</sub> and O<sub>2</sub> which take place on transferring fruit from tropical temperatures to 53° and their relation to the development of abnormal ripening trends (e. g., in chilled fruit). There are 19 references. See also a previous note (E. S. R., 87, p. 63).

**Photoperiodic after-effects in six composites,** V. A. GREULACH (*Bot. Gaz., 103 (1942), No. 4, pp. 698-709, figs. 5*).—Photoperiodic aftereffects were observed in two short-day plants (*Cosmos bipinnatus* and *C. sulphureus*) and four long-day species (*Rudbeckia hirta*, *Matricaria parthenoides*, *Centaurea cyanus*, and *Coreopsis tinctoria*), and the detailed results are reported.

**Effects of photoperiod on sex expression in *Ambrosia trifida*,** L. K. MANN. (Univ. Calif.). (*Bot. Gaz., 103 (1942), No. 4, pp. 780-787, figs. 5*).—This short-day plant, after starting growth on long day, was subjected to 2, 10, and 20 photoinductive cycles at each of the 3 photoperiods 15, 12, and 6 hr., following which the plants were returned to long day to complete growth. The rate of maturity was most rapid and fruit yield greatest in plants exposed to 20 photoinductive cycles at the 12-hr. period. Sex expression as measured by development of pistillate flowers in the position usually occupied by staminate ones increased with the increasing number of photoinductive cycles and decreasing lengths of photoperiod, being greatest in plants exposed to 20 cycles at the 6-hr. period.

**Some effects of radiant energy in relation to etiolation,** J. P. BIEBEL (*Plant Physiol., 17 (1942), No. 3, pp. 377-396, figs. 3*).—The morphological response of kidney bean seedlings increased at a receding rate with increases in incident radiant energy, but the amount of response varied with the manner in which the energy was increased. High irradiances caused more response than the low, even when the total radiant energy incident on the plants was the same. The maximum morphological response followed irradiation 2-3 times daily, and chlorophyll formation increased with the number of cycles of irradiation up to 144 times daily. Albino corn seedlings gave the same morphological response to irradiation as normal green seedlings. The Q<sub>10</sub> of the "light reaction" was apparently unity. Temperature at time of irradiation did not in itself affect the magnitude of response. All plant parts were able to act to some extent as preceptors of radiant energy, and adjacent nonirradiated parts responded

to some degree when any part was irradiated, but the leaves and especially the growing point were the most sensitive perceptrs. No effect was observed when an irradiated bean seedling was grafted to a nonirradiated one, provided neither was irradiated thereafter. Ether extracts of hypocotyls of irradiated and nonirradiated bean seedlings each had about the same amount of auxin per hypocotyl, but the irradiated hypocotyls were smaller and the auxin concentration in them was higher. There are 13 references.

**Stimulation of yeast respiration by ultraviolet radiations**, A. C. GIESE (*Jour. Cell. and Compar. Physiol.*, 20 (1942), No. 1, pp. 35-46, figs. 8).—With age or aeration, the endogenous respiration of yeast cultures declines. Irradiation of cultures with low endogenous respiration in the presence of small amounts of nutrients or none resulted in an increase in respiratory rate which continued for several hours. Similar cultures to which excess glucose had been added before irradiation exhibited a lower respiratory rate than controls. Cultures of *Achromobacter fischeri* aerated until they had a low rate of endogenous metabolism also showed an increased respiratory rate after irradiation, but lower than in yeast. No evidence for a similar stimulation was observed in sea urchin sperm, in a protozoan (*Tetrachymena*), or in the mycelium of *Neurospora*. The author suggests explanations of the increase of endogenous respiration and the decrease of exogenous (saturated) metabolism in yeast following irradiation.

**Symposium on growth and differentiation in plants** (*Amer. Nat.*, 76 (1942), No. 764, pp. 225-279).—The following are included: Regeneration, Development, and Genotype, by C. E. Allen (pp. 225-238) (Univ. Wis.); Induced Chromosomal Changes and Their Significance in Growth and Development, by J. M. Beal (pp. 239-252); The Problem of Internal Differentiation in Plants, by E. W. Sinnott (pp. 253-268); and Effects of Growth-Regulating Substances on Mobilization and Development, by J. W. Mitchell (pp. 269-279) (U. S. D. A.).

**The cytology of some wild species of *Hordeum***, T. C. CHIN (*Ann. Bot. [London]*, n. ser., 5 (1941), No. 19, pp. 535-545, figs. 14).—This is a taxonomic and cytological study of six wild species of *Hordeum*.

**Intermittent growth of fruits of *Cypripedium* and *Paphiopedillum*: A correlation of the growth of orchid fruits with their internal development**, R. E. DUNCAN and J. T. CURTIS. (Univ. Wis.). (*Bul. Torrey Bot. Club*, 69 (1942), No. 5, pp. 353-359, figs. 5).—The ovaries of both orchid groups studied possessed two phases of growth in diameter and one in length. The first phase of growth in diameter and that of growth in length occurred while the ovules were maturing prior to fertilization. The second phase of growth in diameter took place while the embryos were growing most rapidly. Fertilization occurred at a time when growth of the ovary had almost ceased.

**Eccentric growth in the main stem of young white ash trees**, G. P. BURNS (*Vermont Sta. Bul.* 492 (1942), pp. 19, pls. 2, figs. 7).—Regardless of mechanical forces, eccentric growth in white ash stems without side branches was found to be due to excessive cell division of the cambium on the upper side. The fibers were always shortest on the lower and longest on the upper side, and the cell walls, especially fibers, were thicker in cells on the upper than on the lower side. No evidence appears to indicate that compression or tension acted as a stimulus to cell division. In stems bent one way only the most rapid cell division occurred at the point where a very pronounced bending took place. This was not found on the compression or tension but on the so-called neutral sides. Differences in structure of the two sides consisted chiefly in the formation of additional mechanical tissue on the upper side. When a lateral bud develops

near the top of a bent stem the most rapid cell division may be shifted from the upper to the lateral side. When lateral buds on a bent stem developed there was a marked tendency to suppress all morphologically apical buds, including the terminal bud.

## GENETICS

[Genetic and physiological studies by the Missouri Station] (*Missouri Sta. Bul.* 444 (1942), pp. 20, 23-24, 25-28, 33-34, 36-37, 38-39, 40-42, 44-45, 74).—Results are briefly reported by R. Bogart, L. A. Weaver, F. F. McKenzie, F. N. Andrews, D. T. Mayer, J. F. Lasley, W. K. Dinwiddie, H. L. Cooksey, J. E. Parker, C. W. Turner, O. B. Houchin, J. Meites, S. Holst, A. J. Bergman, H. A. Herman, N. P. Ralston, A. A. Lewis, J. P. Mixner, A. C. Ragsdale, C. W. McIntyre, P. T. Cupps, S. Brody, C. F. Winchester, H. H. Kibler, M. J. Regan, W. Gifford, and E. M. Funk of a study of inheritance in swine by breed colors and morphological conditions; inbreeding and improvement of swine through breeding methods; oestrous, ovulation, and related phenomena in the mare; the induction of ovulation in the mare; purification of the gonadotropic hormone in pregnant mare serum; relation of psychological and physiological conditions in the oestrous cycle to the oestrin content of the follicular fluid in urine of the mare; the induction of oestrous and ovulation in the ewe; an artificial vagina for swine; swine, rabbit, and poultry semen collection and storage; the fat metabolism hormone of the pituitary of the rabbit; extraction of lactogen from urine; the lactogen content of the anterior pituitary of the growing rabbit and guinea pig; bird and rabbit response to lactogenic hormone; effect of thyroxine on milk and fat production of dairy cows and goats; mammogen content of pituitary of cattle and other animals; development through breeding of a high producing strain of Jersey cattle; the extraction and separation of certain anterior pituitary hormones; comparison of the guinea and the chick thyroid in the assay of thyrotropic hormone; the thyrotropic hormone in the pituitary of the rat; seasonal rhythms in livestock; artificial insemination of dairy cows; semen examination for indication of fertility in dairy bulls; line-breeding Holstein and Jersey herds; and the relation of size of clutch and position of the egg in the clutch to hatching results.

Some mendelian characters in *Beta vulgaris* and linkages observed in the Y-R-B group, F. V. OWEN and G. K. RYSER. (U. S. D. A.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 3, pp. 155-171, figs. 7).—Linkage relationships of 10 mendelian factors in *B. vulgaris* are reported on, with brief descriptions of the characters represented, including *B*, bolting or annual habit; *bl*, black root; *Cl*, colored leaf; *Cv*, colored leaf veins; *pl*, plantainlike leaf venation; *R*, red plant color; *ru*, russet root; *Tr*, trout or spotted leaf; *v*, variegated foliage; and *Y*, heavy production and extension of pigment. The sequence and approximate genetic spacing of the seven genes in the Y-R-B linkage group were found to be Y 8 R 4 Cl (Cl 0 ? Tr 0 ? Cv) Cv 12 B 10 v. Cl, Cv, and Tr were very closely linked and their order was not determined. Available data suggest that *bl*, *pl*, and *ru* are not in the Y-R-B group. A variegated foliage condition with large albino sectors was observed, and the type of progeny obtained from albino and green sectors gave evidence of maternal or cytoplasmic inheritance.

A photoperiodism accompanying autotetraploidy, J. G. O'MARA. (U. S. D. A. and Mo. Expt. Sta.). (*Amer. Nat.*, 76 (1942), No. 765, pp. 386-393).—"Autotetraploid *Secale cereale* reacted to short days in a manner different from that of the diploid strain from which it was derived. The diploid was fertile throughout the year; the autotetraploid was female sterile under the natural short days of December and January. This photoperiodism constitutes another

instance of a character present in an autotetraploid which is apparently unpredictable from the parental diploid." There are 24 references.

**Frequency of induced chlorophyll mutations in diploid and tetraploid barley.** A. MÜNTZING (*Hereditas*, 28 (1942), No. 1-2, pp. 217-221).—This is a cytogenetic study of X-irradiated barley seed, with special reference to the frequent occurrence of chlorophyll mutations in the diploids and their absence in the tetraploids of the  $X^1$  generation. The detailed results presented are believed to suggest strongly that most of the induced mutations were associated with or caused by structural chromosome alterations.

**The relation of mitotic disturbances to X-ray dosage and polyploidy.** K. FRÖIER, A. GUSTAFSSON, and O TEDIN (*Hereditas*, 28 (1942), No. 1-2, pp. 165-170).—Statistical analysis of mitotic disturbances induced in dormant seed of oats and four species of wheat indicated that diploid, tetraploid, and hexaploid species respond to increasing X-ray dosages by damage differing for each of the three groups of polyploidy. Curves for the single diploid and two tetraploids examined deviated significantly from a straight-line proportionality, whereas no deviation therefrom could be proved for the hexaploids. Whether the sigmoid and the straight-line curves differ fundamentally could not be ascertained, but it is believed that the damage curves of the hexaploids are only flattened sigmoid curves. Instances of straight-line proportionality, inferred from genetic and cytologic experiments, must be reinvestigated with special attention to low-dosage regions (e. g., with respect to X-chromosome lethals to dosages between 50 and 800 r.).

**Studies on the meiotic mechanism of haploid rye.** A. LEVAN (*Hereditas*, 28 (1942), No. 1-2, pp. 177-211, figs. 5).—A detailed cytological study, with 45 references.

[Animal genetic investigations by the Texas Station]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 76, 80-82, 90, 152-154).—Progress reports of studies with livestock are briefly reported from the Texas Station by J. N. Thompson, R. M. Sherwood, G. R. Fuller, B. L. Warwick, R. D. Turk, R. O. Berry, H. Schmidt, S. P. Davis, J. C. Miller, P. B. Dunkle, J. M. Jones, W. H. Dameron, J. H. Quisenberry, F. Hale, H. C. McPhee, and D. A. Spencer, which deal with strain differences in turkeys; resistance of lambs to stomach worms and of mice to loin disease and other pathogens; cytological studies of crosses between sheep and goats; inheritance of fiber characteristics of Rambouillet and Romney sheep and crosses between them; transference of genes for fineness of fiber from non-Angora to Angora goats; selection for polled character in fine wool sheep; inheritance of skin folds on Rambouillet sheep and type in Angora goats; and relationship of genetic factors in inbred rats to vitamin A requirements.

**Vitamin C—For sterility in farm animals.** P. H. PHILLIPS (*Holstein-Friesian World*, 39 (1942), No. 7, pp. 369-370, fig. 1).—Improvement in breeding and fertility of cows and bulls was brought about by ascorbic acid administration.

**Coat color inheritance in bull terriers.** L. C. BRIGGS and N. KALISS. (Cornell Univ.). (*Jour. Hered.*, 33 (1942), No. 6, pp. 223-228, fig. 1). An analysis of the colors of parents and progeny of 1,974 bull terriers produced by breeders all over the world led to the conclusion that brindle was controlled by a single pair of genes dominant to nonbrindle and white was controlled by multiple recessive factors in their entirety, while red was recessive to other colors except white. Fawn, black-and-tan, and tricolor were in disfavor and therefore the data too meager for interpretation. Only 6 of 49 matings of brindle  $\times$  brindle produced all brindle pups and 6 matings in 52 brindle  $\times$  red gave entirely brindle litters, which is within the expectation of heterozygous parents. White  $\times$  white matings gave only white pups. In 1,303 litters the sex ratio was 127  $\delta$ s to 100  $\text{f}$ s, which is a nonsignificant departure from expectation.

**"Ataxia", a hereditary nervous disorder of the rabbit, P. B. SAWIN, M. V. ANDERS, and R. B. JOHNSON** (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 4, pp. 123-127).—A degenerative disorder of the nervous system of rabbits designated as ataxia was found to be caused by a recessive mendelian factor (*at*). There was a posterior paralysis at 58-89 days of age which became progressively worse, with death before sexual maturity. The condition was perpetuated by the progeny of heterozygous parents. There were produced under such conditions 219 individuals, of which 55 showed the condition. The genetic hypothesis was supported and not disproven in outcrosses of heterozygotes with other strains.

**Two hermaphroditic rats, R. O. GREEP** (*Anat. Rec.*, 83 (1942), No. 1, pp. 121-128, pls. 2).—The anatomy of these hermaphroditic rats is described.

**Factors influencing lung lobation in the mouse.—I, Genetic factors: A preliminary report, S. BROWDER** (*Anat. Rec.*, 83 (1942), No. 1, pp. 31-39, figs. 9).—Nine distinct lung patterns were observed in eight sublimes of mice as a result of prolonged inbreeding. The lung patterns were studied on autopsy of from 15 to 71 individuals in the different families.

**Stub, a new mutation in the mouse with marked effects on the spinal column, L. C. DUNN and S. GLUECKSOHN-SCHOENHEIMER** (*Jour. Hered.*, 33 (1942), No. 6, pp. 235-239, figs. 3).—A recessive characteristic designated as stub (*sb*) was found in inbred mice in which the tails were frequently shortened and the entire vertebral column was in such disorder that the numbers of vertebrae could not be ascertained. The numbers of ribs were reduced and fused. From heterozygous normal matings there were produced 54 stubs and 209 normals. The deviation from expectation was not significant and until birth viability was considered normal. Most stub homozygotes die before 1 mo. of age, but three litters were produced by stub ♂s and heterozygous ♀s. "Preliminary tests indicate that *sb* is probably not an allele of the following tail mutations: brachy (*T*), king (*Ki*), fused (*Fu*), lethals *t*<sup>o</sup> and *t*<sup>'</sup>, flexed (*N*), twisted (*tw*), shaker short (*st*), and screw (*sc*)."

**Studies of spotting patterns.—V, Further analysis of minor spotting genes in the house mouse, L. C. DUNN** (*Genetics*, 27 (1942), No. 2, pp. 258-267).—Continuing this series (E. S. R., 80, p. 750), an attempt was made by 10-12 generations' inbreeding by brother and sister matings to separate some of the constituent elements from the *k* complex. Inbred lines and sublimes proved to be quite similar in range of white spotting, although there were variations in the model grade from 6 to 10 percent dorsal white in one family to 21-25 percent in another. It is considered that the spotting was nongenetic since the variations persisted even to the thirteenth generation. Crosses and backcrosses of *k* spotted whites with self-colored dilute brown mice showed the *k* complex of white spotting to differ from self by a complex of mutant genes with minor effects. One or more was dominant and others recessive, with all interacting additively. Four inbred lines derived from different parts of the F<sub>1</sub> population from crossing *k* spotted and self mice differed in that two showed *k* spotting, one showed tail spotting only, and one showed no spotting. Evidently the no spotting race contained mutant spotting alleles since crosses with spotted mice produced spotting.

**An analysis of data on X-ray-induced visible gene mutations in *Drosophila melanogaster*, H. C. FRYER and J. W. GOWEN.** (Iowa Expt. Sta. coop. Kans. State Col.). (*Genetics*, 27 (1942), No. 2, pp. 212-227).—Studies were made of the influence of three wave lengths of two doses with each wave length at 19 specific gene loci on three chromosomes of ♂s at 24 hr. or less of age from five inbred lines. The data analyzed by the  $\chi^2$  test showed that the mutation rate

was proportional to the dosage, but that for a particular gene and a fixed dosage the wave length of the X-ray does not affect the mutation rate. The fundamental rates of mutation on the chromosomes are the same if the sets of genes are representative of their respective groupings of the chromosomes. The genes within the sets observed did not appear to have the same basic mutation rates. Analysis of mutation data reported by other authors substantiated these conclusions.

**The relative effect of environment and heredity upon body measurements and production characteristics in poultry.**—I, **Period of growth**, H. S. GUTTERIDGE and J. B. O'NEIL (*Sci. Agr.*, 22 (1942), No. 6, pp. 378-389, fig. 1).—From study of the variance in body measurements and weights at four weekly intervals from 4 to 24 weeks of age for Barred Plymouth Rock cockerels, hatched at three locations and raised at the same locations and at each of the other localities, it was concluded that environment had a greater effect than heredity upon the course of growth and conformation. Fleshing characteristics indicated by fullness of breast and circumference of tibia were even more markedly affected by environment, but as maturity approached the influence of heritable factors was more apparent.

**Crossbreeding and heterosis in turkeys**, V. S. ASMUNDSON. (Univ. Calif.). (*Poultry Sci.*, 21 (1942), No. 4, pp. 311-316, fig. 1).—The mean weights of ♂ and ♀ turkeys from hatching to 32 weeks of age of White, Black-winged Bronze, Black, Bourbon Red, and Lilac varieties and crosses between them indicated the effects of heterosis which were more pronounced at different ages and in certain crosses. F<sub>1</sub> Black × White, or Black-winged Bronze, exceeded the weights of the Black strain at all ages but did not differ significantly from the weights of the larger parental strain. F<sub>1</sub>s of Black × Bourbon Red and Lilac exceeded both parents in weight by the time they were 8 weeks of age and thereafter. Coefficients of variation showed the F<sub>1</sub>s to be more uniform than the parents. The numbers of each sex included in the tabulation of the strains and crossbreds ranged from 5 to 28 birds. Males were heavier and grew more rapidly than ♀s.

**Immunogenetic studies of species: Segregation of serum components in backcross individuals**, R. W. CUMLEY and M. R. IRWIN. (Univ. Wis.). (*Genetics*, 27 (1942), No. 2, pp. 177-192, fig. 1).—Carrying further the immunogenetic studies of the Pearlneck and ringdove pigeons and crosses and backcrosses between them (E. S. R., 86, p. 614), the species hybrid was shown to have all or nearly all of the species-specific and common components of both parents. A segregation of those specific to Pearlneck was produced by successive backcrosses to the ringdoves in four families. All backcross individuals were descendants of a single Pearlneck ♂ and therefore the possibility of cytoplasmic influence on the serum constituents was ruled out.

**Immunogenetic studies of species: Qualitative differences in the serum of backcross progeny following a generic cross in birds**, M. R. IRWIN and R. W. CUMLEY. (Wis. Expt. Sta.). (*Genetics*, 27 (1942), No. 2, pp. 228-237, fig. 1).—Following methods employed in the above studies, interactions of various antisera against sera of pigeons, ringdoves, and species hybrids between them indicated that at least part of the antigens peculiar to the pigeon are present in the hybrid. The serum of the species hybrids contains nearly all of the antigens of the pigeon serum, and variations between the hybrids are assumed to result from the heterozygosity of the pigeon parents. Likewise the ringdove antiserum contains antibodies for species-specific antigens of both F<sub>1</sub> and ringdove serum. It thus becomes apparent that without great quantitative refinement the serum of the F<sub>1</sub> is indistinguishable from and possibly identical with the serum of the

ringdove. After absorption of the F<sub>1</sub> antiserum with both parental sera there was no evidence of a hybrid substance remaining, but backcrosses gave evidence that genes may influence the chemical constitution of proteins.

**On the incidence of the breeding season in mammals after transference to a new latitude**, DUKE OF BEDFORD and F. H. A. MARSHALL (*Roy. Soc. [London] Proc., Ser. B*, 130 (1942), No. 861, pp. 396-399).—Attention is called to the rapid changes in the breeding season in carnivores when moved to the southern hemisphere. On the other hand, ruminants which do not have fixed breeding seasons and other animals inhabiting tropical areas do not react to the seasonal influence of light.

**Oogenesis in adult mice and starlings**, W. S. BULLOUGH and H. F. GIBBS (*Nature [London]*, 148 (1941), No. 3754, pp. 439-440).—The presence of oogenesis in the adult mouse and starling ovaries was demonstrated. Mitoses were cyclic in the mouse and seasonal in the starling.

**Effect of the gonadotropic substance of pregnant mare's serum on the blood plasma-ascorbic acid of the castrate bovine**, F. N. ANDREWS and R. E. EBB. (Ind. Expt. Sta.). (*Endocrinology*, 30 (1942), No. 5, pp. 671-674, fig. 1).—Decreases of 42 and 56 percent, respectively, in venous blood plasma-ascorbic acid levels of steers were induced within 5 hr. by injection of 1,000 and 2,000 rat units of equine gonadotropin in pregnant mare serum. Recovery to preinjection levels of plasma-ascorbic acid occurred in 44 and 68 hr. following injections periods. The study was conducted by chemical analysis for ascorbic acid from blood from 14 steers before and at periodic intervals after injection of the hormone.

**Effects of hypophysectomy at mid-pregnancy in the mouse**, W. U. GARDNER and E. ALLEN (*Anat. Rec.*, 83 (1942), No. 1, pp. 75-97, pls. 3, figs. 2).—Sixteen of 19 ♀ mice hypophysectomized at mid-pregnancy carried their litters to term and in most cases had normal parturition at the expected time. The follicles destined for post partum ovulation had the hypophyses not been removed were easily identified, but the ovaries were much smaller and less vascular and the follicles devoid or deficient in liquor folliculi. The corpora lutea remaining from the previous litter were normally developed. It thus seems evident that the regulation of the gonadal function of the hypophysis must be altered during pregnancy. Effects on the adrenal gland, development of the mammary glands, and birth mechanisms receive special comment.

**Action of vasopressin and oxytocin in causing premature oviposition by domestic fowl**, W. H. BURROWS and R. M. FRAPS. (U. S. D. A.). (*Endocrinology*, 30 (1942), No. 5, pp. 702-705, fig. 1).—Continuing work by Burrows and Byerly (E. S. R., 84, p. 510), studies of the premature production of hard-shelled eggs by hens with hard-shelled eggs in their uteri indicated that the yields between about 30 and 90 percent could be estimated by the formula  $y = a + b \log x$ , where  $y$  is the percentage yield,  $x$  is the dose of pitocin and pitressin intravenously administered, and  $a$  and  $b$  are constants. Premature oviposition can apparently be effected by vasopressin alone, but oxytocin appears also to contribute to the reaction.

**Gonadotropins of the swine pituitary, I-III** (*Endocrinology*, 30 (1942), No. 5, pp. 635-661, figs. 36).—Three papers in this series are presented.

**I. Various biological effects of purified thyliakentrin (FSH) and pure metakentrin (ICSH)**, R. O. GREEP, H. B. van DYKE, and B. F. CHOW (pp. 635-649).—Injection of metakentrin (E. S. R., 84, p. 609) from swine into hypophysectomized immature ♂ rats caused growth of accessory organs due to stimulation of testicular cells but hypophysectomized castrates showed no glandular growth. Large doses were needed to stimulate immature ♂ pigeons. When given to immature hypophysectomized ♀ rats in conjunction with thyliakentrin it brought

about corpus luteum formation. Ability of the two hormones to induce ovulation in oestrous did not seem to differ greatly. Sheep and hog sources were about equally effective on the prostate although certain quantitative differences in causing ovulation were found.

II. *Preparation and biological and physico-chemical characterization of a protein apparently identical with metakentrin (ICSH)*, B. F. CHOW, H. B. VAN DYKE, R. O. GREEP, A. ROTHEN, and T. SHEDLOVSKY (pp. 650-656).—Electrophoretic analysis showed the metakentrin prepared from hog pituitaries to be a homogeneous substance but differing in isoelectric point from metakentrin isolated from sheep pituitaries.

III. *Immunological specificity of swine metakentrin*, B. F. CHOW (pp. 657-661).—Immunological studies of ICSH isolated from hog pituitary stimulated in rabbits the formation of species specific antibodies demonstrable by the precipitin and complement fixation reactions. The hog metakentrin antiserum did not react with ICSH from sheep or beef. Both lobe and hormone specificity were demonstrated.

*Increase in gonadotropic content of pituitary glands of female rats treated with antigonadotropic serum*, R. K. MEYER, H. S. KUPPERMAN, and J. C. FINERTY. (Univ. Wis.). (*Endocrinology*, 30 (1942), No. 5, pp. 662-666).—Treatment of immature and adult rats for 63 and 54 days with antigonadotropic serum from rabbits which have been treated 2 mo. or more with an aqueous extract of sheep pituitary glands caused the gonadotropic potency of the hypophysis to be like that of the castrates and exceeded normals accordingly. The size of the gonads was reduced by antigonadotropic treatment, but after 19 days' cessation of treatment recovery was essentially normal.

*Responses of the testis to androgenic treatments*, C. R. MOORE and C. F. MORGAN (*Endocrinology*, 30 (1942), No. 6, pp. 990-999, figs. 5).—The testes of the opossum were shown to increase from the sixteenth to sixtieth day after birth and more slowly from the eighty-third day to maturity. Treatments of 1 of each pair of 11 controls with testosterone or testosterone propionate failed to produce consistent modifications. The study was made by comparing the weights of the larger organs and planimeter readings of the smaller ones as a result of the treatment.

*The effects of postnatal androgenic treatment in the female rat*, R. R. GREENE, M. W. BURRILL, and A. C. IVY (*Anat. Rec.*, 83 (1942), No. 1, pp. 19-29, pls. 2).—Differences in the interpretation to the response of the gonads of young ♀ rats treated subcutaneously with testosterone as given by Selye (*E. S. R.*, 84, p. 461) were pointed out. The uteri were stimulated in the author's animals and remained atrophic in Selye's studies, which may be accounted for by strain differences.

*Comparison of methods for standardization of pituitary interstitial-cell-stimulating hormone (ICSH)*, M. E. SIMPSON, C. H. LI, and H. M. EVANS. (Univ. Calif.). (*Endocrinology*, 30 (1942), No. 6, pp. 977-984, figs. 9).—Comparison of different assay methods for ICSH showed that the most sensitive response was obtained by increases in weight of the pigeon testis for which 0.030 mg. gave an effective response. The ventral prostate of hypophysectomized rats was responsive to 0.05-0.1 mg. and the chick testis least sensitive, 0.5 mg. being required.

*Biological properties of pituitary interstitial-cell-stimulating hormone (ICSH)*, M. E. SIMPSON, C. H. LI, and H. M. EVANS. (Univ. Calif.). (*Endocrinology*, 30 (1942), No. 6, pp. 969-976, figs. 4).—Studies of ICSH with normal and hypophysectomized ♀ rats showed that the dioestrous interval was prolonged with increases in weight of the ovaries in normal but not in hypophysec-

tomized animals. Placentoma formed about threads installed in the uteri of normal animals. Pregnancy was prolonged and birth of living young prevented by ISCH in normal pregnant animals. Some repair of the testes and spermatogenesis was maintained by ISCH in hypophsectomized  $\delta$ s. The studies were conducted with groups of about five rats treated daily for 10 days with 1 mg. of hormone. In one test the effectiveness of ICSH on the ovaries of normal rats was destroyed by 4 hours' heating.

**Transformation of males to intersexes by estrogen passed from blood of ring doves to their ovarian eggs,** O. RIDDLE and H. H. DUNHAM (*Endocrinology*, 30 (1942), No. 6, pp. 959-968, pls. 2, fig. 1).—Histological study of the gonads of  $\delta$  embryos of ringdoves showed that the left testis of  $\delta$  embryos from eggs laid by  $\text{qs}$  treated with oestradiol benzoate about the day before ova were released from the ovary showed a temporary development of ovarian cortex which persisted until hatching in 13 of 17 cases and disappeared quickly thereafter. Normal Mullerian ducts were inconspicuous and negligible at and after hatching. Genetic  $\text{qs}$  remained definitely of this sex. Dehydroandrosterone which was weak in oestrogen activity had little effect. The results resembled those of injecting oestrogens into the incubating egg, thus showing the direct transfer of oestrogens from the ovaries of the hen to the egg.

**The estrogens,** E. A. DOISY (*Endocrinology*, 30 (1942), No. 6, pp. 933-941).—The oestrogens are designated with the source, chemical composition, and richness of each.

**Effects of estrogens upon the young of injected lactating rats,** C. K. WEICHERT and S. KERRIGAN (*Endocrinology*, 30 (1942), No. 5, pp. 741-752, figs. 30).—Although rats nursing dams to which daily doses of oestrogens were administered failed to grow after 5 or 6 days there appeared to be no loss in milk secretion. There was loss of maternal instinct and a tendency for the dams to neglect the young. The study was conducted with 15 rats having their litters reduced at parturition to 3  $\delta$ s and 3  $\text{qs}$  each. Doses of 0.025-0.5 mg. of theelin or 0.025-0.1 mg. of diethylstilboestrol were injected daily. The influence on the urogenital system, although variable with young of the two sexes, seemed proportional to the dose of the oestrogen administered, but diethylstilboestrol was more effective than theelin.

**The experimental control of prolonged pregnancy in the lactating rat by means of estrogen,** C. K. WEICHERT (*Anat. Rec.*, 83 (1942), No. 1, pp. 1-17, pls. 2).—Continuing these studies (E. S. R., 84, p. 318), it was shown that the gestation periods of pregnant lactating rats suckling 9 young varied from 27 to 40 days with the majority between 32 and 35 days. There was only a general correlation between the time of implantation and the number of young suckled. Injections of oestrogen in oil into 123 inseminated  $\text{q}$  rats suckling 9 young each permitted normal gestation through the control of normal implantation. Oestrogens necessary for normal implantation may be removed through mothers' milk when a litter is suckled.

## FIELD CROPS

[Findings in field crops research in Arkansas]. (Partly coop. U. S. D. A.). (*Arkansas Sta. Bul.* 417 (1942), pp. 7-9, 15-17, 18-20, 26-28, 29-30, figs. 2).—Recent findings in agronomic research (E. S. R., 84, p. 612) at the station and substations and their application to agricultural problems in Arkansas are reported on winter legumes for soil improvement, by R. P. Bartholomew; plant food requirements for cotton, by C. H. Wadleigh and W. H. Tharp; fertilization for rice production, by L. C. Kapp; development of hybrid corn for Arkansas, by L. M. Humphrey and C. K. McClelland; value of sorghums for feed and food,

by McClelland; and breeding for winter resistance in oats, by H. R. Rosen, L. M. Weetman, and McClelland.

[**Farm crops research in Mississippi**] (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, pp. 1-2, 2-3, 5, 7).—Results from experiments with field crops are reported in articles entitled **Varieties and Kinds of Winter Legumes**, by R. Coleman (pp. 1, 7); **Increased Winter Legumes, To Plow Under, Suggested To Meet Nitrogen Shortage**, by C. Dorman (pp. 1, 3, 5); **Small Grain Varieties, Hill Stations**, by J. F. O'Kelly (pp. 1, 2); **Oat Variety Tests, Rates and Dates of Seeding** (pp. 1, 2, 3), and **Wheat and Barley Varieties** (pp. 1, 3), both by P. W. Gull; and **Fertilizing Oats in the Yazoo-Mississippi Delta**, by R. Kuykendall (pp. 1, 3).

[**Crops experiments in Missouri**]. (Partly coop. U. S. D. A.). (*Missouri Sta. Bul.* 444 (1942), pp. 19, 20, 50-51, 51-61, 79-80).—Field crops studies (E. S. R., 87, p. 52) reported on again by M. M. Jones, L. E. Hightower, R. P. Beasley, B. M. King, J. M. Poehlman, E. M. Brown, C. A. Helm, C. M. Tucker, L. J. Stadler, G. F. Craig, D. C. Anderson, J. G. O'Mara, E. R. Sears, L. Smith, G. F. Sprague, G. E. Smith, and W. A. Albrecht included breeding work with corn, wheat, oats for immunity or resistance to smuts, barley, and soybeans; genetic studies with corn, especially on the production of genetic variations by radiation of pollen with ultraviolet (E. S. R., 87, p. 206) and X-rays; polyploidy studies with wheat (E. S. R., 87, p. 207); variety trials with corn (and hybrids), barley, soybeans, oats, and cotton; effect of fertilizers on the yield and feeding value of timothy; fertilizer placement experiments and efficiency of tillage methods in growing corn; effect of treatment of seed corn on yield; pasture research, including response of Kentucky and Canada bluegrasses, orchard grass, and redtop in growth of roots, rhizomes, and herbage to variations in cutting height and in soil and air temperatures; influence of continuous, rotation, and supplemented (Korean lespedeza) grazing on live-weight gains by beef cattle on bluegrass pasture; pasture fertilization; and rotation pastures v. cultivated crops in production of feed for cattle.

[**Agronomic experiments in Nebraska**]. (Partly coop. U. S. D. A. et al.). (*Nebraska Sta. Rpt.* [1941], pp. 12-31, 34-36, 43-45, 79-81, 85-87, figs. 2).—Field crops research (E. S. R., 86, p. 33) reported on from the station and substations by T. A. Kiesselbach, L. M. Camp, K. S. Quisenberry, W. E. Lyness, R. L. Cushing, H. M. Tysdal, S. Garver, J. M. Slatensek, L. C. Newell, E. C. Conrad, T. E. Brinegar, F. D. Keim, N. S. Hanson, H. O. Werner, R. W. Goss, E. B. Snyder, E. Kneen, J. E. Livingston, L. L. Zook, O. J. Webster, and L. Harris included variety tests with winter and spring wheat, corn and hybrids, oats, barley, flax, grain sorghums, sorgo, alfalfa, sweetclover, soybeans, potatoes, castor-beans, Jerusalem-artichokes, and safflower; breeding work with corn (and hybrids), sorghum, wheat, oats, barley, soybeans, alfalfa (E. S. R., 87, p. 662), sweetclover, brome-grass, and potatoes; crop rotations; response of corn, wheat, and sorghum to fallow and other tillage practices; the influence of manure, alfalfa, and pastured sweetclover on yields of sugar beets, potatoes, and other irrigated crops; pasturing alfalfa with hogs and sweetclover with sheep and harvesting corn with hogs in these rotations; heat and drought endurance studies with potatoes; effect of different humidity and temperatures at various periods of the year in storage in relation to weight loss, rotting, and initiation of sprouting of potatoes; planting tests with wheat, oats, barley, and sorghum; cutting and palatability tests and coumarin determination with sweetclover; cold resistance of wheat, rye, and barley as affected by different factors; the influence of environmental factors and disease on the carbohydrate-enzyme relations in germinating grain; improvement of permanent pastures and meadows, including tests of strains of brome-grass and other grasses, selection and breeding with

bromegrass and other species, methods of producing grass seed and seed yields, response of grasses to intensity of clipping, a study of three methods of grazing sheep on bromegrass-alfalfa pastures, the grazing preferences by cattle and sheep for different species and strains of grasses, and range studies in sand hill and hard land areas; and studies on carbohydrate reserves in the roots of bindweed and bindweed control by cultivation, smother crops, and sodium chlorate and other chemicals.

[Agronomic investigations in Texas]. (Partly coop. U. S. D. A. et al.). (*Texas Sta. Rpt. 1941*, pp. 8-19, 58-64, 96-99, 101-103, 108-109, 112-114, 116-117, 118-120, 124-130, 130-133, 134-135, 135-137, 138-139, 140-141, 147-150, 151-152, 154, 155, 156, 165, 166-168, 168-170, 170-172, 177-178).—Experimentation with field crops and related lines (E. S. R., 86, p. 180) at the station and substations is reported on briefly by E. B. Reynolds, R. H. Stansel, P. R. Johnson, H. F. Morris, D. T. Killough, J. E. Roberts, R. H. Wyche, H. M. Beachell, E. S. McFadden, C. H. McDowell, C. H. Rogers, R. G. Reeves, H. P. Smith, D. L. Jones, M. H. Byrom, R. L. Hensel, G. S. Fraps, J. H. Jones, W. H. Brittingham, D. A. Reid, J. O. Beasley, T. R. Richmond, K. F. Manke, I. P. Trotter, H. E. Rea, R. E. Karper, J. R. Quinby, J. C. Stephens, I. M. Atkins, P. B. Dunkle, R. E. Dickson, W. F. Turner, W. H. Dameron, V. L. Cory, J. F. Wood, W. H. Friend, G. H. Godfrey, L. E. Brooks, and E. Mortensen.

The research comprised variety tests with cotton, corn (and corn and sweet corn hybrids), wheat, oats for grain and winter pasture, barley, rice, grain sorghum, sorgo, broomcorn, flax, soybeans, edible soybeans, alfalfa, clover, sweetclover, vetch, potatoes, sweetpotatoes, sugar beets, castor-beans, and miscellaneous winter and summer legumes and grasses; a production test with safflower; flax as a winter crop for south Texas; breeding work with cotton, wheat, oats, barley, corn and hybrids, rice, grain sorghum, sorgo, sweetpotatoes, Sudan grass, cowpeas, sweetclover, peanuts, and buffalo and other grasses; development of cotton varieties adapted to mechanical harvesting; cytogenetics of cotton; inheritance studies with cotton, corn, and different sorghums; studies of the genetic and cytological relationship of corn, *Euchluena*, and *Tripsacum*; cultural (including planting) tests with cotton, corn, wheat, oats, rice, grain sorghum, potatoes, buffalo grass, flax, safflower, castor-beans, soybeans, sweetclover, and winter legumes; a variety-spacing test with grain sorghum; size of plants, height of bed, date of planting, spacing, rooted v. cut slips, cover crop, cultivation, and harvesting tests with sweetpotatoes; root initiation by seedlings from cottonseed treated with growth-promoting substances; seedbed preparation studies; comparisons of corn and sorghums and their effects on succeeding crops; effect of different types of tillage preparation for wheat with relation to wind erosion; double cropping experiments with sorghum; curing of combined sorghum grain in trenches; irrigation tests with cotton, grain sorghum, safflower, and sugar beets; rotation and sequence experiments with different field crops and green manures; legumes interplanted with oats for hay; effect of gypsum, S, and subsoiling on forage yields; fertilizer tests with crops in rotation, cotton, corn, oats, rice, potatoes, sweetpotatoes, grain sorghum, peanuts, winter legumes, and pasture; methods of applying fertilizers and carriers of N and P for rice; tolerance of rice to different soil reactions; residual effect of cotton burs and manure for cotton; vetch and other green manures for cotton and other crops; soil fertility and improvement studies; rotation grazing, spraying, shading with other plants, and pulling in control of bitterweed; control of mesquite and pasture weeds; production and germination of buffalo grass seed and establishment of buffalo grass pasture; effects of fertilizer treatments on yield and chemical and botanical composition of herbage; relation of sunlight to the yield and quality of vegetation; and grazing tests with new grasses.

**Basis for judging subalpine grassland ranges of Oregon and Washington,** G. D. PICKFORD and E. H. REID (*U. S. Dept. Agr. Cir. 655* (1942), pp. 38, figs. 19).—Results of studies on subalpine grassland areas in eastern Oregon in 1937 and 1938 are summarized as a basis for judging the condition and use of such range. Two important range types found on subalpine grasslands in eastern Oregon and Washington were involved—the green fescue type and the needlegrass-weed type. The characteristics of this range in different condition stages are presented with comparative values for grazing, watershed, and protection of soil from accelerated erosion. Means for field identification of condition stages, trends of range condition, and current proper utilization are also described. The circular is expected to be of value to those using this type of range and of interest to other stockmen and others concerned with range vegetation and soils.

**Cultivated grasses and legumes in Alaska** (*Alaska Univ. Ext. Cir. 2* (1942), pp. [4], fig. 1).—That native grasses will not survive when cut or grazed year after year was shown by experiments of the Alaska Experiment Station. They mature early and quickly lose their feed value and palatability by leaching. Legumes seeded on established grass mixtures have given best results, while those sown alone, except the yellow-blossom Siberian alfalfa (*Medicago falcata*), have seldom survived longer than two or three winters. Varieties of cultivated grasses and legumes found best adapted to the different areas are mentioned. Mixtures of grasses have produced heaviest yields. Grass meadows have responded to applications of 200 lb. of N fertilizer per acre with doubled yield, and legumes have responded equally well to treble superphosphate. Manure, 10 tons per acre, will increase hay or pasture yields about 30 percent. Where pastures or hay land became sod-bound, use of the cutaway disk or spring-tooth harrow will give excellent results. Seed may be either drilled or broadcast on well-prepared soil, preferably cultipacked before and after seeding.

**Influence of soil temperature on the development of colonial bent grass,** I. H. STUCKEY. (R. I. Expt. Sta.). (*Plant Physiol.*, 17 (1942), No. 1, pp. 116–122, figs. 5).—Colonial bent, Kentucky bluegrass, and timothy seedlings, when grown for 6 weeks in tanks of nutrient solution with the roots at 45°, 60°, and 90° F. and the tops at one temperature, showed striking differences in development. Colonial bents grown for 5.5 mo. in soil with the roots at 50°, 60°, and 80° showed like differences. Root growth closely resembled that found out of doors when the soil temperature approximated the experimental temperature. Maturation of roots, accelerated by high soil temperatures, occurred before extensive ramification of roots took place in plants growing at the highest temperature. Death of plants at the highest temperature was attributed to early maturation and death of the root system.

**Winter legumes for green manure in the Cotton Belt,** R. MCKEE and A. D. MCNAIR (*U. S. Dept. Agr., Farmers' Bul. 1663, rev.* (1942), pp. 11+20, figs. 7).—This is a revision (*E. S. R.*, 65, p. 223).

**Growing winter barley in New Jersey,** C. S. GARRISON (*New Jersey Stas. Cir. 447* (1942), pp. 4).—Practical information is given on the soil and fertility needs of winter barley, varieties, seeding and planting, harvesting and use of feed, companion crop, and fall or spring pasture. Maryland Smooth Awn, Kentucky No. 1, and Tennessee Winter have made satisfactory yields. Nassau, a new variety recently developed at the station and to be released for general distribution in 1943, is a high-yielding, smooth-awn, stiff-straw, early-maturing, six-row winter barley.

**Effects of artificially drying seed cotton on certain quality elements of cottonseed in storage,** R. A. RUSCA and F. L. GERDES (*U. S. Dept. Agr. Cir. 651* (1942), pp. 19, figs. 4).—A 2-yr. study of wet and dry cottonseed of the 1939 and 1940 crops, handled to simulate oil-mill and cotton-gin storage conditions, re-

vealed that the process of artificially drying seed cotton at the gins has a beneficial effect on the storage qualities of the seed. Seed moisture content and temperature were decreased by the drying process with the result that development of free fatty acids was definitely retarded. Viability was increased slightly. A free fatty acid content of 2 percent was shown to be critical insofar as germination is concerned.

**Potato growing on the Cumberland Plateau, J. J. BIRD** (*Tennessee Sta. Bul. 181 (1942), pp. 66, figs. 22*).—Practical recommendations on potato production as to soils, rotations, varieties, seed and planting, seed production, fertilizers, control of diseases and insects by spraying, cultivation, harvesting, and storage are based on cooperative experiments, 1936-40, on 27 farms near Crossville.

Some of the better practices indicated by the experiments included use of the Chippewa, Pontiac, Sequoia, and Sebago varieties; seed of known origin; green sprouting of seed; use of a cutting table; blocky seed pieces weighing 1.5-2 oz.; planting between April 1 and 10; use of one-row potato planter; spacing 12 in. or less in the row or 8 in. apart when leafhopper and early blight are controlled with bordeaux; 1,000 lb. per acre of 4-10-4 fertilizer under average conditions on relatively old land, or 2,000 lb. with adequate spraying; combination of spray and fertilizer; use of the weeder to reduce row cultivations; harvesting by the use of a standard elevator digger, a low rubber-tired wagon, and crates; and sawdust-insulated above-ground storage.

Power-sprayed bordeaux mixture controlled early and late blight and hopper-burn effectively when applied weekly, while hand spraying or dusting proved unsatisfactory. The four-row engine-mounted, team-drawn sprayer was the most practicable for the average commercial acreage. Proprietary copper compounds failed to equal bordeaux in disease and insect control. Seven bordeaux sprays increased yields about 40 percent whether yields were high or low. Soil packing and damage to plants by sprayer wheels reduced yields considerably. Potato diseases and insects commonly found on the plateau are listed with characteristics and control measures.

Study of production costs and income on 12 farms in 1939 having average salable yields of 130 bu. per acre revealed an average labor income of 16.5 ct. per hour of man labor and yields averaging 170 bu. salable 44 ct. per hour. About three-fourths of the labor was expended in planting and harvesting when special equipment was not available. Effects of residual fertilizer on subsequent crops may be evaluated as part of the returns from the potato enterprise.

**Interrelationship of storage temperature, concentration, and time in the effect of carbon dioxide upon the sugar content of potato tubers, F. E. DENNY and N. C. THORNTON** (*Contrib. Boyce Thompson Inst., 12 (1942), No. 5, pp. 361-373, figs. 3*).—Tubers were stored at 2°, 5°, and 7° C. in atmospheres containing 0, 5, and 20 percent CO<sub>2</sub> and 21 percent O<sub>2</sub>, and at 30, 60 and 90 days samples were removed for determinations of the reducing sugar and sucrose contents of the juice and for preparation of potato chips. The rapid increase of reducing sugar in tubers stored at 2° was inhibited for 30 days by 5 percent CO<sub>2</sub>, and for 60 days by 20 percent CO<sub>2</sub>, but after 90 days the values for CO<sub>2</sub>-treated lots were one-half to one-sixth of those for the controls (without CO<sub>2</sub>). At 5° the reducing sugar increase was prevented by 5 percent CO<sub>2</sub> for 90 days with Irish Cobbler and for 30 days with Katahdin varieties; with Green Mountain the 5 percent CO<sub>2</sub> values were kept down to about one-half those of the controls. A retarding effect of 5 percent CO<sub>2</sub> was also noted at 7°. Treatment with 20 percent CO<sub>2</sub>, though exerting a retarding effect for 30 days at 5° and 7°, then had the reverse effect, so that in 90 days at 5° the

reducing sugar values were equal to the controls, and at 7° were three to five times those receiving no CO<sub>2</sub>. Changing the temperature from 2° to 7° reversed the effect of 20 percent CO<sub>2</sub> on reducing sugar content. The general effect of CO<sub>2</sub> on sucrose content was to increase it greatly (about sixfold at 5° and 7°). At 2°, treatment with CO<sub>2</sub> first retarded sucrose increase as compared with the untreated, and then greatly increased it. Part of this anomalous effect is said to be due to the fact that the temporary maximum (formed in the sucrose curve of the juice from untreated tubers after about 30 days at 2°) does not occur in the presence of suitable amounts of CO<sub>2</sub>.

**Soybeans in brief: A war crop for Delta farmers**, P. S. McCOMAS and E. L. LANGSFORD. (Coop. Miss. Expt. Sta. et al.). (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1942, *F. M.* 28, pp. [2]+11).—This report on soybeans for oil in the Mississippi Delta area "summarizes the experience of 50 farmers who have produced soybeans for oil, the results of experiment station work, and the opinions of experiment station and extension service workers."

**Irrigation of sugar beets grown for seed**, C. PRICE and M. R. HUBERTY. (Coop. Calif. Expt. Sta.). (*U. S. Dept. Agr. Cir.* 658 (1942), pp. 7).—Irrigation experiments with sugar beets grown for seed in the Hemet Valley of California were made during five seasons. When adequate moisture was supplied during blooming, irrigation at 7-day intervals gave no better results in yield and percentage of seed germinating than water at 14- and 21-day intervals.

**Juice quality affected by lodging**, R. J. BORDEN (*Hawaii. Planters' Rec. [Hawaii. Sugar Planters' Sta.]*, 46 (1942), No. 2, pp. 39-42, fig. 1).—Cultures in which 31-1389 sugarcane was grown upright and in a horizontal or lodged position provided data showing that lodging, generally caused by heavy winds or rains, results in a poorer quality and an actual loss of sugar especially in that part of the stalk which remains recumbent. Apparently these effects from lodging were not altered by increased N fertilization.

**Growing tobacco as a source of nicotine**, J. E. McMURTRY, JR., C. W. BACON and D. READY. (Coop. 11 State expt. stas. et al.). (*U. S. Dept. Agr., Tech. Bul.* 820 (1942), pp. 39, figs. 10).—Comprehensive studies, 1934-38, were concerned with the nicotine production of different species and varieties of tobacco, effects of irrigation, and variations in planting and harvesting dates, topping, suckering, and spacing; and direct field planting, a sucker crop from a single planting, and distribution of nicotine in different plant organs. Inheritance studies have been noted (*E. S. R.*, 86, p. 458).

Under favorable conditions *Nicotiana rustica* consistently produced more nicotine than ordinary tobacco. On fertile soils under irrigation over a period of years its consistent yield was 150 lb. or more of nicotine per acre, about double the quantity from ordinary tobacco. Of numerous varieties or strains of *N. rustica* tested, Brasilia appeared to be the most satisfactory variety currently available. A new strain designated as 68 (Winnebago × Brasilia) has better growth habits than Brasilia but does not always yield more nicotine. For high yields of nicotine stunting of *N. rustica* plants at any growth stage must be avoided, topping and suckering done at regular intervals, and the crop as a rule harvested late, up to 60 days after topping, provided no excessive loss of lower leaves by leaf spot or drying occurs. The leaf was found to contain the bulk of the nicotine, but *N. rustica* stalks contained enough to justify their use for nicotine recovery. Temporary drought during growth constituted an important weather hazard in most humid regions. New disease and insect hazards in growing this crop were found in certain areas outside of the present tobacco-producing regions.

"As the problem now stands, growing high-nicotine tobaccos solely for their nicotine content apparently is feasible but does not offer a wide margin of profit on the basis of prices now paid for byproduct leaf. Commercial development would depend upon information obtained from more definite cost studies in both the producing and manufacturing phases of the problem. Development of higher yielding strains possessing desirable growth habits seems to furnish the most promising outlook for increasing the output per acre of nicotine."

Approximate hours of man labor (271) and horse work (90) needed for producing an acre of *N. rustica* tobacco and their distribution between the main cultural operations are estimated on the basis of requirements for growing burley and dark-fired tobacco in Kentucky (E. S. R., 57, p. 479).

**Recent work on germination** (*Nature* [London], 149 (1942), No. 3789, pp. 658-659, fig. 1).—A brief review of recent studies on seed germination, including references to some hitherto unpublished data.

## HORTICULTURE

**Effects of synthetic growth substances on cuttings, seeds, and transplants**, J. C. SWARTLEY and L. C. CHADWICK (*Ohio Sta. Bimo. Bul.* 217 (1942), pp. 125-144).—Herein are discussed the results of treatments of various plants with synthetic growth substances. The treatment of leafy cuttings of woody plants was markedly beneficial in 8 of 17 species. The response was shown in a quicker production of a greater number of roots. In only one case (*Pyracantha coccinea pauciflora*) did rooting occur all along the stem instead of the usual location just above the thorns. Amide compounds compared favorably with the acid compounds but, in general, the latter were more effective provided they were used in the proper concentration. Synthetic growth substances adjusted to a pH of 3 acted in somewhat the same manner as did stronger concentrations. Acid mixtures proved particularly effective with fall cuttings of the Pfitzer juniper but were for the most part toxic with winter and spring cuttings of the same species. Talc alone apparently was beneficial in some tests with Pfitzer juniper and Japanese yew. Bottom heat at 80°-85° F. was detrimental. Treatments of seeds of various perennials gave increased germination, and in some cases the plants grown from treated seeds were larger at 2.5 mo. Treatment accelerated the growth of rooted cuttings of *Lonicera fragrantissima*, crabapple seedlings, coreopsis, viola, aster, tomato, and certain other species.

**Plant-growth regulators**, J. W. MITCHELL and R. R. RICE (*U. S. Dept. Agr., Misc. Pub.* 495 [1942], pp. [2]+75, figs. 10).—Information is presented on the history of the discovery of the function of growth-regulating substances, their preparation and use in various forms, methods of treating cuttings, and their use in controlling preharvest dropping of fruits and in transplanting. In tabular form, the results of trials by Department and other workers on the propagation of a large number of different plants are summarized.

**[Horticultural studies by the Arkansas Station]** (*Arkansas Sta. Bul.* 417 (1942), pp. 12-13, 25, 28-29).—Progress of the following studies is discussed: The canning quality of different peach varieties, by H. Reynolds and J. R. Cooper; the effect of lime on the growth and production of various vegetables, by V. M. Watts and Cooper; and the effect of fertilization and pruning on flower development and structure in the strawberry and cucumber, and the nature and causes of winter injury and hardness in brambles, both by J. E. Valle.

**[Horticultural studies by the Missouri Station]** (*Missouri Sta. Bul.* 444 (1942), pp. 64-65, 66-70).—Progress reports are presented on the following studies: The nutrition of vegetable crops and the influence of soil temperature

on the growth of cucumbers, both by R. A. Schroeder; the control of apple scab, correctives for reducing spray injury, and the nutrition of grapes, all by H. G. Swartwout; substitutes for lead arsenate, by C. G. Vinson; the propagation of forest trees and shrubs, site requirements and growth rate of native and exotic trees, and Christmas trees as a farm crop, all by R. H. Peck; control of biennial bearing in the apple by defoliation with various chemicals, by A. E. Murneek and Swartwout; performance of apple branches of various ages on both pruned and unpruned trees, by Murneek and D. G. White; effect of branch ringing on the set and size of fruit, and a comparison of spring and fall fertilization of apple trees, both by Murneek; induction of flower bud formation in young apple trees, by Murneek and W. H. Griggs; methods of determining carbohydrates in plant tissues, by Murneek and P. H. Heinze; and the effect of flower-producing hormones on the initiation of flower-buds in various plants, by Murneek and E. J. Airola.

[**Horticultural studies by the Nebraska Station**] (*Nebraska Sta. Rpt.* [1941], pp. 31-34, 36, 82).—Included are reports upon the effect of the November 11, 1940, freeze on fruit plants, the effect the naphthaleneacetic acid in promoting parthenocarp in the Dunlap strawberry, and soil management in the orchard, all by C. C. Wiggans and R. E. Baker; the use of supplemental water for orchards in eastern Nebraska, by Wiggans, Baker, and E. E. Brackett; the effect of sodium thiocyanate upon the coloring of Duchess apples, by Baker and E. H. Hoppert; relation of hardy rootstocks to tree injury during the November blizzard, by Baker; and tomato breeding, carrot breeding and improvement, irrigation and mulching of vegetables, and variety studies with vegetables, all by H. O. Werner. A brief report is given on the effects of the November freeze on fruit and shelterbelt plants at the North Platte Substation, by H. A. McComb.

[**Horticultural studies by the Texas Station**]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 46-56, 57, 58, 99, 103-104, 109-110, 117, 137, 139, 141-142, 160, 161-162, 162-163, 164, 165, 166, 172-174, 174-177, 178-180).—In this current report (U. S. R., 86, p. 189), there are presented brief progress statements on variety, adaptability, culture, fertilizer, pruning, propagation, pollination, breeding, and other studies with vegetables, fruits and their products, nuts, ornamentals, and slash pine, and other plants at the main station, substations, and field laboratories by S. H. Yarnell, J. F. Rosborough, J. C. Ratsek, B. S. Pickett, T. E. Denman, U. A. Randolph, H. F. Morris, E. Mortensen, W. H. Friend, J. F. Wood, H. M. Reed, W. S. Flory, Jr., [M. L.] Tomes, L. R. Hawthorn, F. R. Brison, [H. T.] Blackhurst, R. A. Hall, E. M. Neal, R. H. Wyche, R. M. Sherwood, D. L. Jones, and J. J. Bayles.

**Effects of partial defoliation at transplanting time on subsequent growth and yield of lettuce, cauliflower, celery, peppers, and onions**, J. E. KRAUS (*U. S. Dept. Agr., Tech. Bul.* 829 (1942), pp. 35, figs. 5).—"Pruning" or partial defoliation was without significant effect on survival of transplanted plants, regardless of hardening treatments or time of irrigating after transplanting. Removal of from 70 to 90 percent of the leaf area of lettuce plants reduced the number of early-harvested heads by one-half to three-fourths, and the total heads marketable by one-fifth to one-fourth. This pruning was without consistent effect on the characteristics of the heads that became marketable. Removal of from 40 to 50 percent of the leaves of cauliflower had no important effect, but removing from 70 to 90 percent at transplanting delayed maturity and sometimes reduced total yield. Heavy pruning of celery plants sometimes reduced the yield of celery but was without effect on onion and pepper. Heavy pruning of "large" transplants of celery was more harmful than pruning small ones, but in cauliflower the size

of plants pruned was without measurable effect. Leaf-pruned plants transpired less water per plant than unpruned, but more per unit of leaf area, when the root systems of both groups were of comparable extent. In general, the rate and amount of root growth in celery and cauliflower subsequent to pruning were reduced in proportion to severity of leaf pruning. Plant recovery and resumption of growth appeared directly correlated with the amount of carbohydrate reserves available in the plant as it was transplanted.

**Lima beans' response to seed treatment in field tests, G. L. McNEW.** (N. Y. State Expt. Sta.). (*Canner*, 94 (1942), No. 17, pp. 10-12, figs. 2).—In a series of laboratory and greenhouse tests designed to establish whether any of the treatments ordinarily used on vegetable and cereal seeds would be effective on the lima bean, Spergon, New Improved Semesan Jr., and tetramethylthiuram disulfide were found promising for field use. In field trials in 1941 Spergon gave particularly good results, as measured in the percentage of emergence, vigor of growth, and increased yield of shelled beans.

**Quality in the Chantenay carrot and its relation to seed production, N. K. ELLIS.** (Purdue Univ.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 536-538, fig. 1).—Refractive index readings on the expressed juice of a group of 46 carrots carefully selected for outward uniformity showed considerable variation. Edibility was correlated with the quantity of soluble solids as expressed in percentage sucrose. An examination of several different lots of Chantenay carrots showed well-marked differences with respect to degree of uniformity of soluble solids contents. Some evidence was obtained that the higher quality roots rot more readily under unfavorable conditions, with the result that a given seed stock may actually deteriorate in quality through no fault of the seed producer.

**Heat and drought tolerance of sweet corn as influenced by tillers, S. A. McCORRY.** (S. Dak. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 424-428, fig. 1).—Observations in plantings of the more common sweet corn hybrids showed pronounced differences in the time that tillering occurred and in the number of tillers per plant, but the time of tillering was not correlated with the date of ear maturity. In another experiment, in which the tillers were removed from half the plants of each variety, it was observed that in a very warm period there was more heat injury in the tiller-bearing plants. In extreme cases every plant showed top firing where tillers were present, and no injury in adjacent rows where the tillers had been removed. Apparently the period when tillers develop is as important to heat and drought resistance as are the number of tillers that are found.

**Sugar content of sweet corn pollen and kernels of inbred and hybrid strains susceptible to tassel infestation by aphids, E. S. HABER and W. G. GAESSLER.** (Iowa Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 429-431).—The tassels of some inbred lines of sweet corn were observed to be more heavily infested with aphids than were others. Chemical examination of the pollen showed a variation in the percentage of total sugars present, but there was no correlation between aphid susceptibility and the amounts, and no evidence that tassel infestation by aphids is the result of high sugar content of the pollen. Inbred 45, highly susceptible to aphids, had a relatively low sugar content in the pollen. There was little difference between the various strains as regards nitrogen and ether extracts.

**Value of molybdenum for lettuce, W. E. BRENCHLEY and K. WARINGTON** (*Nature* [London], 149 (1942), No. 3772, p. 196).—The inclusion of 1 part of molybdenum in 10,000,000 parts of nutrient solution supplied lettuce resulted in larger, deeper green, and apparently more disease-resistant plants. The beneficial effect was observed whether molybdenum was used alone or in conjunction

with one or more other minor elements such as strontium, titanium, vanadium, chromium, and zinc. There was some suggestion that molybdenum fended off symptoms of boron deficiency for some time during the early stages of growth.

**Quality lettuce production under Mississippi conditions**, L. R. FARISH (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, pp. 1, 4-5, figs. 5).—Information is presented on climatic requirements, varieties, effect of time of planting, seeding methods, cultural practices, harvesting and marketing, etc.

**Growing and handling cantaloupes and other melons**, G. N. DAVIS and T. W. WHITAKER. (Coop. U. S. D. A.). (*California Sta. Cir.* 352 (1942), pp. 40, figs. 20).—This circular, which supersedes Circular 308 (E. S. R., 56, p. 236), gives general information on the importance of the industry; areas used; soils; fertilizers; planting practices; culture; irrigation; determination of picking maturity; harvesting, grading, and picking; seed production; varieties; control of insect and fungus pests; etc.

**The production of first-generation hybrid tomato seed for commercial planting**, K. C. BARRONS and H. E. LUCAS. (Mich. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 395-404, figs. 3).—Information is presented on the methods of technic employed in producing hybrid tomato seed, the possible costs, and the advantages of first-generation seed.

**$\beta$ -naphthoxyacetic acid as an inductor of parthenocarp in tomatoes**, F. G. GUSTAFSON. (Univ. Mich.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 387-389).—Seedless fruits produced with  $\beta$ -naphthoxyacetic acid were larger than seeded fruits produced by pollination. Fruit setting was also somewhat greater than with open pollination.

**Bay State, a red forcing tomato bred for resistance to leaf mold**, E. F. GUBA (*Massachusetts Sta. Bul.* 393 (1942), pp. 8, pls. 8).—Herein is discussed the development of a new tomato variety developed for resistance to the leaf mold fungus *Oladosporium fulvum*. Resistance was obtained in an original cross between commercial varieties and the Red Currant tomato *Lycopersicon pimpinellifolium*. The new variety, named Bay State, is described as to plant and fruit characters. Unfortunately, there appeared in 1940 a new physiologic strain of leaf mold which injured the new variety and its resistant parent, the Red Currant tomato. There was some indication, however, that the Bay State variety possessed some resistance to this new physiologic strain.

**November 1940 cold damage to fruit plants in Illinois**, V. W. KELLEY and R. L. McMUNN. (Univ. Ill.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 220-224).—Observations following the disastrous early November freeze of 1940 showed that the degree of injury was largely associated with degree of hardening of the tissues at the time of the freeze. Plants that had dropped their leaves suffered little or no injury. The trunk tissue, which normally hardens later than that of small branches and limbs, suffered much more injury than the limbs and buds. The exposure of the orchard was an important factor, with trees on high land and on the windward side of the orchard suffering most severely. The behavior of various species and varieties is discussed.

**Fruit tree injury resulting from the Midwest blizzard of November 1940**, T. J. MANEY. (Iowa Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 215-219, figs. 2).—A record is presented of temperatures and conditions prevailing before and during the disastrous November 1940 blizzard and of the effects of the abnormally low and unseasonable temperatures on various fruit and ornamental plants. Because of the unusual conditions, varieties of recognized hardiness were in some cases badly injured. In general, however, hardy varieties came through best, and new varieties developed in the colder regions of the country survived better than those developed in the warmer areas.

**Budding and grafting on hardy apple stocks**, C. W. ELLENWOOD, T. E. FOWLER, and C. A. GREENE (*Ohio Sta. Spec. Cir. 65 (1942), pp. 29, figs. 26*).—Largely in the form of illustrations, information is presented on methods of budding and grafting apples, with a view to assisting in the top working of commercial varieties on hardy understocks, such as Virginia Crab, Hibernial, or Haas.

**Apple varieties: Behavior of two hundred varieties following the freeze of November 1940**, B. S. PICKETT and H. L. LANTZ. (Iowa Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 40 (1942), pp. 212-214*).—Observations in an apple orchard composed of trees top-grafted on Virginia Crab showed only 6 varieties, Anoka, English Russet, Malinda, Peter, Repka Malenka, and Hibernial, and 13 seedlings to have escaped some injury. A second group of 13 varieties showed upward of 90 percent recovery, and a third group of 23 kinds was classed as having recovery values of from 70 to 90 percent. In addition to an intermediate group of questionable value, there were 45 varieties and 4 seedlings rated as unworthy of saving. Unfortunately some of the most important market varieties, such as Jonathan and Delicious, were included in the unworthy group.

**Red varieties of early apples**, C. W. ELLENWOOD (*Ohio Sta. Bmo. Bul. 217 (1942), p. 124*).—Comments are given on several early-maturing red apples, including Close, Anoka, Crimson Beauty, Early Red Bird, Red Astrachan, Duchess, and Early McIntosh.

**Investigations on the time of blossom induction in Wealthy apple trees**, B. E. STRUCKMEYER and R. H. ROBERTS. (Wis. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 40 (1942), pp. 113-119, figs. 4*).—The blossoms from on-year trees and 85 percent of the leaf area of off-year trees were removed to obtain evidence on the time of blossom bud induction. When blooms were removed at the time of full bloom, larger leaves were produced and some blossom buds were formed. A reduction of leaf area from early defoliated spurs inhibited the formation of blossom buds. Spurs defoliated at the time of full bloom and 2 weeks later produced new leaves and some blossom buds. Spurs defoliated 3 weeks after full bloom did not form new leaves and developed only vegetative buds. Spurs defoliated 5 weeks after full bloom formed a number of blossom buds, indicating that induction had proceeded to the extent that total leaf area was no longer needed in the formation of blossom buds. Differences in the anatomical structure of the spurs from off-year and on-year trees were apparent about 4 weeks after full bloom and from 9 to 10 days before defoliation failed to inhibit completely blossom bud formation. A study of the mineral pattern of incinerated sections of off- and on-year spurs showed a different localization of the mineral residues. Reducing the area of the two-tip leaves of a spur shortly after full bloom reduced blossom bud formation, but not to the extent of complete defoliation.

**Thinning the apple crop by spraying at blooming**, V. R. GARDNER (*Mich. State Hort. Soc. Ann. Rpt., 69 (1939), pp. 112-114*).—In preliminary trials, three varieties were sprayed, after the removal of all unopened buds, with various materials designed to kill a portion of the blooms. Duchess blooms were by far the most susceptible to injury, Wealthy intermediate, and Ontario least susceptible. Generally, the addition of a wetting agent slightly increased the blossom-killing capacity of the materials used. Much of the success of the operation depended on the use of a proper concentration of materials.

**Further studies on the removal of spray residues from eastern-grown apples**, M. H. HALLER, C. C. CASSIL, E. GOULD, and A. L. SCHRAEDER. (Coop. W. Va. and Md. Expt. Stas.). (*U. S. Dept. Agr., Tech. Bul. 828 (1942), pp. 32, figs. 3*).—In this further report (E. S. R., 80, p. 49), the authors discuss the interrelation of a number of factors, such as variety, season, spray treatments,

maturity of the fruit, and type of washing treatment used in the removal of lead spray residues from apples. In fruits of equal size there were lower residue values on York Imperial than on Stayman Winesap and Delicious. Growth of the apples and weathering have very little apparent effect on the reduction of the residue during the harvest period, and rainfall also had little tendency to wash off residues. The general effect of a delay between harvest and washing was to increase the difficulty of residue removal. The addition of mineral-oil emulsion to the second-brood cover sprays of lead arsenate and bordeaux mixture increased the residue at harvest by nearly 50 percent, but had little effect when added to the first-brood cover sprays. Heating the washing solutions to 100° F. increased their efficiency. With the most effective washing treatment for each type of machine tested, there were no large or consistent differences between the different machines. In the flotation machine the addition of 1 percent of a wetting agent to the acid solution increased greatly the effectiveness of the wash. Washing treatments using heated solutions did not increase the amount of spoilage in York Imperial and Stayman Winesap apples in subsequent storage.

**Days from bloom as an index of maturity for apples, M. H. HALLER.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 141-145).—A study of indexes of early picking maturity for Williams, Jonathan, Grimes Golden, and Yellow Newtown apples grown under middle Atlantic conditions showed that pressure tests, ground color readings, and seed color and starch tests were unreliable. Regardless of locality and seasonal variations, the number of days from bloom to maturity was found rather constant during 3 yr. and proved to be a more reliable index of maturity than the other factors studied. It is suggested that harvest should not begin until at least 70, 130, 135, and 150 days after full bloom for Williams, Jonathan, Grimes Golden, and Yellow Newtown, respectively. The optimum maturity stage would be somewhat later.

**Pectic changes in Jonathan apples as a measure of ripening under differential carbon dioxide treatments, H. H. PLAGGE and D. V. FISHER.** (Iowa Expt. Sta. et al.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 169-171).—Analyses of Jonathan apples following storage in four CO<sub>2</sub> concentrations showed that such treatments retarded the hydrolysis of protopectin to soluble pectin. The soluble pectin content varied proportionately with the CO<sub>2</sub> concentration and with storage temperatures of 32° and 36° F. A residual effect of inhibiting soluble pectin formation was evident, since proportionate differences between samples from the different CO<sub>2</sub> atmospheres existed after the fruit was exposed at room temperature for 2 weeks. Under the same temperature, air-stored apples were consistently higher in soluble pectin than the fruit from any of the CO<sub>2</sub> atmospheres.

**The influence of one lot of apple fruits on another, R. M. SMOCK.** (Cornell Univ.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 187-192, figs. 4).—The gaseous emanations of ripe apples stimulated to a marked degree the respiration rate of preclimacteric Duchess, Wealthy, and McIntosh apples. In one case the ripe apples were of the same variety as those under treatment. Definite ethylene injury was apparent as a result of passing the vapors from ripe Yellow Transparent over proclimacteric Wealthy fruits. The emanations from ripe McIntosh apples had no effect on the respiration of postclimacteric Yellow Newtown fruits. The blue mold *Penicillium expansum* did not generate sufficient ethylene to stimulate the ripening of Duchess or Wealthy apples.

**Handling apples from tree to table, D. F. FISHER** (U. S. Dept. Agr. Cir. 659 (1942), pp. 39, figs. 18).—Information is offered on the importance of the proper handling of apples following harvest, the correct stage for picking, factors affecting condition during storage, modified atmospheres in the storage room,

undesirability of storage with certain other products, diseases in storage and their prevention, effects of type of package on fruit in storage, the responsibilities of the shipper, dealer, and industry in the proper handling and display of apples, etc.

**Interrelation of pollination, position on cluster, and set of pears, E. W. JENKINS** (*Vermont Sta. Bul.* 493 (1942), pp. 27, figs. 2).—As was shown in an earlier bulletin (E. S. R., 85, p. 764), pear blossom position on the cluster is an important factor in fruit setting when more than two blooms are left on the cluster. This further study shows that when only the terminal and basal blossoms of a cluster are left and pollinated neither the position of the blossom on the cluster nor the time of pollination causes significant differences in the set of fruit when cross-pollination is practiced. In the case of self-pollinations, time of pollination appeared to be an important factor since the earlier applications of pollen always produced a greater set of fruit and more good seed.

**The response of peaches in Kentucky to cultivation and cover crops and to sod cultures, A. J. OLNEY and W. D. ARMSTRONG.** (Ky. Expt. Sta.) (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 123-125).—A soil management study with Elberta peaches conducted at Princeton, Ky., indicated the advisability of maintaining the clean cultivation cover-crop system during the early years of the orchard. On level land not subject to erosion, this system was most satisfactory throughout the entire experiment. On sloping land, however, clean cultivation resulted in erosion and a progressive decline in growth and yield. Because of dry weather that occurs frequently in Kentucky during September and October, it was found difficult to establish winter cover crops sufficient to protect the soil. Sod plats suffered practically no erosion, despite the fact that the annual lespedeza died down each autumn.

**New peach varieties found good in Delta, E. A. CURREY** (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, p. 8).—General information is offered on the time of ripening, productivity, fruit characteristics, and general value of a number of the new peach varieties. Oriole, Halehaven, Valiant, and Kalhaven were found particularly desirable and are recommended as valuable additions to home planting.

**Selection of criterion leaves for the identification of blueberry varieties, J. H. CLARK and S. G. GILBERT.** (N. J. Expt. Stas.) (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 347-351).—On the basis of measurements of leaves located on different portions of the twig, the fourth, fifth, and sixth leaves from the tip of lateral branches 8-12 in. long were found to exhibit a minimum of variability and are suggested as criterion leaves for measurements made for the purpose of identifying varieties. The tip angle, base angle, and leaf width: length ratio were found valuable and relatively constant variety characters. The base angle of leaves on weak plants tended to be both absolutely and relatively narrower than on vigorous plants.

**Effect of soil media, photoperiod, and nitrogenous fertilizer on the growth of blueberry seedlings, F. PERLMUTTER and G. M. DARROW.** (U. S. D. A.) (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 341-346, figs. 3).—An analysis of leaf area and total linear growth measurements on blueberry seedlings grown on eight different soil mediums indicated that a mixture of two-thirds forest litter with one-third potting soil was most favorable. The vegetative growth of blueberry seedlings was greatly increased by providing longer days during winter, and the final size at the end of the season was in general proportional to the number of months of supplemental light that the plants had received. No significant difference was evident in the average number of leaves per plant due to exposure to various monthly light periods. There was, however, a signifi-

cant difference in leaf area. No significant increase in growth was obtained by applications of nitrogenous materials, such as urea, sodium nitrate, or ammonium sulfate, during the early stage in the life history of the seedling.

**Growth response of blueberries under clean cultivation and various kinds of mulch materials**, E. F. SAVAGE and G. M. DABROW. (Ga. Expt. Sta. and U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 338-340).—Mulching in one form or another was found essential to the best growth of highbush blueberries in northern Georgia under the prevailing conditions of high temperature and frequent deficiency of soil moisture. Sawdust, because of its greater power for retaining soil moisture by reducing surface evaporation and runoff, was by far the best mulch tested, and because of cheapness and availability is recommended for mulching blueberries in the Southeast. Looser materials, such as rye straw and oak leaves, were better than clean cultivation, but not so effective as the sawdust.

**The influence of various renewal systems and width of row on yields of the Blakemore strawberry**, J. C. CRANE and I. C. HAUT. (Md. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 368-372).—In the case of Blakemore strawberries grown under a previously fruited thinned-row system, greater yields were obtained when all runners were removed and the original plants fruited the second year than from either the conventional renewal system or a reversion to the matted row. Evidently when thinned rows are allowed to revert to a matted-row condition for second-year fruiting, yields equal to a conventional "barring off" may be obtained. Compared with first-year yields, fruiting the original plants the second year resulted in about 8-percent reduction in yield as compared with 40-percent reduction with the other two renewal systems. Apparently under the 2-yr. plant-renewal system, the plants were able to accumulate larger leaf areas, larger root systems, and food reserves. In the case of 10-, 20-, 30-, and 40-in. spacings between rows, there was a progressive decline in yield as the distance increased.

**Some plant-spacing results with six strawberry varieties**, W. H. CHILDS. (W. Va. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 357-360).—At Morgantown, W. Va., Blakemore, Catskill, Culver, Fairfax, and Howard 17 strawberry plants spaced 8 in. apart outyielded the same varieties in matted rows. The Gandy variety did not give the same response. The beneficial effect of spacing rested in a greater number of berries and in increased size of berries. In general, production was earlier in the spaced plants, although this did not hold true for all varieties in the 1938 season.

**Strawberry plant behavior as influenced by mulch (preliminary report)**, W. D. ARMSTRONG. (Ky. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), p. 367).—Following the very cold winter of 1939-40 with extremely low temperatures and no snow cover, even the heaviest mulches did not prevent some winter injury. However, injury was very much more severe in beds lightly mulched or receiving no mulch. Heavy December and February mulching retarded blossoming and ripening and reduced weed growth.

**Effects of rootstock upon composition and quality of fruit of Concord, Campbell Early, and Moore Early grapes**, H. REYNOLDS and J. E. VAILE (*Arkansas Sta. Bul.* 421 (1942), pp. 39, figs. 9).—Based on 3-yr. averages, Campbell Early and Moore Early grapes grown on certain rootstocks were lower in sugars and higher in acidity than fruit from own-rooted vines. On other rootstocks there were no significant differences. With Concord grapes the differences in composition between fruit from grafted and own-rooted vines were not significant. The effects of various stocks on Campbell Early and Moore Early are discussed statistically. The estimation of juice quality by taste of pasteurized

samples showed the juice from fruit produced by grafts on certain stocks to be definitely inferior to juice of fruit from own-rooted vines. Total solids of Concord, Campbell Early, and Moore Early were increased by grafting on certain stocks, but the effects on yield and composition were not correlated. With the exception of grafts on Xinta roots, Moore Early fruit from own-rooted vines was smaller in berry size than when grown on various rootstocks. Of the various stocks tested, Wine King, 1202, Cynthiana, and 41-B were most satisfactory for Concord; Cynthiana and 41-B for Campbell Early; and Cynthiana and Wine King for Moore Early.

**Resistance of grape varieties to the freeze of November, 1940, G. F. GRAY.** (Okla. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 329-331).—A study of the effect of the unseasonable and severe freeze of November 1940 on varieties in the station vineyard showed great differences in response. Of 75-odd varieties, 8 had less than 25 percent of their buds injured, 30 had less than 50 percent injured, and 7 had all of their above-ground buds killed. The 1941 crop was very light, and in the 5 highest-yielding varieties—Mericadel, Edna, Extra, Bailey, and Worden—only a few vines produced more than one cluster per shoot, suggesting a high percentage of secondary shoot growth.

**Maturity studies with California grapes.—II, The titratable acidity, pH, and organic acid content, M. A. AMERINE and A. J. WINKLER.** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 313-324).—The present paper (E. S. R., 86, p. 484) deals with changes in titratable acidity, pH, and the organic acids present during maturation and with some of the applications of the data to the appraisal of varieties for wine production. The principal acids of vinifera grapes are tartaric, malic, tannic, phosphoric, and citric, with the first two constituting well over 90 percent of the total. Methods for the separation and determination of tartaric and malic acids and their salts in grape musts are discussed. The pH of grapes grown in California was found higher than in most producing areas, and, generally speaking, the pH of a wine was the same as that of the must, except in fortified wines where it was increased markedly. As the fruits ripen, there is a marked difference in the percentage of the total titratable acidity which is due to tartaric acid and potassium acid tartrate. Varieties could be readily grouped on the basis of these differences. The steady rise in pH during ripening reflects the change in the ratio of acid salts to free acid. In green fruits from 50 to 80 percent of the tartrates are present as free acid, while at maturity only from 10 to 20 percent are in this form.

**Leaf sap concentration and cold resistance in the avocado, F. F. HALMA.** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 231-235, figs. 4).—At 2-week intervals from May 1938 to April 1940 the osmotic value and the percentage of total soluble solids in the leaf sap were determined for eight varieties of avocados, all grown on Mexican seedling rootstocks. No relationship was observed in the several varieties between osmotic value of expressed leaf sap and cold hardness. Percentages of total soluble solids were in most cases consistently higher in the leaf sap of the harder varieties.

**The Amazon Basin Brazil nut industry, W. R. SCHREIBER** (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Foreign Agr. Rpt. 4* (1942), pp. [2]+36, figs. 16).—A description is presented of the tree and nuts, natural distribution, methods of harvesting and handling the crop, markets, future possibilities, etc.

**Influence of fertilizer and time of its application on growth, yield, and quality of pecans, J. H. HUNTER and R. D. LEWIS.** (*U. S. D. A.*). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 2, pp. 175-187, fig. 1).—In this experiment, located on Greenville sandy loam soil in Lee County, Ga., and dealing with the fertilization of Moore pecan trees 14 yr. of age at the beginning of the study, tree growth and

nut yields were increased by all fertilizer treatments used. The time of application had no significant effect on yield, and split applications did not prove significantly better than a single application in February. There was an inverse correlation between yield and the size of nuts. The quality of nuts, as measured by specific gravity and percentage of well-filled nuts, was influenced by fertilizer treatment. The nuts of the lowest quality were produced on trees receiving one-half of the fertilizer in February and one-half in June. The best quality nuts were produced on the unfertilized trees. No definite relationship was noted between oil and protein contents and fertilizer treatments.

**Medicinal plants of tropical and subtropical regions**, A. F. SIEVERS and E. C. HIGBEE (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Foreign Agr. Rpt. 6* (1942), pp. [2]+47).—Information is presented on a large number of species utilized in the preparation of medicines on their botanical sources; habitat; type of plant; part of plant utilized; commercial uses, sources, and importance; and methods of handling.

**Sleepiness in carnations**, W. FERGUSON (*Sci. Agr.*, 22 (1942), No. 8, pp. 509-518, figs. 4).—Sleepiness, a condition characterized by the partial closing of the flower due to the incurving or curling of the petals, was observed in carnations following shipment in express cars. Since blooms stored in various parts of the grower's establishment showed no signs of sleepiness, the conclusion was reached that some factor present during shipment was the active agent. Carnations were shipped without injury in electrically lighted cars, while those in gas-lighted cars showed much injury. Exposure of carnations to such small concentrations of Pintsch gas as 100 p. p. m. for 24 hr. or 250 p. p. m. for 10 hr. caused severe sleepiness. The minimum concentration was not established. Suggestions are given for the safe handling of carnations in the cars and in the express sheds.

**The effect of pruning established rose bushes on bloom production**, J. C. RATSEK. (Tex. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 562-564).—Production of blooms of the Talisman and Red Radiance roses was reduced in proportion to the severity of pruning. Length of stem was reduced by pruning, especially if the plants were cut back severely to 4 in. Severe pruning was again observed (E. S. R., 86, p. 633) to reduce the color of the blooms.

## FORESTRY

**Economic management of western white pine forests**, K. P. DAVIS (*U. S. Dept. Agr., Tech. Bul. 830* (1942), pp. 78, figs. 11).—With the end of abundant virgin timber in the western white pine forests of northern Idaho in sight, case analyses were made of timber-management problems and possibilities in representative mature and immature stands. In high-quality, mature stands consisting largely of western white pine, the dominant management considerations are (1) liquidation of the high and rather perishable stumpage values which are gaining little if any in value and (2) regeneration. Liquidation offers no difficulties if maintenance of a forest cover is the primary objective, reasonably adequate slash disposal being the only silvicultural cost necessary. An understory of western hemlock, present in most stands, takes over the site following the removal of the white pine and affords a complete although almost entirely unmerchantable forest cover. Regeneration of white pine is costly, as valuable seed trees must be reserved and most of the understory removed, or else the land must be clear-cut, burned, and planted. In the average-quality mature stand of about one-half white pine and one-half associated species, a two-cut installment plan of harvest is commercially practicable. In a young, thrifty, well-stocked stand of western white pine and associated species just reaching merchantable

size, considerable partial-cutting possibilities exist, and a plan of action is offered. Protection problems of fire, insects, and disease in the region are briefly evaluated from a timber-management point of view. The large question mark in the future of western white pine is the control of blister rust, without which continued commercial exploitation of the species is deemed impossible.

A case analysis of the cost of growing western white pine forests on a long-time basis is presented, and conclusions are drawn. With a fully regulated forest operated on a partial-cutting plan, estimated returns slightly exceed costs. Opportunity for private investment in long-time timber growing is slight, despite the fact that the costs of blister rust and insect control and part of the fire protection are largely carried by public funds.

**Management of loblolly pine in the pine-hardwood region in Arkansas and in Louisiana west of the Mississippi River, H. H. CHAPMAN (Yale Univ. School Forestry Bul. 49 (1942), pp. [61]-150, pls. 20, figs. 8).**—Based on observations and studies extending over a long period of years, information is presented on the relations of loblolly pine with associated species, conditions influencing reproduction and establishment of loblolly pine, systems of cutting loblolly pine, the importance of sustained yields, the basis of selection of trees for cutting, principles and methods of thinning and pruning young even-aged stands, effects of thinning on the growth of individual trees, the prediction of yields of pulpwood and lumber, and the control of pests. A summary of rules for management is presented.

**Competition in some coniferous plantations, W. R. ADAMS and G. L. CHAPMAN (Vermont Sta. Bul. 489 (1942), pp. 26, pls. 4, figs. 6).**—An examination after 28 years' growth of 5 coniferous species of forest trees planted on poor loamy soils typical of the Champlain Valley sand plains showed marked differences between species in their capacity to grow and produce economic timber crops. The trees were spaced at various intervals from 2 to 8 ft. apart to simulate conditions comparable to those of managed and unmanaged stands. Severe competition in dense stands resulted in stagnation in jack pine with reduced growth even by the crop trees. With Scotch pine many of the trees died early, providing the remainder with more growing space. With Norway (red pine) and northern white pine some of the trees assumed dominance and grew more rapidly so that the dense stand conditions were not so inhibiting. However, timber yields were not so large as in the less closely planted stands. Pitch pine grew slowly and was classed as a low-producing tree on soils of the type included in the study. The Norway, white, and jack pines grew satisfactorily. In the less-dense stands the jack pine was slightly more productive of timber in the 28 yr. than were Norway and white pines, but the latter species had the larger bole diameters. Norway and white pines are recommended for planting on sandy soils but require good management with adequate thinnings to produce good lumber. It is concluded that the poor, abandoned water- and wind-eroded light loamy soils, totaling more than 250,000 acres in northwestern Vermont, can be returned to a productive condition by planting with coniferous species.

**Mycorrhizal inoculation of soil of low fertility, R. F. FINN (Black Rock Forest Papers, 1 (1942), No. 19, pp. 115-117, fig. 1).**—In soils of low fertility, inoculation of white pine seedlings with known mycorrhiza-forming fungi and mycorrhizas resulted in significant growth increases. N and K were absorbed in significantly larger amounts by mycorrhizal seedlings. N deficiency in the non-inoculated seedlings produced a characteristic yellow-green color in the needles.

**Improvement cuttings in mixed hardwoods, H. H. TAYLOR and R. F. FINN (Black Rock Forest Papers, 1 (1942), No. 20, pp. 119-126, figs. 12).**—In general, very good natural reproduction followed one or more light thinnings yielding not

over 5 to 6 cords per acre per year, especially if the thinning was done in good seed years. Too severe thinning was found harmful. Good hardwood sprouts were obtained from low stumps not over 5 in. in diameter. Initial selective weedings or releases in young hardwoods should be withheld for at least four or five seasons following the first thinning in the overwood.

**The comparative influence of leaf mould and inorganic fertilizers on the growth of red oak, R. F. FINN and H. H. TRYON** (*Black Rock Forest Papers, 1* (1942), No. 17, pp. 107-109).—In May 1938, plats established in a mixed hardwood stand, consisting generally of red, chestnut, and white oaks and red maple, were fertilized with leaf mold at the rate of 2.5 tons per acre, nitrate of soda at rates of 200 and 400 lb. per acre, and superphosphate at the rate of 400 lb. per acre. Measurements in 1940 of the radial increment of the trees in the several plats showed the greatest gain in the humus plats, followed next by the superphosphate plat. Nitrogen and phosphorus percentage in the leaves were somewhat higher in these two plats than in the nitrate plats.

**Notes on the resampling of certain fertilized plots, R. F. FINN** (*Black Rock Forest Papers, 1* (1942), No. 16, pp. 103-105, figs. 4).—A comparison of the results of analyses of red oak leaves collected in September 1940 from plats that were differentially fertilized in 1935 showed, since analyses in 1936, a significant decrease in available N in the sodium nitrate-ammonium sulfate area and a significant increase in N in the area fertilized with dried blood. The rock phosphate plats showed a significant decrease in available P. K availability increased significantly in all areas in all plats in the K series except one. N availability was increased in the control area, suggesting that the thinning given the plats before fertilizing had increased the supply of N available to the remaining trees.

**Tests of chemical control of hardwood sprouts, H. H. TRYON and R. F. FINN** (*Black Rock Forest Papers, 1* (1942), No. 18, pp. 111-113, fig. 1).—Evidence was obtained that either calcium chloride (1 lb. per gallon of water) or ammonium thiocyanate solution (0.75 gal. of liquor and 0.25 gal. of water) would insure practically 100 percent prevention of sprout development if accompanied by complete hacking or ringing of the stumps.

**Equipment and methods for harvesting farm woodland products, C. J. TELFORD.** (Coop. Univ. Wis.). (*U. S. Dept. Agr., Farmers' Bul. 1907* (1942), pp. [2]+25, figs. 22).—This deals with felling trees and the making, skidding, hauling, loading, grading, and scaling of logs; poles and piling; posts, mine timbers, excelsior, and pulpwood; ties; fuel wood; shakes; sharpening crosscut saws; air-drying lumber; and the control of blue stain and checking in logs. Proper care of tools and safety precautions in their use are emphasized throughout. The making of some of the hand tools and certain loading and hauling equipment, of circular saw set-ups, and of an electrically driven crosscut saw ( $\frac{1}{4}$  hp. motor) are also discussed.

**Wood fuel in wartime, R. T. HALL and M. B. DICKERMAN** (*U. S. Dept. Agr., Farmers' Bul. 1912* (1942), pp. [3]+22, figs. 11).—This publication, prepared in collaboration with the Northeastern and Lake States Forest Experiment Stations and the Forest Products Laboratory, is intended to point out the best sources of wood fuel, its heating value, and some recently developed technics in producing, transporting, and utilizing fuel wood. The primary topics dealt with are wood fuel and Nation-wide war production; increasing the use of wood fuels; production, marketing, and purchase of fuel wood; and selection of material to cut.

**Forest products statistics of the Central and Prairie States, R. V. REYNOLDS and A. H. PIERSON** (*U. S. Dept. Agr., Statis. Bul. 73* (1941), pp. 94, figs. 3).—As the sixth and last of a series covering the entire Nation (*E. S. R.*, 84, p. 480),

this bulletin presents forest-products statistics for seven Central and five Prairie States.

[**Stumpage and log prices for the calendar years 1939 and 1940**], H. B. STEER (*U. S. Dept. Agr., Statist. Buls. 75 (1941), pp. 67, figs. 4; 76 (1942), pp. 67, figs. 4*).—Prepared in the usual manner (*E. S. R.*, 84, p. 341), these bulletins contain data presented largely in tabular form on total stumpage and log sales for the Nation and by States, with information on prices, etc.

## DISEASES OF PLANTS

**The Plant Disease Reporter**, [September 1 and 15, 1942] (*U. S. Dept. Agr., Bur. Plant Indus., Plant Disease Rptr.*, 26 (1942), Nos. 16, pp. 341–373; 17, pp. 375–388).—In addition to the host-parasite check-list revision, by F. Weiss (Nos. 16, *Schaefferia* to *Smilax*, and 17, *Sophora* to *Sorbus*), the following are included:

No. 16.—1939, 1940, and 1941 additions to the list of causes of fungus and bacterial plant diseases in Maine, by M. T. Hilborn; some estimates of losses from plant diseases in the United States prior to 1917, by N. E. Stevens; notes on diseases of soybeans and other legumes in Oklahoma, by J. H. McLaughlin; soybean diseases in Iowa, by G. C. Kent; *Sclerotium rhizodes* on grasses in Pennsylvania, by K. W. Kreitlow; single-virus streak of greenhouse tomatoes, by R. W. Samson; garlic mosaic in Texas, by G. E. Altstatt; observations on cucurbit downy mildew in South Carolina, by C. J. Nusbaum; tomato diseases reported from New York; vegetable diseases in Massachusetts, by O. C. Boyd; plant diseases occurring in Nebraska prior to July 18, 1942, by J. E. Livingston; some new records for *Verticillium* diseases; susceptibility of some common rose understocks to nematode root knot, by G. E. Altstatt; reports on potato late blight in North Dakota, Rhode Island, and New York; and brief notes on downy mildew on celtuce (*Lactuca*) in Pennsylvania, scarcity of sweet corn bacterial wilt, parasitization of rusts in Kansas, and sources of ergot for drug purposes.

No. 17.—*Thyronectria austro-americana* disease of honey locust (*Gleditsia triacanthos*) in the South, by B. S. Crandall; Sperguson and Thoson as seed treatments for small grains, by R. W. Leukel; reports on barley and wheat scab in Virginia, scab on *Paspalum notatum* in Florida, and wheat and barley scab absent in western North Dakota; reports of an unusual amount of damage by *Helminthosporium turcicum* leaf blight on field corn in Pennsylvania and Ohio, and of *Diplodia macrospora* leaf spot in Mississippi; cereal diseases in the Pacific Northwest and Intermountain States in 1942, by C. A. Suneson; reports on soybean diseases, including an undetermined apparently virus disease of edible soybeans in Rhode Island, tobacco ring spot on edible soybeans in Indiana in 1941, soybean diseases in Virginia and western North Dakota, and two new records for the frogeye leaf spot (*Cercospora diazu*) in Maryland and Virginia; late blight of potatoes in Maryland, southwestern Virginia, the Gainesville section of Florida, and Ohio and early blight of potatoes in western North Dakota, tomato fruit rot and early blight in Pennsylvania, tomato leaf spots destructive in Ohio, and negative report on tomato virus tip blight for Minnesota, North Dakota, South Dakota, and Nebraska; and brief notes on fire blight on pears in Florida, and tetrachloro-*p*-benzoquinone as a growth stimulant.

**Report of the twenty-sixth annual meeting of the Pacific division of the American Phytopathological Society** (*Phytopathology*, 32 (1942), No. 9, pp. 826–830).—Abstracts of 19 papers on plant diseases and/or their control are included.

[Phytopathological studies by the Arkansas Station] (*Arkansas Sta. Bul.* 417 (1942), pp. 30-34, fig. 1).—Progress reports by S. B. Locke, E. M. Cralley, and V. H. Young are given on development of disease-resistant tomatoes, with special reference to early blight and *Septoria* blight as well as to wilt; the reactions of cotton varieties to strains of the *Fusarium* wilt fungus; and treating cottonseed for control of seedling blight and boll rot.

[Plant disease studies by the Missouri Station] (*Missouri Sta. Bul.* 444 (1942), pp. 29-32, 65-66, 95).—Brief reports by C. M. Tucker, J. E. Livingston, J. T. Middleton, M. A. Smith, and C. G. Vinson are included on the effects of seed treatments on stands, yields, and control of *Fusarium moniliforme* infection in corn, on winter hardiness, yields, and disease control in barley, and on yields of oats; breeding tomatoes for *Fusarium* wilt resistance; morphologic and physiologic studies of the genus *Phytophthora* (coop. Calif. and Oreg. Expt. Stas.); spraying for control of apple scab and pear leaf spot (*Fabrea maculata*) (coop. U. S. D. A.); purification and properties of plant viruses; and cottonseed treatment for anthracnose control.

Plant diseases (*Nebraska Sta. Rpt.* [1941], pp. 37-41).—Brief reports of station work, by R. W. Goss, J. H. Jensen, J. E. Livingston, M. W. Felton, E. Kneen, E. Wright, and C. E. Dallimore, are included on the physiology of and breeding for resistance to halo blight in beans and variation in strains of the causal bacteria (*Phytomonas medicaginis phaseolicola*); *Fusarium* wilt, scab, spindle tuber, ring rot, and haywire disease of potato; inoculation method for wheat bunt; charcoal rot of corn and sorghum; damping-off of broadleaf seedlings and *Phomopsis* blight of eastern red cedar in the nursery (coop. U. S. D. A.); and sugar beet diseases.

[Phytopathological work by the Texas Station]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 64-73; 104-105, 114, 115, 120-121, 135, 144-147, 161, 162, 163, 166, 168, 170, 174, 181-182).—Brief notes of progress, by W. N. Ezekiel, C. H. Rogers, [J. E.] Simpson, [C.] Nelson, [Jr.], L. M. Blank, P. J. Talley, Mason, F. M. Eaton, N. E. Rigler, A. A. Dunlap, A. L. Harrison, G. E. Altstatt, G. KenKnight, H. P. Smith, E. W. Lyle, Watkins, H. F. Morris, B. C. Langley, E. C. Tullis, C. E. Minarik, P. A. Young, G. H. Godfrey, and S. S. Ivanoff, are presented on cotton (*Phymatotrichum*) root rot investigations, including weather relations, attenuation of cultures by repeated mycelial transfer, resistance of seedling trees, susceptibility test of various plant species in the nursery, organic acids as growth substances for the fungus, eradication methods for nurseries and orchards in deep sandy soil, winter cover crops, tillage, and fertilizers v. control, relationship between pH and inorganic N sources in cultures of the fungus, its growth reactions to amino nitrogens, absorption and utilization of inorganic and organic N, cotton plant physiology v. root rot susceptibility, cotton plant inoculations under various nutrient conditions and fruiting studies in relation to nutrients, root rot sclerotia, rotations in relation to root rot, and sulfur and crude oil in control; cotton infection from acid delinted treated seed v. untreated fuzzy seed; control of angular leaf spot of cotton; cotton varieties resistant to wilt and root knot and two kinds of resistance to wilt as affected by root knot, and preferable varieties of wilt-resistant cotton; tomato disease studies, including spraying for and breeding for resistance to *Alternaria* early blight, *Stemphylium* gray spot in Texas, nematode reactions of tomato varieties and species, rosette of unknown cause, *Fusarium* wilt resistance, white flowers as a marker for *Fusarium* wilt immunity, varietal resistance to blossom-end rot, effects of Cu sprays on Marglobe tomato yields, and lethal gene leaf spot abnormality; seed treatments for beets, cucumbers, peas, and spinach; peanut disease studies, including southern blight and *Cercospora* leaf spot; field tests

of *Fusarium* wilt resistant watermelons; spraying and dusting cantaloups for downy mildew; garlic diseases; onion neck rot prevention in cold storage, and leaf blight (cause unknown); spraying peaches for scab and brown rot; rose diseases, including root knot resistance, spraying for black spot, *Diplodia* die-back, streak disease, chlorosis control, and crown gall and hairy root control; rice diseases, including incidence of leaf spots, *Curvularia lunata* in relation to black kernel disease, white tip in relation to Ca and Mg, and straighthead disease factors; charcoal disease (*Sclerotium bataticola*) of sorghums; disease resistance in grain sorghums and Sudan grass hybrids; *Pijthium*-resistant milo strains; soil fumigation for control of crop pests, including root knot and southern blight (*Sclerotium rolfsii*); burning of tomato plants avoided by improved fertilizer drill; cabbage damping-off control, *Alternaria* leaf spot varietal reactions, and seed treatment for black rot; citrus stem-end rot, mineral-deficiency chlorosis, N-starvation chlorosis, chemical deposits on foliage of citrus and other plants and their possible relation to chlorosis and yield, and pruning-wound protectants; strawberry chlorosis; *Alternaria* leaf blight of carrot; virus-induced "yellows" of eggplant; and sulfur in relation to chlorosis in cowpeas and root-nodule production, and root knot susceptibility of cowpeas.

**Investigations on copper deficiency in plants, C. S. PIPER** (*Jour. Agr. Sci. [England]*, 32 (1942), No. 2, pp. 143-178, pls. 5, fig. 1).—A water-culture technic is described, making possible the precision determination of effects on plant growth of the absence of traces of the various heavy metals. The essentiality of Cu for plant growth was confirmed, and the quantitative data presented indicate that addition of traces to a nutrient solution leads to growth increases of the order of 200-1,200 percent. The characteristic symptoms from growing oats, peas, wheat, Wimmera ryegrass, *Phalaris*, flax, tomato, subterranean clover, and alfalfa in nutrient solutions without Cu are described. Analytical data are also included. The degree of moisture saturation of the soil had little effect on the Cu uptake of plants. An increase of soil acidity to pH 4.7 increased the availability somewhat, but partial sterilization by heat had a greater effect. In neither case, however, was the increase of the same order of magnitude as the corresponding increase in Mn availability. The increased absorption of Cu by plants as the result of  $\text{CuSO}_4$  applications to the soil was small. Rye absorbed more Cu from a given soil than oats, and could be grown normally to maturity in a soil on which oats failed from Cu deficiency. There are 40 references.

**Method of obtaining pure cultures of *Corticium stevensii* from sclerotia, E. C. TIMS and F. BONNER.** (La. State Univ.). (*Phytopathology*, 32 (1942), No. 9, pp. 824-825).—In attempting to obtain pure cultures of this fungus, about 1,500 sclerotia from fig and tung branches were given various types of sterilization and plated out on aqueous agar. Best results were obtained by soaking them in a mixture of 1-1,000  $\text{HgCl}_2$  in 50 percent ethyl alcohol for 2 min. and washing in sterile water.

**Effects of some mild forms of mosaic on potato and a few other plants, W. E. STONE.** (Vt. Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 4, pp. 195-207, figs. 5).—Width of palisade layer and thickness of leaf in potato were found little affected by mild mosaic virus, but, in general, intercellular spaces were larger than in normal leaves. Chloroplasts were reduced in size and number in leaves showing mild mosaic mottle. Those in affected areas could be readily distinguished by staining reactions, and their starch grains were smaller and more numerous than in healthy leaves and were not readily removed from the plastids during darkness. The nuclei of mottled potato leaves were considerably smaller than in comparable healthy leaves. On raspberry, cells in the upper leaf epidermis of yellow parts were appreciably smaller

than those of green parts of either the same or of healthy leaves. Blackberry leaves with rugose mosaic had upper epidermal cells in green parts larger than in yellow parts and lower epidermal cells smaller than in yellow parts. Comparisons of size and number of stomata in green and yellow parts of affected leaves showed no consistent difference. In blackberry infected with mild mosaic, epidermal cells were smaller in yellow than in green parts, but the stomata were larger and more numerous. In groundcherry, epidermal cells were considerably larger in healthy than in mosaic leaves, but stomata varied little in size or number, at least on an area basis. There are 23 references.

**Antibiosis in the elimination of *Phymatotrichum omnivorum* sclerotia from soil**, F. E. CLARK and R. B. MITCHELL. (U. S. D. A.). (*Jour. Bact.*, 44 (1942), No. 1, p. 141).—An abstract.

**Factors affecting the activity of *Pseudomonas-Phytomonas* fluorescent bacteria in soil**, R. B. MITCHELL and F. E. CLARK. (U. S. D. A.). (*Jour. Bact.*, 44 (1942), No. 1, p. 141).—An abstract.

**The spread of virus diseases of the yellows type under field conditions**, V. L. FRAMPTON, M. B. LINN, and E. D. HANSING. (Cornell Univ.). (*Phytopathology*, 32 (1942), No. 9, pp. 799-808, figs. 6).—The various factors related to wind and weather, which vary in an indeterminable manner and which influence insect behavior, probably are considered as insurmountable barriers to a rational consideration of the spread on insect-transmitted diseases, but an understanding of the pattern produced under field conditions would be of obvious value to plant pathologists. The authors have attempted such a rational consideration of disease spread in a special case of the insect transmission of viruses of the yellows type. A differential equation describing the dissemination of viruses of this type in the field has been derived and integrated, and data obtained in two experiments are said to satisfy two demands of the integrated form. The assumptions involved in the derivation of this equation were that the movements of the insect vectors are random, that the number of plants becoming infected is proportional to the number fed upon, and that spread from plant to plant within the field is of small importance. The boundary conditions set up in obtaining the field data were that the insect population in the newly plowed field was negligible, that the insect reservoir was not substantially depleted during the course of the experiment, and that the effects at the ends of the fields be neglected. Although an evaluation of constants cannot be undertaken, the general equation developed seems to describe adequately the distribution pattern, inasmuch as data on hand satisfy the demands of the equation. The observations reported include the dissemination of yellow dwarf of potatoes into potato fields and the dissemination of aster yellows into endive and lettuce beds.

**Extraction of auxin from maize, from smut tumors of maize, and from *Ustilago zae***, J. E. MOULTON (*Bot. Gaz.*, 103 (1942), No. 4, pp. 725-739).—For a given weight of smut tumors, water extraction yielded a greater amount of auxin than that by ether. Dry ether extracts were not active. Water is necessary for liberating auxin from the tissue, and its action may be hydrolytic. Corn smut tumors yielded auxin slowly with either water or ether extraction. The auxin was almost completely removed from *U. zae* in one ether extraction. Smut tumors from corn leaves or stems yielded more auxin than healthy leaves or stems. Strains of *U. zae* grown on a synthetic medium containing neither proteins nor amino acids produced auxin. Extracts of both types of medium on which *U. zae* had grown for 2 mo. contained much auxin, and practically the same amount in each case. The pathogenicity of strains of *U. zae* was apparently correlated with their ability to produce auxin in a bactotryptone or a synthetic medium. There are 22 references.

**Host and pathogen indices to the diseases observed on grasses in certain western States during 1941**, G. W. FISCHER, R. SPRAGUE, H. W. JOHNSON, and J. R. HARDISON. (Coop. Wash. and N. Dak. Expt. Stas.). (*U. S. Dept. Agr., Bur. Plant Indus., Plant Disease Rptr., 1942, Sup. 137, pp. 87-144*).—Data from collections and observations of grass diseases in Arizona, California, Idaho, Minnesota, Nebraska, Oregon, North and South Dakota, Utah, Washington, and Wyoming in 1941 are summarized. Due to the unprecedented rainfall of the growing season in most of the areas, foliage diseases were considerably favored as shown by the unusual number and extent of development of leaf spots, rusts, and bacterial diseases. The report includes 259 species and varieties of grasses on which a total of 161 diseases are recorded, among them 62 leaf spots, streaks, etc., 30 rusts, 28 primary and secondary root rots, and 25 smuts.

**Claviceps yanagawaensis in imported seed of Japanese lawn grass**, C. L. LEFEBVRE. (U. S. D. A.). (*Phytopathology, 32 (1942), No. 9, pp. 809-812, figs. 2*).—Sclerotia of *C. yanagawaensis* (new to the United States) were found in Japanese lawngrass (*Zoysia japonica*) seed from Japan. Treating it with a 75 percent solution of  $H_2SO_4$  for 20-30 min. killed the ergot sclerotia and improved the germination of the seed. A rye hybrid, highly susceptible to *C. purpurea*, failed to become infected when inoculated with mature ascospores of *C. yanagawaensis*.

**Mercury substitutes for turf disease control**, P. P. PRONE (*New Jersey Stas. Nursery Disease Notes, 15 (1942), No. 1, pp. 4*).—Following the preliminary work (E. S. R., 87, p. 810), extensive tests have been made, not only with tetramethyl thiuram disulfide (T. M. T. D. or Thiosan) but also with the organic compounds Spergon and Lawn Sinox, on outdoor turf under environal conditions so favorable for dollar spot that it was doubtful whether even mercurials would have given good control. In two blocks of Seaside Bent and of a mixture of Creeping and Colonial Bent, respectively, both Thiosan and Sinox gave marked reductions in dollar spot, but Spergon was considerably less effective.

**Breeding corn hybrids for smut resistance**, G. H. STRINGFIELD and D. H. BOWMAN. (U. S. D. A. and Ohio Expt. Sta.). (*Jour. Amer. Soc. Agron., 34 (1942), No. 5, pp. 486-494, figs. 3*).—Corn smut (*Ustilago zeae*) counts in 48 performance tests indicated about three-fourths of the hybrid entries to carry less infection than the open-pollinated varieties, and 12 inbred lines appeared to be more or less resistant. Hybrids in which half or more of the parentage consisted of these resistant inbred lines showed less than a third as much smut as the open-pollinated varieties. Furthermore, it is shown that hybrids have been developed that combine a high degree of smut resistance with other desirable agronomic characters, and such hybrids are being grown extensively. Use of these and similar hybrids in other States is said to constitute the first significant advance in the control of corn smut. There are 17 references.

**A root rot of cotton caused by *Thielaviopsis basicola***, C. J. KING and J. T. PRESLEY (*Phytopathology, 32 (1942), No. 9, pp. 752-761, figs. 3*).—It was determined in 1938 that this new cotton disease, especially injurious to American-Egyptian varieties in two widely separated areas of Arizona, is due to *T. basicola*. Seedling stands are often destroyed, but surviving plants tend to recover under prevailing high midsummer temperatures. However, in the fall occluded root lesions of such plants may become active and cause their death. Taproots of the unthrifty infected seedlings exhibit a purplish-black rot and often cavities in the central cylinder, and affected mature plants have a taproot swollen near the collar and an internal purplish-black rot of the vascular system. The brownish chlamydospores in the conductive tissues of diseased plants are char-

acteristic. In culture, the cotton isolate from Arizona resembled tobacco isolates from Tennessee and Missouri, though slight differences in color, density, and sectoring habits of colonies were observed. Reactions of these various isolates on the hosts were essentially the same, as shown by inoculations and cross-inoculations on the cotton varieties used and on Maryland Broadleaf tobacco. Under greenhouse conditions, nearly all inoculated plants developed symptoms but only a few of them died.

**Cotton wilt in Alabama as affected by potash supplements and as related to varietal behavior and other important agronomic problems,** H. B. TRISDALE and J. B. DICK. (Ala. Expt. Sta. coop. U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 5, pp. 405-426, figs. 3).—From several 1- to 4-yr. field tests on *Fusarium* wilt-infested plats at various Alabama locations, it was indicated that development of the disease varies greatly among localities, by seasons within localities, and among varieties within localities by seasons. In areas where tests were conducted for 3 yr. or more, there was an average of 45-83 percent of wilt-infected plants in the highly susceptible group and much fluctuation in the weakly tolerant group with an average of 9-56 percent. In most areas the resistant and highly tolerant groups were distinguishable only with difficulty. The increased severity of the infection in the tolerant-resistant groups at three stations may have been due to a deficiency of K, and in a fourth area with severe infection root knot may have been a contributing factor. The relatively constant ranking of varieties or strains with respect to percentage of wilt, regardless of general wilt severity, is interpreted as field evidence against the existence of physiological races of the fungus differing greatly in their ability to parasitize specific varieties. The differential response of varieties to K and the influence of seasons and other environal factors are indicated as of greater practical concern than are possible races that might complicate the breeding program.

"The potash-variety-wilt studies at Auburn, Moundville, and Alexandria showed that varieties differ with respect to potash needs for normal development or for withstanding wilt attacks. This differential response of varieties to potash treatments appears to be associated with the grouping of varieties with respect to resistance. At Auburn and Alexandria, where the wilt was not severe except on the susceptible and highly susceptible varieties, these varieties continued to respond favorably to increasingly heavy applications of potash. Where wilt was exceptionally severe, as at Moundville, heavy applications of potash did not enable such varieties to overcome wilt. At Moundville heavy applications of potash were of greatest value to the resistant varieties. On the other hand, 3 years' results at Auburn showed that resistant varieties require only a moderate amount of potash for maximum yields and that greater amounts are harmful. There was a rather close, but inverse, relationship between yield of seed cotton and the percentage of wilt-affected plants at the midseason count."

**Treatments recommended for prevention of heavy annual loss from oat smuts,** J. A. PINCKARD (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, p. 6).—An informative paper on loose and covered smuts of oats, including directions for preventive seed treatment by New Improved Ceresan and by liquid formaldehyde.

**Survey of potato diseases in peat soils in California,** E. J. PETERS (*Amer. Potato Jour.*, 19 (1942), No. 5, pp. 105-106).—The author's culture survey of 129 wilted plants grown under conditions obtaining in peat soils gave about 68 percent infected by *Rhizoctonia solani*, nearly 21 percent by *Erwinia phytophthora*, and about 3 percent each for ring rot alone and plus blackleg. The need for more careful and critical examination of plants in the field along with laboratory tests is emphasized for determining the causal agents in such cases.

**Three years' comparisons of dusts and bordeaux spray for potato production in central Jersey.** R. H. DAINES, J. C. CAMPBELL, and W. H. MARTIN. (N. J. Expt. Stas.). (*Amer. Potato Jour.*, 19 (1942), No. 5, pp. 90-96).—Tests over a 3-yr. period (1938-40) with bordeaux mixture and copper lime dust are compared with pyrethrum and rotenone, used alone or jointly, as foliage protectants in central New Jersey for control of foliage diseases, flea beetles, and leafhoppers. From the results under a wide variety of growing seasons it was clear that no one foliage protectant is best under all conditions. Detailed results for each season are summarized.

**A histological study of hollow heart of potatoes.** J. LEVITT. (Minn. Expt. Sta.). (*Amer. Potato Jour.*, 19 (1942), No. 7, pp. 134-143, figs. 6).—Hollow heart was found to arise in a necrotic patch of cells after it had become surrounded by a cambium layer. Though the largest hollows usually occurred in the largest tubers, early stages were observed in those weighing as little as 1.8 gm. The condition was noted in the earliest harvest examined (July 24), its incidence being double that in the latest. Treatments affected its incidence only when given early in the season, indicating that the disorder must have originated in all tubers at that time. Measurements revealed the perimedulla cells adjacent to the edge of the hollow to be larger than the pith cells adjacent to the face. This may indicate more rapid growth in the former tissue, a possible factor in hollow heart formation. All six of the minerals investigated (K, Cu, Mg, Fe, Mn, and Ca) occurred in larger amounts (dry weight) in the healthy than in the affected tubers. The excess in the pith as compared with the perimedulla was also reduced.

**Incidence of hollow heart in potatoes as influenced by removal of foliage and shading.** F. A. KRANTZ and E. P. LANA. (Minn. Expt. Sta.). (*Amer. Potato Jour.*, 19 (1942), No. 7, pp. 144-149).—Foliage removal at successive stages of tuber development (1940-41) was followed by a decrease in the number of hills free from hollow heart when done at the time of tuber setting but not later. Shading with black sateen cloth for 5-10 days tended to increase the number of unaffected hills when done at time of tuber setting but not 21 days later. About the same incidence was observed in hills harvested when their average weight was 157 gm. and the individual tuber weight 7.5 gm. as when the plants matured and the average weight per hill was 776 gm. and the tuber weight 53 gm. Removal of 20, 40, 60, and 80 percent of the foliage did not significantly influence the average number of tubers set per hill, mean yield per hill, or mean weight of individual tubers. Foliage removal was followed by a very active renewal of vine growth and a delayed vine maturity. This active renewal of vine growth may have been a significant contributing factor in increasing the incidence of hollow heart in the early period of tuber enlargement.

**Accuracy of the ultraviolet-light method for selecting ring rot free potato seed stocks.** V. E. IVERSON and F. M. HARRINGTON. (Mont. Expt. Sta.). (*Amer. Potato Jour.*, 19 (1942), No. 4, pp. 71-74).—In comparisons of the ultraviolet-light and gram-stain methods for selecting seed stocks free from ring rot it was found that the former is as effective as the latter, that examinations require less than one-tenth the time of the gram stain, and that the ultraviolet method has additional value in reducing the incidence of other "vascular" diseases.

**Resistance of certain potato varieties and seedling progenies to ring rot.** R. BONDE, F. J. STEVENSON, C. F. CLARK, and R. V. AKELEY. (Maine Expt. Sta. and U. S. D. A.). (*Phytopathology*, 32 (1942), No. 9, pp. 813-819).—*Phytophthora aepedonica* has spread rapidly, and the presence of even a trace of infection is a menace to successful production from susceptible potato varieties. Seeking to determine the availability of resistant or immune potato strains, the authors

tested 54 named foreign and American varieties and a number of unnamed seedling varieties for susceptibility. Among these, 2 foreign varieties and 2 seedlings appeared to be resistant, and of the latter one had attractive tubers and the other desirable commercial qualities. Nearly half of the progeny of a cross between the resistant President and the susceptible Katahdin varieties proved resistant, and a few selections from a cross between 2 susceptible varieties were more resistant than either parent. Judging from these results it should not be very difficult to develop strains combining ring rot resistance with other commercially important qualities.

**Prevention of potato seed piece decay, O. H. ELMER.** (Kans. Expt. Sta.) (*Amer. Potato Jour.*, 19 (1942), No. 2, pp. 19-23).—The results of this 6-yr. investigation indicated that under Kansas conditions seed-piece decay can be largely prevented by treatment with acidulated corrosive sublimate or with yellow oxide of mercury. The former also proved effective for sterilizing tuber-borne *Rhizoctonia sclerotia* and for preventing spread of ring rot bacteria from infected to noninfected seed pieces during planting operations. Hot formaldehyde treatments and preplanting suberization of cut seed pieces were not so effective against seed-piece decay as were the mercurials.

**Formation of biologically active tobacco-mosaic virus in vivo, as affected by nitrogen supply, E. L. SPENCER** (*Jour. Bact.*, 43 (1942), No. 5, p. 646).—An abstract.

**The control of damping-off of vegetables by formaldehyde and other chemicals, W. J. DORAN, E. F. GUBA, and C. J. GILGUT** (*Massachusetts Sta. Bul.* 394 (1942), pp. 20).—The original object of this study was to determine the relative merits of certain chemicals for controlling damping-off of vegetables in hotbeds and coldframes, where at least 90 percent of the trouble in the State proved due to *Pythium* spp., with *Rhizoctonia* important on crucifers and *Aphanomyces euteiches* often responsible on celery. No one best dry chemical treatment was found for seeds of all vegetables. A list of vegetables together with the seed treatments found best to improve the stand of each is given. Applied to the soil after seeding, chloropicrin gave very good control, but is not preferred by the authors. Vinegar gave more effective control in acid than in alkaline soils, and both this and acetic acid were good substitutes for formaldehyde but in general not equal to it. Spraying seedbeds and seedlings with bordeaux, red cuprous oxide, or zinc oxide were less satisfactory than soil treatments with formaldehyde or certain seed treatments. Substances containing sodium hypochlorite were inferior to formaldehyde, acetic acid, or chloropicrin. Salicylic acid, pyroligneous acid, and oxyquinoline sulfate gave good results with the vegetables on which they were used. Calcium cyanamide was more especially useful where it was necessary to treat the soil before seeding. Ammonium hydroxide and ammonium sulfate applied to soils of high pH gave very good control. Pea stands were much improved by formaldehyde applied in the rows at seeding time. Formaldehyde gave good results on vegetables when applied by subirrigation, provided the soil was not too moist. Plant growth was usually improved when it was applied to nonsterilized soil, but not to soil recently steamed. Applied before seeding, formaldehyde gave good protection against damping-off for about 5 days after soil treatment, but little or none after 11 days. Detailed directions and results for these and other treatments are presented and discussed. There are 20 references.

**Resistance of cucumber seedlings to damping-off as related to age, season of year, and level of nitrogen nutrition, T. T. McCUBRE and W. R. ROBBINS.** (N. J. Expt. Stas.). (*Bot. Gaz.*, 103 (1942), No. 4, pp. 684-697, figs. 20).—When

cucumber seedlings were cultured in sand at high and low N levels during several different seasons of the year and inoculated at various ages with a *Pythium*-type fungus, the young seedlings proved more susceptible than the older ones. Those grown under the relatively poor light of winter remained susceptible longer than those grown under the good light conditions of spring and early summer. Seedlings grown with no external supply of N remained susceptible to infection longer than those supplied with a complete nutrient solution. Resistance to infection was accompanied by a deposition of lignin in the cell walls of the tissue surrounding the area of infection, and susceptibility was accompanied by incompleteness or absence of this lignification. It is suggested that such lignification, when continuous, may serve as a barrier to the spread of the pathogen. Deposition of lignin was found to be a function of living parenchymatous cells and to occur in the vicinity of a wound or of fungus infection. In a healthy plant these cells did not become lignified. There are 25 references.

**Resistance to mosaic virus in the cucumber,** O. SHIFFRIS, C. H. MYERS, and C. CHUPP. ([N. Y.] Cornell Expt. Sta.). (*Phytopathology*, 32 (1942), No. 9, pp. 773-784, figs. 4).—In this preliminary report the genetic control of virus symptoms in the cucumber and criteria for measuring resistance are discussed. In understanding the mechanism involved, two developmental phases are distinguished, viz, the cotyledon and the composite true-leaf stages. Three complementary genes apparently control the ability or the failure to produce chlorosis at the cotyledon stage, the genetic ratio in  $F_2$  being 27 nonchlorotic to 37 chlorotic. This ratio is constantly changing at the composite true-leaf stage, where several gene modifiers also take part in the genetic control of virus symptoms. Thus, the frequency of symptomless plants here is very low. The presence or absence of chlorosis on the cotyledons determines whether the tested plant is susceptible or tolerant to mosaic. The degree of tolerance can be determined by the severity or mildness of symptoms and by the relative distance from the inoculated cotyledons to the true leaf on which symptoms first appear, the greater the distance the higher being the resistance. All resistant stocks possess the three basic dominant genes. They vary among themselves in the relative number of dominant modifiers. Suggestions to breeders are included.

**A study of spreaders for use on hops in the field control of downy mildew,** G. R. HOERNER. (Oreg. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 9, pp. 820-823, figs. 2).—The author presents a study of spreaders for use with fungicides in spraying hops against downy mildew (*Pseudoperonospora humuli*). Laboratory apparatus devised for comparing various spreaders is described. The lowest effective dilutions of 36 spreaders are presented, and a field formula for rosin-soap, one of the most promising, is given.

**Distribution and relative importance of various fungi associated with pea root-rot in commercial pea-growing areas in New York,** O. A. REINKING (*New York State Sta. Tech. Bul.* 264 (1942), pp. 43, figs. 12).—Isolations and microscopic examinations indicated that practically all root rot organisms reported on peas in this and other countries are widely distributed in the older pea soils of western New York. The following fungi, listed in order of importance, were found primarily responsible for pea diseases in the State: *Fusarium solani martii* f. 2, *Aphanomyces cuteiches*, *Pythium ultimum*, *Rhizoctonia solani*, and *Ascochyta pinodella*. None of the other fungi commonly associated with root rot caused serious disease either under greenhouse or field conditions. The destructive organisms and disease were found in a wide range of soils at pH 6.25-7.48 and in a few soils at pH 5.4 and 5.5. *F. solani martii* f. 2, *P. ultimum*, and *R. solani* were found to be indigenous to certain virgin pea soils. The first two multiplied in the soil with repeated pea plantings, the severity of root rot apparently depending on the build-up of destructive fungi.

A 6-yr. study of fields on the station's canning crops farm at Geneva where peas have been grown in rotation for 16 yr. showed that the important root rot organisms were not entirely eliminated by a 3-, 4-, or 5-yr. rotation. Nevertheless, profitable yields were obtained during favorable growing seasons on the sufficiently fertilized fields in spite of the presence of pathogens. One strain of *F. solani martii* f. 2 isolated from root rot in California red kidney bean proved extremely pathogenic to peas and capable of attacking and living as a weaker parasite on various dry beans. The latter, therefore, should be excluded from a rotation where peas are to be planted. There are 27 references.

**Notes on the influence of microorganisms on growth of squash plants in water culture with particular reference to manganese nutrition.** H. A. BARKER and T. C. BROYER. (Univ. Calif.). (*Soil Sci.*, 53 (1942), No. 6, pp. 467-477, figs. 2).—Squash plants grown in Mn-deficient solution cultures exhibited typical deficiency symptoms whether or not the roots were sterile. Highly contaminated soil-inoculated plants were usually smaller and less healthy than those with sterile root systems, whether grown in "complete" or Mn-deficient nutrient solutions. The influence of micro-organisms was first manifested by root injury, but very soon the whole plant became affected. The relation of these phenomena to the trace-element deficiency symptoms of plants grown on certain disease-producing soils is not yet clear. Heavily contaminated excised roots had a consistently higher respiratory rate than comparable sterile roots. The relative O<sub>2</sub> deficiency that may result under certain conditions from the greater O<sub>2</sub> consumption of contaminated roots may play a role in root injury, but other undefined factors are believed more important. The apparent Fe requirements of sterile plants are smaller than those of heavily contaminated plants. This is believed due to two factors, viz, the pH of culture solutions in which sterile plants are grown tends to be lowered rather than raised as with contaminated plants, and the organic radical of the Fe salt is not decomposed. Excised sterile roots produced about one-third as much CO<sub>2</sub> anaerobically as aerobically. The comparative behavior of sterile and contaminated roots indicated that CO<sub>2</sub> produced anaerobically by the latter is largely due to the plant component of the plant-microbe system.

**Relative resistance of tomato varieties, selections, and crosses to defoliation by *Alternaria* and *Stemphylium*.** C. F. ANDRUS, G. B. REYNARD, and B. L. WADE (U. S. Dept. Agr. Cir. 652 (1942), pp. 23, figs. 6).—The preliminary results are presented of an extended breeding project planned to develop tomatoes resistant to defoliation diseases, the methods described including field grading of a large number of hybrid populations, commercial varieties, and foreign introductions. An efficient inoculation technic, involving use of finely cut mycelium, was developed and used for testing large numbers of plants under controlled greenhouse conditions for resistance to early blight (*A. solani*) and gray leaf spot (*S. solani*), considered the most important leaf spot diseases in the southeastern United States and among the outstanding causes of defoliation. All varieties proved susceptible to early blight, but when the severity of infection was adjusted at a suitable level by dilution of the inoculum, significant degrees of tolerance were found in selections of the currant tomato (*Lycopersicon pimpinellifolium*) and in *L. peruvianum*, and to a lesser extent in certain commercial tomato varieties. Outstanding resistance to gray leaf spot was found in selections of *L. pimpinellifolium* and in its hybrids with the common tomato. Many selections resistant to gray leaf spot were also resistant to *Fusarium* wilt and some of them showed significant tolerance to early blight. No large-fruited resistant segregates were obtained from crosses of *L. pimpinellifolium* with large-fruited tomatoes, but many selections were intermediate in size and are a definite advance toward commercial types. In the hybrid progenies examined there were no significant

correlations in resistance to *Stemphylium* and to *Alternaria* as indicated by inoculations, but in trials with varieties and P. I. accessions, significant correlations were usually found.

**Gall formation by *Phytomonas tumefaciens* extract and indole-3-acetic acid in cultures of tomato roots,** B. A. FRIEDMAN and T. FRANCIS, JR. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 9, pp. 762-772, figs. 4).—When excised tomato roots were cultured in 125-cc. Erlenmeyer flasks containing 50 cc. of P. R. White's yeast extract (E. S. R., 72, p. 185) or synthetic media, addition of ether extract of 6.5 l. of potato-dextrose broth in which *P. tumefaciens* had grown for 3 days reduced growth, caused excess root-hair development, and resulted in swellings of cut ends of some roots. Roots grown in solution to which indole-3-acetic acid ( $10\text{--}0.0125$  mg./l.) had been added responded by gall formation. The tumors were characterized by hypertrophy, stimulation of root primordia, hyperplasia, occasional multinucleate cells, excess root-hair production, and callus formation. Galls were formed only in those concentrations of indole-3-acetic acid causing growth inhibition. Up to dilutions of about 7 by  $10^{-8}$  moles/l., indole-3-acetic acid reduced root elongation, number of rootlets, and total dry weight. Concentration of  $10^{-10}$ ,  $10^{-12}$ , and  $10^{-14}$  M did not appear to accelerate root growth.

**Wound dressings on apple trees,** J. S. COOLEY (U. S. Dept. Agr. Cir. 656 (1942), pp. 19, figs. 6).—In an attempt to discover treatments that did not kill the cambium around wounds and the effects of season of wounding on the healing of wounds, a large number of dressings were tried and the most promising were later tested on mature apple trees in Oregon and Virginia. These included white lead and linseed oil, shellac, and two waxlike dressings, one (No. 541) containing 8 parts by weight of rosin and 3 of sardine oil and the other (No. 540) copper soap in addition. Healing was more rapid transversely than longitudinally, in the latter case wounds enlarging even where the best dressings were used. Wounds made in June or later produced little or no callus, enlargement due to death of tissues taking place in both directions. Longitudinal extensions of wounds made in winter was usually greater than in those made in spring. The slightly injurious dressings caused less killing when applied in spring than at any other time. Shellac gave the best callus formation and less dying or longitudinal wound extension than any other dressing tried, and No. 541 gave better healing in general than white lead and linseed oil or No. 540. Untreated wounds usually healed better than those treated with white lead and linseed oil, but poorer than those treated with shellac. For combined wound and woolly apple aphid protection, dressing No. 541 is recommended. In case the best approved materials are not available under existing war priorities the latest information should be sought. A wound dressing only slightly toxic may have injurious effects on apple tree wounds, and the hazard of the treatment might be even greater than that of possible heart rot injury. There are 16 references.

**A progress report on the yellow-leaf disease of sour cherry,** E. J. RASMUSSEN and D. CATION. (Mich. Expt. Sta.). (*Amer. Pomol. Soc. Proc.*, 57 (1941), pp. 133-140).—Yellow leaf, present in Michigan for at least 20 yr., is a slow-acting disease of considerable economic importance because it causes premature defoliation, progressive reduction in spur growth, reduced yields, and shortening of the profitable life of the orchard. It is a virus disease transmissible by budding, and sprays, fertilizers, or cultural practices are of no avail in eliminating it. Its apparent orchard spread varies from year to year, but the mechanism of spontaneous transmission is unknown, though some evidence points to leafhoppers as possible vectors. Montmorency cherry

selections appear to vary in susceptibility. Nursery tree propagation from healthy high-producing strains or selections promises to become an important control measure.

**Prune dwarf, E. M. HILDEBRAND.** (Cornell Univ.). (*Phytopathology*, 32 (1942), No. 9, pp. 741-751, figs. 5).—Originally found only in Niagara County, N. Y., prune dwarf is now also known in Canada. Since both Bradshaw and Damson plums were found to be symptomless carriers, the virus may be more widespread than is realized. The disease spreads slowly and, ordinarily, to the immediately adjacent trees in orchards in spurts which have been correlated with severe green plum aphid infestations, but insect transmission tests have been negative. Yields on the prune types of plums average less than 10 percent of normal. The Lombard plum, which suffers foliage symptoms but not abortion of the pistils, yielded slightly below normal, apparently because of the reduced foliage. Fruiting of the Damson plum, which masked symptoms, seemed to be normal.

The only essential for successful transmission to susceptible plants was tissue union between scion and stock, and the shortest incubation period for prune was 5 weeks. Of the *Prunus domestica* varieties tested, only Lombard plum (besides the prune types) developed typical foliage symptoms. None of the *P. salicina* varieties developed marked symptoms, but a distinct chlorotic line pattern virus was prevalent in Red June and also present in Abundance. The Damson plum (*P. insititia*), though failing to develop typical foliage symptoms, was, subsequent to budding, found to contain the virus. Transmission tests from prune to cherry have all been negative, but the peach proved susceptible with production of foliage symptoms from which the trees largely recovered as the season advanced. Peach fruits on affected trees were retarded in development, especially on the suture side. The symptoms appearing in both outdoor and greenhouse tests with Elberta peaches were a stunting of terminal growth and a tendency toward wavy margins on some of the leaves, but the following year the affected peaches had largely recovered. Studies are under way to determine whether any relation exists between prune dwarf and peach-rosette mosaic.

**Infection of perennial delphiniums by California-aster-yellows virus, H. H. P. SEVERIN** (*Hilgardia* [*California Sta.*], 14 (1942), No. 8, pp. 411-440, pls. 8).—Among the virus diseases of perennial delphiniums, the one under discussion was found due to the virus of California aster yellows. The delay in discovery of its identity was caused by the fact that the short-winged aster leafhopper (*Macrostelus divinus*) rarely recovers this virus from infected delphiniums, the latter being unfavorable food plants for both the long-winged and short-winged aster leafhoppers. The mountain leafhopper (*Thamnotettia montanus*) and the geminate leafhopper (*T. geminatus*) proved the most important vectors to delphinium, and both species breed normally on this host plant. The main abnormalities induced by the virus in delphiniums are described. The incubation periods in seedlings of four varieties infected during June by four vectors averaged 19.5 days; in plants infected during the second year in February, March, and April before appearance of the spikes they averaged 43.5 days, and after the spikes appeared 45 days. So far as determined the range of the California-aster-yellows virus includes Oregon, Washington, Utah, Wyoming, and Colorado. The disease of delphiniums resembling aster yellows is known in Oregon, Washington, Utah, and Idaho, where either the mountain or the geminate leafhopper or both are known to occur. There are 38 references.

**Celery calico on perennial delphiniums and certain other host plants, H. H. P. SEVERIN** (*Hilgardia* [*California Sta.*], 14 (1942), No. 8, pp. 443-464,

pls. 6).—This disease proved due to the celery calico virus. In delphiniums the symptoms were confined to the basal and intermediate leaves and were variable, including pale-yellow, amber, or lemon-yellow areas, or line or ring patterns, but not abnormal flowers or breaking in their color. The incubation period was 11–178 days. Plants spontaneously or experimentally infected during the first year may be symptomless carriers during the second year. Calico is often found associated with aster yellows in delphiniums, but the inoculum from such plants induced calico rather than aster yellows. The aster-yellows virus was recovered from the virus complex by three species of leafhoppers. Tomatoes are sometimes infected with a mixture of viruses. Cucumbers, when inoculated with the virus extract, filtered out ordinary tobacco mosaic virus and retained the calico virus. Aphids of nine species were shown to be vectors of calico virus.

**Perennial-delphinium ringspot**, H. H. P. SEVERIN and R. C. DICKSON (*Hilgardia* [California Sta.], 14 (1942), No. 8, pp. 367–390, pls. 4, figs. 4).—Perennial delphinium was found spontaneously infected with an undescribed ring spot virus the host range of which as determined by mechanical inoculation included 11 species of 8 genera in the 5 plant families Ranunculaceae, Chenopodiaceae, Malvaceae, Solanaceae, and Cucurbitaceae. Plants proving nonsusceptible on inoculation included 28 species of 26 genera in 12 families. Thermal inactivation of the virus occurred at 65° C. for 10 min. Inactivation also took place after extracted juice from diseased cucumber plants had been exposed to the air at room temperature for 5 days, and the tolerance to dilution from delphinium or cucumber was 1:1,000. All attempts to find a vector failed.

**Some species of Papulaspora associated with rots of gladiolus bulbs**, H. H. HORSON (*Mycologia*, 34 (1942), No. 4, pp. 391–399, figs. 2).—As associated with gladiolus bulb rots, the author isolated *P. dodgei*, *P. rubida*, *P. appendicularis* n. sp., and *P. coprophila*. These fungi are saprophytic on bulb tissues rotted by primary infection of some other organism, in this case *Sclerotinia* (*Botrytis*) sp. A note by D. H. Linder is appended in which *P. dodgei* n. sp. is proposed to replace the name *P. gladioli* (E. S. R., 87, p. 381), which had been previously used for another fungus.

**Specificity of pyridoxine for Ceratostomella ulmi**, W. J. ROBBINS and R. MA (*Bul. Torrey Bot. Club*, 69 (1942), No. 5, pp. 342–352, figs. 5).—The effects of 12 analogs of pyridoxin on the growth of *C. ulmi* were determined in agar culture, the diacetate and triacetate of vitamin B<sub>6</sub> proving as beneficial as pyridoxin. Of the 10 additional analogs, 4 had 5 percent or less of its beneficial effect, 2 were inactive, and 4 inhibited growth more or less. Pyridoxin was found to antagonize the detrimental analogs. The possibility of investigating its analogs as an aid in controlling the Dutch elm disease is briefly discussed. There are 12 references.

**The variability in resistance to decay of the heartwood of home-grown western red cedar (*Thuja plicata* D. Don.) and its relation to position in the log**, K. ST. G. CAETWRIGHT (*Forestry*, 15 (1941), pp. 65–75, figs. 4).—Resistance to decay of home-grown timber of this tree was found to be of the same order as that of the imported. The heartwood from the base of a tree about 65 yr. old grown in Scotland showed little variation across the trunk in resistance to attack, the timber from this region being very resistant. There was, however, an indication that the outer wood is more resistant to *Polystictus versicolor* than that next the pith. It is believed probable that this variation would be more marked in a mature tree. The difference in resistance to decay of the wood across the trunk was highest in material taken from the base of the tree, and showed a progressive decrease upwards. This was true for both white and brown rots, but was exhibited most clearly by *Poria incrassata* (brown rot), which appears to be more sensitive to variations in resistance. The

amount of material soluble in hot water was determined in samples from different positions in the trunk, and the toxicity of these extracts to *Fomes annosus* was examined. In each of the cross sections studied, it was noted that the amount of material extracted by hot water was greater in the outer heartwood adjoining the sapwood than in the central heartwood and that the toxicity of the extracts was correspondingly higher. The resistance to decay of the samples thus appeared to be closely correlated with the amount of extractable substances present therein. In the material examined serious decay occurred only in wood containing less than 5 percent by weight of hot-water extractives.

**A cedar seedling blight in Puerto Rico**, L. A. ALVAREZ GARCÍA. (P. R. Univ. Expt. Sta.). (*U. S. Dept. Agr., Forest Serv., Caribbean Forester*, 1 (1940), No. 2, p. 26, *Span. abs.*, p. 26).—A note reporting *Phyllachora balansae* as causing severe seedling blight on the timber tree *Cedrella mexicana*, apparently new to Puerto Rico.

**Cytospora abietis**, the cause of a canker of true firs in California and Nevada, E. WRIGHT. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 3, pp. 143-153, figs. 3).—In 1929 this canker was first observed extensively on white fir (*Abies concolor*) and red fir (*A. magnifica*) in the northern Sierra Nevada forests, and studies thereon were begun the ensuing year. Typical symptoms include early resin infiltration of the bark, followed by canker development and production of yellow spore horns. Infections on white fir begin in the lower branches and may gradually progress into the stem and upward. On red fir, infections are commonly associated with mistletoe hypertrophies. Slit inoculations were generally unsuccessful, much better results being obtained by a cork-borer method. Cross-inoculations with isolates from either host attacked both, and there seemed to be no significant difference in the virulence of "strains." The fungus is classed as a semiparasite, usually infecting through wounds. Diameter-growth comparisons from increment borings in healthy and attacked trees suggested that drought may be an important factor, particularly in weakening fast-growing white firs previous to infection. Fire-scorched trees appear to aid in perpetuating *C. abietis* between droughts. Other agents, such as bark beetles, aphids, and ants are believed to spread the disease locally and predispose individual branches to infection. The fungus is apparently endemic in the Sierra Nevada forests and assumes epidemic proportions only when the true firs are weakened by environal or other factors. There are 13 references.

**Experimental autoccism and other biological studies of a gall-forming Peridermium on northern hard pines**, M. A. MCKENZIE. (Mass. Expt. Sta. et al.). (*Phytopathology*, 32 (1942), No. 9, pp. 785-798, figs. 2).—From *Pinus banksiana* and *P. rigida*, inoculations were made on *P. sylvestris*, *P. banksiana*, and *P. rigida* with aeciospores (binucleate) of a gall-forming *Peridermium*, presumably referable to *Cronartium quercuum*. The mycelia giving rise to the aecia bearing the spores were uninucleate. Germination of aeciospores always showed them to form germ tubes, and no basidia or secondary spores were observed. Inoculations were successful on all the hosts, but only on *Pinus sylvestris* inoculated with aeciospores from *P. banksiana* were galls formed. No aecia or pycnia appeared on these galls. On all pine species inoculated with aeciospores from all collections, numerous cases of slight roughening, swelling, or discoloring of the bark (not resulting in gall formation) were observed. Studies of discolored bark showed the presence of typical rust mycelia and haustoria. Microchemical tests of infected trees indicated certain differences among the various plants after infection, but no significant differences were apparent prior to infection. In some infected trees bark discoloration, abundant mycelia, haustoria, galls, and witches'-brooms were observed; in others defoliation and death of leaders or complete necrosis resulted. There are 44 references.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

[Work in economic zoology and entomology by the Missouri Station] (*Missouri Sta. Bul.* 444 (1942), pp. 48-50, 73).—A progress report (E. S. R., 87, p. 85) noting work by L. Haseman, W. W. Smith, L. Jenkins, H. E. Brown, C. W. Wingo, and E. M. Funk on strawberry insects and their control, studies with insecticides, control of the squash bug and cucumber beetle, the periodical recurrence of insect pests, the artificial propagation of game birds, and increasing the egg production of chukar partridges by artificial lighting.

Control of the brown snail in citrus orchards, H. C. LEWIS and J. R. LA FOLLETTE (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 359-362).—In tests made of poison baits consisting of bran, or substitutes, with calcium arsenate or metaldehyde, alone or in combination, for the control of the European brown snail *Helix aspersa* Müller in California citrus orchards, arsenical baits were somewhat more effective than metaldehyde baits. "Metaldehyde baits are relatively ineffective when broadcast and are less effective during cold weather. When used they should be placed in small piles in the sunshine. The season for best control is rainy weather in late winter and spring when snails are most active. Arsenical baits should be broadcast onto the trees, and this method of application is essential during the period when greatest tree damage is being done by immature snails. Fresh-pressed orange pulp, a citrus byproduct, with calcium arsenate is the most effective bait yet tried."

[Notes on economic insects and their control] (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 449-462, figs. 9).—Contributions presented (E. S. R., 87, p. 821) are: Control of the Striped Blister Beetle [*Epicauta lemniscata* F.] Through Its Gregarious Habits, by W. R. Horsfall (p. 449) (Ark. Expt. Sta.); Killing Codling Moth Larvae With Low Temperatures, by L. Haseman (pp. 449-450) (Mo. Sta.); Sprays to Kill Overwintering Codling Moth Larvae, by M. A. Yothers, F. W. Carlson, and C. C. Cassil (pp. 450-451); Toxicity of Trichloroacetoneitrile to the California Red Scale, by R. L. Busbey, H. R. Yust, and R. A. Fulton (pp. 452-453); Notes on the Biology of the Citrus Thrips, by F. Munger (p. 455), and Insect Pests Breeding in Vegetable Refuse in Arizona, by C. C. Deonier (pp. 457-458) (all U. S. D. A.); A Natural Habitat for the Black Carpet Beetle, Attack of the Lead Cable Borer on Asphalt Roofing Material, and Wood-Boring Habit of the Drugstore Beetle [Weevil], all by E. G. Linsley (p. 452) (Univ. Calif.); An Unusual Injury to Peas by Thrips [*Frankliniella helianthi* (Moult.)], by P. T. Rihard (p. 453), and *Orius insidiosus* [Say], a Predator on Cotton Insects [Cotton Flea Hopper, Bollworm, and Cotton Leafworm] in Western Texas, by W. S. McGregor (pp. 454-455), (both Tex. Sta.); Observations on the Relationship of Alsike Clover Nectar to Relative Humidity, by H. A. Scullen (pp. 453-454) (Oreg. Sta.); Transmission of the Causal Agent of the Ring-Rot Disease of Potatoes by Insects, by G. M. List and W. A. Kreutzer (pp. 455-456) (Colo. Sta.); The Larval Meconium of Parasitic Hymenoptera as a Sign of the Species, by S. E. Flanders (pp. 456-457), and Analytical Isolation of Rotenone From a Spray Solution, by F. A. Gunther (p. 458) (both Calif. Citrus Sta.); Control of *Brachyrhinus sulcatus* Fab. in Southern California, by D. B. Scott, Jr. (pp. 459-460); The Prickly Pear Cactus Thrips *Rhopalothrips bicolor* [Hood], by S. F. Bailey (pp. 460-461) (Univ. Calif.); and The Block Method of Mounting Insects, by F. E. Guyton (pp. 461-462) (Ala. Polytech. Inst.).

[Insect investigations by the Arkansas Station] (*Arkansas Sta. Bul.* 417 (1942), pp. 34-41).—A progress report noting work by D. Isely, W. R. Horsfall, and W. J. Baerg with the boll weevil, cotton aphid, cotton leafworm, bollworm, common red spider, and cotton flea hopper, as well as control for the striped blister beetle, grape rootworm, and fall armyworm.

[Insect investigations by the Nebraska Station]. (Partly coop. U. S. D. A. et al.). (*Nebraska Sta. Rpt.* [1941], pp. 45-50, figs. 2).—A progress report noting work by H. D. Tate, R. Roberts, and R. E. Hill on the hessian fly, chinch bugs, grasshoppers, corn earworm, southern corn rootworm, potato flea beetles, potato psyllid, *Lygus* spp. on potatoes, Colorado potato beetle, potato leafhopper, and cockroach and ant control.

[Entomological investigations by the Texas Station]. (Partly coop. U. S. D. A., Iowa and Wyo. Expt. Stas., et al.). (*Texas Sta. Rpt.* 1941, pp. 19-20, 21, 29-38, 56, 160-161, 163, 164-165, 166, 182).—Included are brief reports (E. S. R., 86, p. 213) on studies at the station and substations by H. B. Parks, A. H. Alex, H. J. Reinhard, F. L. Thomas, J. C. Gaines, Jr., W. L. Owen, Jr., J. N. Roney, R. K. Fletcher, S. E. Jones, A. J. Chapman, V. A. Little, S. W. Bilsing, W. S. McGregor, M. J. Janes, and P. T. Rihard on the activities of bees; queen rearing; queen rearing for resistance to American foulbrood; biology, control, and taxonomy of white grubs (*Phyllophaga* spp.); cotton insects, including the boll weevil, cotton flea hopper, bollworm, flower thrips, *Adelphocoris superbus*, *Lygus hesperus*, *Chlorochroa ligata*, rapid plant bug, southern green stinkbug, vegetable weevil, and the pink bollworm; devil's shoestring as an insecticide; fruit and nut insects, including the pecan nut casebearer, plum curculio, oriental fruit moth, and bark beetles (*Stephanoderes flucus* Hopk.); truck crop insects, including the cabbage looper, flea beetle *Phyllotreta vittata discedens* (Wise), turnip aphid, and squash bug; sulfur injury to potatoes; thrips on roses; the leaf crumpler; control of leafhoppers and the grape berry moth on grapes; incidence of citrus insects; Florida red scale; population studies of citrus rust mites; cabbage webworm; harlequin bug; garden flea hopper of tomatoes; tomato fruitworms on beans; corn earworm; onion thrips; and wingless May beetles.

Notes on the temporary establishment of insect and plant species on Canton Island, R. H. VAN ZWALUWENBURG (*Hawaii. Planters' Rec.* [Hawaii. Sugar Planters' Sta.], 46 (1942), No. 2, pp. 49-52, fig. 1).

Insect pests of stored rice and their control, A. I. BALZER (*U. S. Dept. Agr., Farmers' Bul.* 1906 (1942), pp. [2]+22, figs. 16).—The most destructive insects to rough rice are the angoumois grain moth, the lesser grain borer, and the rice weevil. Several other species are of some importance. More important milled rice pests are the saw-toothed grain beetle, red flour beetle, confused flour beetle, cadelle, flat grain beetle, Indian-meal moth, rice moth *Corcyra cephalonica* (Staint.), corn sap beetle, psocids, lesser grain borer, and the rice weevil. Rice may become infested in the field, in farm storage, warehouses, elevators, and in transit. Control measures discussed include the use of hydrocyanic acid, methyl bromide, chloropicrin, and ethylene oxide as fumigants; mill and warehouse sanitation; and heating and drying; as well as sprays and dusts.

Pantry insects, J. B. SCHMITT (*New Jersey Stas. Cir.* 441 (1942), pp. [2]).

Insect food caches as reservoirs and original sources of some stored products pests, E. G. LINSLEY. (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 434-439).—The known occurrence of stored products pests and certain other household pests in the nests of bees and wasps and the importance of such foci as sources of infestation led to the examination of eight nesting sites of five species of *Anthophora* in seven localities in central and southern California. Dermestids of several types were abundant in all of the sites; the California spider beetle *Ptinus californicus* Pic and the confused flour beetle were present in three; the Indian-meal moth, the drugstore weevil, and the black flour beetle *Aphanotus parallelus* Csy. in two; and the saw-toothed grain beetle and the webbing clothes moth, each in one site. In a single colony on the edge of the Mojave Desert, approximately 10 miles from the nearest human habitation, the

drugstore weevil, the saw-toothed grain beetle, and one of the so-called cabinet beetles, *Trogoderma faja* Csy., were found, and in a second area, only slightly less isolated, the Indian-meal moth and the webbing clothes moth were both present. This brief report is followed by a review of the present knowledge of such occurrences, presented with a list of 59 references to the literature cited.

**Variations in tolerance of narcissus bulbs to hot water-formalin treatment associated with locality of production or of storage, C. F. DOUCETTE.** (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 403-405, fig. 1).—In order to determine the influence of differences in environment, bulbs from distinct regions in the Pacific Northwest were used in comparing the effects of hot water-formalin treatment for the control of bulb pests. "The treatment consisted of presoaking in water at 75° to 80° F., followed by immersion for 4.5 hr. in water at 111° containing formalin at a dilution of 1:400. The similarity of response of all lots following early season treatment, 6 to 8 days after digging, indicated that no important variation was associated with growing conditions of the localities. The bulbs stored at the several localities until treatment given near the end of the storage season varied considerably in their response, exhibiting decreased tolerance as the locality shifted from south to north."

**The determination of kerosene oil deposit on citrus leaves, F. A. GUNTHER and W. EBELING.** (Calif. Citrus Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 333-339, figs. 4).—Account is given of a new method for determining the amount of kerosene deposited on citrus leaves by toxic kerosene sprays. This method involves the selective chemical disintegration of the leaf cells, accompanied by a steam distillation of the stable oils present. The apparatus necessary for this method is described in detail. Typical results obtained when the method was applied to field experiments are presented. In one such experiment the coefficient of variation of this method was determined to be 0.0467. The only probable source of error is discussed. It is shown that the major portion of the kerosene "absorbed" by the leaf probably goes into solution in the natural waxes and oils elaborated inside the leaf cells.

**Some observations on oil deposit, H. KNIGHT** (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 330-332, figs. 3).

**The New Caledonian cockroach wasp *Ampulex compressa* in Hawaii, F. X. WILLIAMS** (*Hawaii. Planters' Rec. [Hawaii. Sugar Planters' Sta.]*, 46 (1942), No. 2, pp. 43-48, figs. 6).—Biological notes on this beneficial wasp, recently introduced into Hawaii from New Caledonia, are presented.

**A method for rearing citrus thrips in the laboratory, F. MUNGER.** (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 373-375, figs. 3).—A technic developed for the rearing of thrips in the laboratory for toxicological tests, in which use is made of a cage consisting of two sheets of glass with oval holes cut therein and separated by an oval ring of plaster, is described. The upper surface of a citrus leaf is sealed against the opening in one of the sheets of glass and the other surface is placed in contact with a moist pad.

**Calcium cyanamid, a possible practical control for pear thrips in prune orchards, E. P. BREakey.** (West. Wash. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 376-382, figs. 4).—The timely application of pulverized and oiled calcium cyanamide (5 percent oil) of commercial grade to the surface of the soil in prune orchards at the rate of 300 lb. per acre or less reduced the number of overwintering thrips to emerge from the soil by approximately 90 percent. Large-scale applications of calcium cyanamide dust were made in the prune orchards of Clark County, approximately 300 acres having been dusted in the spring of 1941. The dust was applied in two applications of 150 lb. each, the initial application being timed for maximum effectiveness against the thrips

and the second application made approximately 10 days later in order to prevent the development of the apothecia of the brown rot fungus. Blossom counts made over treated and untreated areas at the close of the emergence period of the thrips indicate results in keeping with those obtained experimentally.

**The grape or vine thrips, *Drepanothrips reuteri*, S. F. BAILEY.** (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 382-386, figs. 4).—Account is given of the economic importance and biology of *D. reuteri* Uzel, together with notes on other species of thrips on grapes. So far it has been unnecessary for growers to practice specific control measures, since the contact sprays and dusts of oil, pyrethrum, and nicotine used for the grape leafhopper considerably reduce the thrips population. A spray composed of 2 lb. of tartar emetic and 4 lb. of sugar per 100 gal. of water is said to give a remarkable kill of adults and larvae. When necessary, such a spray applied in May or June will prevent further injury to young shoots and berry clusters. A list is given of 23 references to the literature cited.

**Evaluating the economic status of Phymata, W. V. BALDUF.** (Univ. Ill.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 445-448).—An appraisal of the economic role of the common ambush bug *P. pennsylvanica americana* Melin on the basis of 832 prey records obtained in the field near Urbana, Ill., in the years 1938, 1939, and 1940, is reported. This is followed by a discussion of the obstacles encountered in attempting such an evaluation of this form and which will presumably be met also, more or less, in similar attempts on any other insect.

**Lime zinc spray as a repellent for leafhoppers on citrus, H. C. LEWIS** (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 362-364).—In combating the potato leafhopper, which has become an important pest of citrus in the San Joaquin Valley of California, injury being caused to ripening oranges through puncturing of the rind of the fruit resulting in a blemish, a light whitewashing composed of zinc and lime has been used for several years and is effective in repelling the migrating adults. Only overwintering adult leafhoppers are present during the winter months when injury takes place. No immature forms of this pest occur on citrus.

**Trap-light studies on leafhoppers of the genus *Empoasca* (Homoptera: Cicadellidae), 1932-1941, N. H. WHEELER.** (U. S. D. A.). (*Ent. Soc. Wash. Proc.*, 44 (1942), No. 4, pp. 69-72).—Operation of trap lights at the Arlington Experiment Farm, Arlington, Va., over a period of 10 yr., for the purpose of collecting leafhoppers of the genus *Empoasca* is reported upon. During this period a total of 60,938 specimens was collected, of which 26,062 were females and 34,876 males. A total of 30 species was collected, 21 being the maximum number obtained during a single season. *E. fabae* (Harris), represented by 24,953 males, was followed by 4 species represented by more than 200 specimens (males), namely, *E. erigeron* DeLong 2,685, *E. pergandei* Gillette 558, *E. albocurva* Gillette 239, and *E. solana* DeLong 201.

**Biology and control of *Empoasca filamenta*, H. C. MANIS and E. L. TURNER.** (Idaho Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 416-418).—In the study reported 14 wild plants and numerous farm and garden plants were found to be suitable hosts for the leafhopper *E. filamenta* DeL., which occurs abundantly on potatoes in Idaho and for which the common name intermountain potato leafhopper is suggested. The average incubation time for eggs of the leafhopper was 12 days. The average length of time for nymphal development was 16 days. There are three and a partial fourth generations each season. Pyrethrum-cube-talc dust and pyrethrum extract-lime-sulfur spray were effective in controlling *E. filamenta*. Bordeaux mixture and the dusts containing sulfur, which control the potato leafhopper, do not control *E. filamenta*. Cube-talc dust and lime-sulfur spray also did not control this leafhopper, but it does

very little injury to the foliage and is not responsible for reduced yields in potatoes, since no increase in yields was obtained on plats where it was controlled.

**Time of seeding as a method of control for the pea aphid on fall-sown legumes in the Pacific Northwest**, L. P. ROCKWOOD and M. M. REEHER. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 420-423).—The recommended means of control of the pea aphid on fall-sown legumes in Oregon and Washington is that common vetches and Austrian Winter field peas for seed be sown in well prepared ground that is free from earlier self-sown annual legumes, about October 20 and not before October 16, and that hairy vetch for seed be sown not earlier than October 11. If late seeding is to secure its maximum effect in reducing aphid abundance, cover crops and green manure crops should be plowed under by April 7 (the calculated mean date for first spring flight of the pea aphid is April  $7 \pm 3$  days). This practice would greatly reduce the ever-present threat of aphid damage to fall-sown annual legumes in the western parts of those States.

**Life history of *Diaspis boisduvalii* and its control on cattleya with calcium cyanide**, R. M. BOHART. (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 365-368).—Report is made of a study of the biology of *D. boisduvalii* Signoret, one of the most common pests attacking cattleya and the most abundant and injurious of the several species of scale recorded in California. In the studies conducted in the laboratory at 75° F. and high humidity it was found that the life cycle from egg to adult male averaged 33 days and from egg to egg-laying female 50 days. About 200 eggs were laid by a single female. In a study of population increase on an orchid leaf in the laboratory, approximately 10,000 scales, of which 50 percent were females, were produced over a period of 5 mo. by 7 original specimens. Effective control was obtained by use of dosages of granular calcium cyanide as low as 0.10 oz. per 1,000 cu. ft. Fumigation for 3 successive weeks reduced the scale population by 98.4 percent. A small amount of injury in the form of leaf burn occurred on the older leaves, especially in the slow-growing varieties.

**The stupefaction of California red scale with sublethal dosages of hydrocyanic acid**, H. R. YUST, H. D. NELSON, and R. L. BUSBEY. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 339-342).—It was found in laboratory fumigations of nonresistant mature female scales with hydrocyanic acid at 59° F. that exposure to a sublethal dosage for 10 min. immediately before exposure to the lethal dosage produced marked protective stupefaction, but the stupefaction was lost at this temperature when 1 hr. elapsed between exposure to the sublethal and the lethal dosage. At 77° nonresistant mature female scales were not markedly stupefied when exposed to the same sublethal dosage immediately before the lethal dosage, but were stupefied to a significant extent when 1 hr. elapsed between the sublethal and the lethal dosage. In laboratory fumigations simulating conditions in field fumigations resistant mature female scales were stupefied with a 45-min. exposure to a sublethal dosage applied immediately prior to the lethal dosage. The stupefying effect was partly lost in 2 hr. but not completely lost in 3 hr. Under the same conditions scales in the second molt were stupefied with the same sublethal dosage immediately prior to the lethal dosage, and the stupefying effect was dissipated in 2 hr. The stupefactive effect of exposure for three successive 45-min. periods to a sublethal dosage was the same as that of a single 45-min. exposure.

**A comparison of the susceptibility of the so-called resistant and non-resistant strains of California red scale to methyl bromide**, H. R. YUST and R. L. BUSBEY. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 343-345).—In experiments with the California red scale the so-called resistant scales in the

mature female stage were also resistant to methyl bromide, and the so-called nonresistant scales of the same stage were nonresistant to methyl bromide, but the difference that existed in the susceptibility between the two strains to methyl bromide was less than the difference that existed between the two strains to hydrocyanic acid. Scales of the so-called resistant strain in the early gray adult stage of development were more susceptible to methyl bromide than scales of the so-called nonresistant strain in the same stage of development in 40-min. fumigations, but not in 120- to 180-min. fumigations. There was no difference in susceptibility of the two strains of scales in the second molt to methyl bromide in the limited number of tests made.

The effect of magnesium deficiency on infestations of purple scale on citrus, W. L. THOMPSON. (Fla. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 351-354, figs. 2).—It was found that purple scale populations on bronzed leaves of citrus, known in Florida as "bronzing" and due to magnesium deficiency, were significantly lower than on green leaves of the same age. Collectively, trees with a high percentage of bronzed leaves were not so heavily infested as adjacent trees with a high percentage of green leaves where the magnesium deficiency had been corrected. Indirect factors influencing lighter infestations on magnesium-deficient trees are sparsely foliated trees and the abnormal dropping of leaves.

Influence of tartar emetic on the yellow scale and its parasite *Comperiella bifasciata* (How.), J. K. HOLLOWAY, C. F. HENDERSON, and H. V. MCBURNIE. (U. S. D. A. coop. Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 346-347).—In laboratory work with the yellow scale tartar emetic was found to be toxic to adults of the parasite *C. bifasciata*. In field experiments this insecticide did not influence yellow scale populations, nor were there any significant differences in parasitization by *Comperiella* in the treated and check plats. This has led to the conclusion that as a source of food the deposits are not attractive to the parasites under field conditions.

Sulfur dust as a supplement to cyanide fumigation for control of black scale and its effect on citrus red mite, E. A. MCGREGOR. (U. S. D. A. et al.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 355-358).—It was demonstrated in studies at Placentia, Calif., in 1937-38 and at North Whittier Heights in 1938-40 that two applications of 325-mesh sulfur dust applied during the period of hatching significantly reduced the populations of the black scale. When the sulfur treatments were followed in August by hydrogen cyanide fumigation the populations of mature scales the following spring were materially reduced below the levels occurring the year previous. In most cases where fumigation alone was applied the populations of maturing scales became higher than the year before. Sulfur dust applied during May and June caused very high mortalities of the citrus red mite at Placentia in 1937 and at North Whittier Heights in 1939.

The seasonal vertical distribution of wireworms in the soil in relation to their control in the Pacific Northwest, E. W. JONES and F. H. SHIRCK. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 3, pp. 125-142, figs. 4).—Trends in the numbers of wireworms occurring at different depths in the soil were studied near Walla Walla, Wash., and Parma, Idaho, in relation to soil temperature, moisture, and cropping conditions. From 10 to 20 1-sq.-ft. soil units to a depth of 18 or 24 in. were examined for wireworms on each observation date. It was found that there is an upward migration of wireworms from the subsoil layers to the surface layers in the spring when temperatures range from 40° to 68° F. at the 6-in. depth. Wireworms leave the surface 3 in. and return to deeper layers when surface temperatures of 75° and above are reached. Avoiding seeding early in May, when the highest percentage of wireworms are in the surface 6 in. of soil, tends to minimize the loss of seed of summer crops

from wireworm feeding. The effectiveness of soil fumigants is related to wireworm depth distribution. The application of carbon disulfide would be most effective in July, August, or September, whereas naphthalene would be more effective during April, May, and June. The time to attract wireworms to any form of baits is also during April, May, and June.

The flight of sugar-beet wireworm adults in southwestern Idaho, F. H. SHIRCK. (U. S. D. A. coop. Wash. and Idaho Expt. Stas.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 423-427, fig. 1).—Collections of adults of sugar beet wireworms made over a 4-yr. period by the use of standard insect nets have shown the flight period in southwestern Idaho to extend from the middle of April to the end of May.

Will click beetles mate more than once and are they parthenogenetic? C. E. WOODWORTH. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 418-419).—The experiments reported have shown that since the males of the Pacific Coast wireworm can successfully mate several times the practical value of trapping these individuals is lost. This is true even though the females cannot reproduce parthenogenetically.

White grub control with dichloroethyl ether, P. O. RITCHIE and H. H. JEWETT. (Ky. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 441-445).—In experimental work conducted, the details of which are presented in four tables, poor control of third instar *Phyllophaga* and green June beetle larvae in bluegrass sod resulted from the use of dichloroethyl ether solution containing 32 cc. of ether per gallon and applied at a rate of approximately 1 gal. per square yard. The same solution, with or without Tergitol 7 penetrant, gave excellent control with one application of 2 to 2.25 gal. per square yard. This dosage gave control of *Phyllophaga* larvae ranging from 65.4 to 99.3 percent with a mean of 81.3 percent. The same dosage gave control of the green June beetle larvae ranging from 67.8 to 93.2 percent with a mean of 79.3 percent. The addition of 0.05 or 0.1 percent Tergitol 7 penetrant caused no significant increase in the percentage of control of either genus of grubs but was beneficial in effecting solution of the dichloroethyl ether. In general, there was no significant difference between the control of *Phyllophaga* and green June beetle larvae effected with dichloroethyl ether and sodium cyanide at optimum dosages. Dichloroethyl ether solution had little or no effect on bluegrass when applied at dosage and strength needed for good control of grubs. Severe injury to spiny sida, dandelions, and small tobacco plants was observed.

Life history and control of the giant apple root borer [California prionus], J. R. EYER (*New Mexico Sta. Bul.* 295 (1942), pp. 14, figs. 11).—This reports a continuation of earlier work (E. S. R., 60, p. 64).

In New Mexico adults of this long-horned beetle emerge from pupae in the soil during the latter part of June and early in July. The apple tree is the preferred host of this species. Most of the feeding by first- and second-year larvae occurs on the surface of the larger roots, which are usually killed by being girdled. At this stage the larvae are often in close contact with the soil and can be easily killed by soil fumigants which possess the property of rapid penetration. Third- and fourth-year larvae usually burrow deeply into the living wood of the crown and are difficult to eradicate. Pupae are vulnerable, since this stage is generally formed in the soil and easily reached by fumigants. Based on observations made during this investigation it was concluded that vigorous apple trees are least subject to attack and trees up to 6 yr. of age may be protected by strawboard bands treated with  $\beta$ -naphthol or  $\alpha$ -naphthylamine placed just before adult emergence (June 1) and allowed to remain until August, while older infested orchards should be treated at least every 2 yr. with

paradichlorobenzene at the rate of 1.5 to 2 oz. to a pint of "white" gasoline and applied at the rate of 1 pt. to each foot of tree circumference.

**Powder post beetles**, J. B. SCHMITT (*New Jersey Stat. Cir.* 442 (1942), pp. [2]).

**Spraying and dusting experiments with bush lima beans on Long Island for control of the Mexican bean beetle**, H. C. HUCKETT (*New York State Sta. Bul.* 702 (1942), pp. 45, figs. 3).—Results from these experiments, carried on during the seasons of 1936 to 1941, inclusive, indicated that dusting as expressed in yield was inferior to spraying for foliage protection against the Mexican bean beetle. Copper sprays on their own merits were superior to sulfur sprays. Pyrethrum or rotenone when added to copper sprays served to increase slightly their effectiveness in foliage protection. Sulfur sprays were improved by the addition of rotenone as expressed by foliage protection and yield of pods.

**Commercial control of the pepper weevil in California**, R. E. CAMPBELL and J. C. ELMORE. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 369-373).—Control work with the pepper weevil in southern California in 1941 in which a cryolite-talc-cube dust mixture was used at the rate of 15 to 25 lb. per acre per application, applied with power and hand dusters, is reported. The program recommended, consisting of three dustings at 5-day intervals, starting when the first pods commence to set, a 10-day interval with no dustings, and then three more dustings at 5-day intervals, was followed by many growers, who installed adequate washing equipment so that poisonous residue was successfully removed. In comparing treated with untreated fields, the average number of pods per plant was used, 200 plants per field being examined, with 46 fields included in the survey. The treated fields produced more than three times as many pods as the untreated. Fields dusted six to nine times produced more pods than those dusted two to five times. Late-planted fields were more severely damaged by the pepper weevil than fields planted earlier.

**Platynota stultana as a pest of field-grown carnations**, R. M. BOHART. (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 399-403).—Account is given of the host relationships, an outline of its life history and seasonal history, and control work with *P. stultana* Wlsm., known in the literature as the orange webworm, orange calyx worm, and rose leaf roller, which has a broad host range but in California is responsible for damage chiefly to carnation, rose, and orange. "On carnation it persists throughout the year in cloth houses but is dormant for a few months during the winter. Damage to carnation is of three types, leaf tying, bud boring, and stem boring, in descending order of frequency. At an average temperature of 75° F. the life cycle from egg to adult was found to vary from 43 to 46 days. Six species of hymenopterous parasites were reared in the laboratory, but, except for a short period toward the end of summer, these did not appear to be of much consequence. Materials used in control studies included paris green, acid lead arsenate, pyrethrum-rotenone combinations, cuprous cyanide, natural cryolite, dichloroethyl ether, nicotine-bentonite, and a nitrated phenol. The first three of these had undesirable effects on foliage. The most promising material was natural cryolite, used as a spray at the rate of 6 lb. to 100 gal., applied to 6,000 mature plants."

**Variability of diapause in *Melissopus latiferreanus***, S. M. DOHANIAN. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 406-408).—Of the seven varieties (A to G) of the filbert worm, recognized by taxonomic specialists as due to variability in color, size, and structure, A, B, and C have been found west of the Rocky Mountains and the remaining four east of the Rocky Mountains to the Atlantic coast. Collections from the three Pacific Coast States during the past 4 yr. have shown that variety A infests hazelnuts and oak galls, while

variety C was reared from Catalina cherries, acorns, and filberts. No specimens of other varieties have been reared by the author in that area. In rearings of variety C from the Catalina cherry material from Catalina Island some individuals in the first two collections emerged in time to produce another generation the same season; about two-thirds of the insects collected emerged the following season; seven of the larvae hibernated through two winters before issuing as adults; and three remained in the soil through three winters. The summer-generation larva forms a thin, frail cocoon only sufficiently strong to permit the easy egress of the moth from the pupal shell. However, the cocoons of the overwintering forms are spun finely and closely and are firm, tough, and strong, with particles of soil and gravel adhering all around their exterior. They are impervious to water, and their texture would seemingly protect the enclosed larvae from desiccation in severe or prolonged droughts. A few specimens of variety C that hibernated through two winters were reared from infested acorns and filberts collected in the Willamette Valley in northwestern Oregon.

**Efficiency of nicotine sprays for codling moth control in the Pacific Northwest.** F. P. DEAN, E. J. NEWCOMER, C. C. CASSIL, and C. C. ALEXANDER. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 387-392, figs. 3).—The tests reported are considered to show that the standard tank-mix nicotine bentonite would not be a satisfactory substitute for lead arsenate in the control of the codling moth in the Pacific Northwest. Until sufficient tests have been made on a large scale no suggestion can be made for the use of nicotine for combating this pest in that region, with the exception that it might be used in lightly infested areas, particularly in pear orchards.

**Studies on the prevalence of the European corn borer in the East North Central States.** A. M. VANCE (U. S. Dept. Agr. Cir. 649 (1942), pp. 24, figs. 3).—The European corn borer has spread since 1921 in the East North Central States until by 1939 infestations were found in all of Ohio, much of Michigan, the northeastern half of Indiana, part of eastern Wisconsin and northeastern Illinois, and four counties in northern Kentucky. Fall abundance of this insect in parts of Ohio, Michigan, and Indiana has ranged from an average low of 12.6 larvae per 100 plants in 1934 to a maximum of 111.2 in 1939. Certain corn borers produced two generations in each of the years 1936 to 1939 in parts of Ohio, Michigan, and Indiana. Extreme drought conditions were unfavorable to the corn borer and caused decreases in its population. Probably drought in July was most detrimental to survival. The egg stage and the period of establishment of the first and second instars constitute two of the most critical phases in the life history of this pest. From 53.2 to 95.4 percent of the eggs in a given year and locality hatched normally. In a sweet corn area west of Toledo, Ohio, the average peak of oviposition for a 13-yr. period (1927-39) was July 8-12, and the number of eggs per mass for the 10-yr. period (1930-39) was 16.6.

**Experiments for controlling the western peach borer.** A. E. MICHELbacher and R. F. SMITH. (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942). No. 3, pp. 393-398).—The control experiments reported indicate that ethylene dichloride is not as effective against the western peach borer in California as it is against the eastern species. "The work has shown that it is possible to control the borer during the cooler parts of the year with ethylene dichloride at a time when paradichlorobenzene would be ineffective due to the low temperatures. It is very possible that kills obtained in late summer and fall treatments could be increased if the treatment followed an irrigation. If the soil for mounding was moist there is likelihood of it forming a better seal, thus retaining the vapor of ethylene dichloride and resulting in a better kill. The soil moisture content certainly would be more like that found in the South and East and the treatment more comparable. Because the fall treatment with ethylene dichloride emulsion has

not proved greatly superior to the paradichlorobenzene treatment it would seem wise that farmers continue with the latter method of control."

**Experiments with poisoned bait to control armyworms in wheat, R. C. DAHMS and F. A. FENTON.** (U. S. D. A. and Okla. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 439-440).—It was shown in experiments conducted during a severe outbreak in 6 acres of wheat on the Washita River Bottom near Chickasha, Okla., that poisoned-bran bait spread at the rate of 10 lb., dry weight, per acre was not enough for effective control of the armyworm in that crop. Bait spread at the rate of 20, 30, and 40 lb. per acre gave approximately the same kill, an indication that not over 20 lb. per acre need be applied to kill armyworms in wheat. The insects were killed in a shorter time when 2 qt. of sodium arsenite were used per 100 lb. of bran than when 1.5 qt. were used, but at the end of 72 hr. the mortality was not significantly greater in the plots that received bait containing 2 qt. of sodium arsenite. Eight armyworms per square yard did not injure the kernels, but 42 worms, or more, per square yard injured some kernels. The findings indicate that bait should be applied when the worms are in the early instars, and that if they are not killed until they are nearly mature the reduction in injury to the wheat will be rather small.

**Flight and oviposition habits of the Clear Lake gnat, A. W. LINDQUIST and C. C. DEONIER.** (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 411-415, figs. 2).—Observations of the habits of the Clear Lake gnat, a nonbiting midge, which causes considerable annoyance and discomfort to residents along the shores of Clear Lake in Lake County, Calif., as previously reported upon by Herms (E. S. R., 78, p. 80), are presented.

**The mosquitoes of the Southeastern States, W. V. KING, G. H. BRADLEY, and T. E. MCNEEL** (U. S. Dept. Agr., Misc. Pub. 336, rev. (1942), pp. 96, pls. 6, figs. 26).—A revision (E. S. R., 81, p. 819).

**The seasonal distribution of myiasis-producing Diptera, M. A. STEWART and E. B. ROESSLER.** (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 408-411, fig. 1).—Trap collections of myiasis-producing Diptera at Davis in the southern part of the Sacramento Valley of California, made continuously from November 26, 1935, to December 17 of the following year, are reported upon. The findings indicate that *Phormia regina*, because of its greater abundance over a longer period of time, is the most important myiasis producer in the Sacramento Valley. The secondary screwworm, because of its greater abundance as well as its higher efficiency as a wound invader, becomes the most important myiasis producer during August, September, and the first part of October. The *Lucilia* spp. become most important during the colder part of the year. The screwworm assumes importance in this part of California only in exceptional years.

**Histological effects of pyrethrum and an activator on the central nervous system of the housefly, A. HARTZELL and H. I. SCUDDER** (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 428-433, figs. 3).—In the histological studies conducted pyrethrum and its activator, isobutyl undecylene amide, each was found to show rather distinct and characteristic effects upon the central nervous system and associated tissues of the adult housefly. Pyrethrum has a widespread clumping effect on the chromatin of the nuclei, while the activator seems to cause a chromatolysis or dissolution of the chromatin. A combination of these two agents (as in Pyrin) shows a histological picture that is a summation of the effects of both. The interaction of these two types of nuclear destruction may be the true basis of "activation."

**Bee poisoning in Washington, R. L. WEBSTER.** (Wash. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 324-326, figs. 2).—Observations conducted in potato fields in Kittitas County in 1940, where many commercial bee yards are

located within easy bee flight of potato fields dusted several times with a cryolite-rotenone dust, failed to reveal any honeybees frequenting the potato foliage and no reported cases of bee poisoning. Similar observations in Yakima County in 1941 also failed to show the presence of bees in the potato fields, although some evidence of bee poisoning was observed in July and was thought to be from sprayed fruit trees although in one case the bees were quite isolated from such trees. On an asparagus planting at Prosser in 1940 honeybees ceased working on asparagus blossoms for pollen about June 20, when the main honey flow started and at a time when the asparagus beetle population began to rise and spraying for the beetles was opportune. In 1941, however, cutting the asparagus continued until a later date. Asparagus bloom furnished pollen until July 1, and bee activity almost coincided with that of the asparagus beetles. It is pointed out that honeybee activity in an asparagus planting appears to depend upon (1) the time when pollen is available and (2) the date of the main honey flow.

**The mechanism of colony resistance to American foulbrood, A. W. WOODROW and E. C. HOLST.** (U. S. D. A. coop. Ark., Iowa, Texas, Wis., and Wyo. Expt. Stas.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 327-330).—Use was made of a new method for the controlled inoculation of individual honeybee larvae with spores of *Bacillus larvae* in the investigation of the mechanism of resistance to American foulbrood. The disease was produced in the brood of resistant colonies as readily as in that from susceptible ones. All diseased brood was removed by the bees of some resistant colonies before ordinary symptoms of the disease were manifest. In a resistant colony no diseased brood remained long enough to permit the disease organisms to reach the spore stage, whereas in a susceptible colony spore formation occurred in numerous infected larvae. *B. larvae* in the rod stage was found to be noninfective. The data show that resistance to American foulbrood in the honeybee colony consists in its ability to detect and remove diseased brood before the causative organism, *B. larvae*, reaches the infectious spore stage in the diseased larvae.

**Royal jelly and bee bread as sources of vitamins B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, C, and nicotinic and pantothenic acids, M. H. HAYDAK and L. S. PALMER.** (Minn. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 319-320).—A biological assay made on royal jelly and bee bread showed that the former contains about 50 µg. of pyridoxin per gram of fresh substance and the latter about 5 µg. Microbiological and microchemical determinations revealed the presence of thiamin, riboflavin, ascorbic acid, nicotin acid, and pantothenic acid in both royal jelly and bee bread in various amounts. These variations were greater in bee bread than in royal jelly. The presence of pyridoxin could not be established either in royal jelly or in bee bread by the microchemical method. A table showing the vitamin contents of the royal jelly and the bee bread is given.

**The composition of pollens, F. E. TODD and O. BREThERICK.** (U. S. D. A. coop. Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 312-317).—Analyses were made of samples of pollen from 32 plant species and 1 uredospore, 6 being hand collected and 27 bee collected. Pollen composition varies greatly, the mean percentages for bee-collected samples being crude protein 21.60, ether extract 4.96, water 11.19, ash 2.70, reducing sugar 25.71, nonreducing sugar 2.71, starch 2.55, and undetermined matter 28.55. Pollen ash showed the following average values: Potassium 20.7, phosphorus 13.6, calcium 10.5, magnesium 6.7, and iron 0.07 percent. As a food material pollen compares favorably in crude protein with alfalfa leaf meal, coconut meal, flaxseed, and navy beans; in ether extract with corn, bran, shorts, middlings, and soybean meal; and in ash with grain and seeds. That the composition of pollen is of interest not only as a bee food but

as a possible apiary product is emphasized, it being estimated that the bee industry could produce 80,000 tons of pollen per year if a market were available.

**Orange nectar and pollen in relation to bee activity**, G. H. VANCELL, W. G. WATKINS, and R. K. BISHOP. (U. S. D. A. coop. Univ. Calif. et al.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 321-323, figs. 2).

**The pollen required by a colony of honeybees**, J. E. ECKERT. (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 309-311, fig. 1).—In the study conducted it was found that the total amount of pollen collected in the traps of a normal colony of bees was not the total amount gathered by the bees, as sufficient pollen was carried through the traps into the hive to maintain brood rearing on a reduced scale. The amount of pollen used by the average normal colony in the apiary in which the records were taken was at least equal to and conceivably greater than the amount recorded for a normal colony. The amount of pollen recorded in 1940 was 122.24 lb. and in 1941, 111.67 lb. per normal colony. Since pollens from different sources vary in chemical composition, the relative food value of a given pollen would have to be considered, along with the amount available, in determining the potential worth of a known pollen plant to a colony.

**Various kinds of soybean flour as pollen substitutes**, M. H. HAYDAK and M. C. TANQUARY. (Minn. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 317-318).—The results of experimentally feeding bees four brands of solvent-extracted soybean flour mixed with skim milk powder in proportions of 4:1 are reported. It was found that with the decrease of the fat content and of the protein efficiency of the food the mortality of experimental bees increased while their brood rearing capacity decreased. The restoration of the fat content to 5.5 percent by an addition of the crude oil extract to the most promising brand brought about a decrease in mortality and an improvement in the brood rearing capacity of the bees. An addition of 10 percent of dried egg yolk to the dry pollen substitute increased the food value of the latter still further. An addition of raw egg yolk improved the food value of the diet, but a diseased condition which appeared in some larvae would speak against its use as a supplement to pollen substitutes.

**Population increase of citrus red mite associated with the use of sprays containing inert granular residues**, J. K. HOLLOWAY, C. F. HENDERSON, and H. V. MCBURNIE. (U. S. D. A. coop. Calif. Citrus Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 3, pp. 348-350).—Sprays containing copper, zinc, manganese, lime, and soda ash were tested to determine the influence of the inert deposits on citrus red mite populations. These were found to increase following the use of a fungicidal spray containing zinc sulfate, copper sulfate, and hydrated lime and after the use of a deficiency spray containing zinc sulfate and soda ash. A predatory mite, *Sciulus* sp., was the only natural enemy in sufficient numbers to be recorded.

**Additions to the spider fauna of Puerto Rico**, E. B. BRYANT (*Jour. Agr. Univ. Puerto Rico [Univ. Sta.]*, 26 (1942), No. 1, pp. 19, figs. 21).

## ANIMAL PRODUCTION

[Livestock investigations by the Arkansas Station] (*Arkansas Sta. Bul.* 417 (1942), pp. 20-21, 21-25).—Results are briefly reported by M. C. Kik, E. L. Nielsen, R. M. Smith, N. W. Hilston, and S. R. Johnson on studies of the nutritive value of four grasses and three legumes as ascertained by chemical analyses and feeding experiments with laboratory animals; comparisons of rough rice and corn for egg production; the use of corn silage, sorgo silage, sorgo fodder, and Sudan grass hay for feeding beef calves; and skim milk in swine rations.

[Investigations in livestock production by the Missouri Station] (*Missouri Sta. Bul.* 444 (1942), pp. 6-7, 10-12, 17-18, 20-23, 24-25, 28, 43-44, 71, 71-74, 74-75, figs. 2).—Progress is briefly presented by A. G. Hogan, L. R. Richardson, J. G. Lee, E. L. Powell, W. H. Bond, J. C. Woolley, C. Kincaid, E. A. Trowbridge, H. D. Elijah, J. E. Comfort, M. W. Hazen, E. M. Brown, J. D. Baldrige, L. A. Weaver, A. J. Dyer, A. G. Hogan, V. F. McRoberts, S. Brody, J. Campbell, H. L. Kempster, and E. M. Funk on vitamin requirements of the pigeon; nutritional requirements of poultry; anemia in chicks; the relation of environmental conditions to egg production and mortality; growth in draft colts; methods of management and production of beef cattle; systems of grazing bluegrass pastures with beef cattle; grains and protein supplements for pigs at weaning; beef produced with minimum grain and maximum roughage; barley for fattening cattle; effect of manganese in rations for brood sows; gains of runt pigs on special rations; nicotinic acid for swine; a comparison of open pollinated and hybrid corn for brood sows; relation between body weight, amount of wool or feathers, and temperature; the influence of environment on winter egg production; the normal growth of chickens under normal conditions; relation of growth in chickens and date of hatching; the gains of chickens of different breeds; the influence of incidence of paralysis on the early growth rate of Rhode Island Reds; the relation of fowl weight at 8 weeks to length of life; comparison of soybean meal and corn gluten meal as protein supplements for turkeys; effects of feeding dehydrated green feeds on hatchability of hens' eggs; seasonal variation in fertility in poultry; influence of washing eggs on hatchability; keeping quality in cold storage of eggs as influenced by prestorage treatment; and the relation of time of hatching to egg production.

[Livestock investigations by the Nebraska Station] (*Nebraska Sta. Rpt.* [1941], pp. 50-55, 61-65, 82-84, 87-88).—The results of comparisons of feeds for cattle, sheep, and swine are briefly presented by L. E. Hanson, W. J. Loeffel, R. R. Thalman, M. A. Alexander, I. L. Hathaway, F. D. Keim, W. E. Ham, F. E. Mussehl, M. L. Baker, and E. M. Brouse on artificially dried Sudan grass meal in comparison with alfalfa meal and protein supplements for growing and fattening pigs on Sudan grass pasture; soybean meal v. cottonseed meal for fattening cattle; old-process v. solvent-process linseed meal as supplements to corn and silage for fattening heifer calves; cracked Early Kalo and cracked corn for fattening cattle; additions of fish meal and alfalfa hay to Early Kalo, silage, and cottonseed cake rations for heifer calves; Early Kalo, soybean pellets, fish liver oil, limited quantities of alfalfa hay and other feeds for lambs; the vitamin content of eight Nebraska grasses; the utilization of feeds by growing chicks; protein utilization from various sources by poult; grain sorghums and corn milling byproducts for poultry; supplemental value of various grain products for chicks; corn products and silage in poultry rations; S-4 lamp radiation for hens; rations for beef cattle, including grain sorghum, silage, stover, prairie hay, soybean meal, dried beet pulp, and alfalfa hay, together with studies of effect of alfalfa pasture; sorghum grains for pigs; and soybean meal for wintering and fattening beef calves.

[Livestock investigations by the Texas Station]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 73-76, 82-85, 90-91, 94, 99-101, 117, 130, 133-134, 138, 152, 154-156, 172).—The results are presented and brief progress reported by R. M. Sherwood, J. H. Couch, G. R. Fuller, G. S. Fraps, L. E. James, C. W. Carter, R. L. Baker, W. E. Paulson, G. P. McCarthy, J. N. Thompson, J. M. Jones, W. H. Dameron, B. L. Warwick, J. H. Jones, R. E. Dickson, P. T. Marion, F. E. Keating, J. J. Bayles, L. E. Brooks, R. A. Hall, E. M. Neal, L. H. Tash, Black, J. C. Miller, S. P. Davis, C. M. Lyman, F. Hale, P. B. Pearson, H. Schmidt, R. H.

Wyche, P. B. Dunkle, and V. L. Cory, on studies of protein requirements of chicks; varying amounts of vitamin D with high levels of manganese in the poultry ration; the carotene-destroying power of animal protein feeds; the maximum crude fiber content of chick rations; rations for finishing poults; the calcium and phosphorus requirements of poults; the protein needs of poults; relation of age to fineness of wool and mohair; vitamin A requirements of beef cattle and sheep; mineral and carotene feeding as it affects beef production; ground hegari fodder v. ground red top fodder in rations for fattening steers; alfalfa v. ground quadron stover and ground and-unground quadron heads for fattening lambs; linseed meal v. cottonseed meal for fattening beef cattle and lambs; blackstrap molasses in beef cattle fattening rations; fattening Angora goats v. lamb wethers in dry lot; size of sample and determination of grades and shrinkage of Texas wools; quantitative requirements of vitamin A for pigs; concrete wallows for fattening hogs; Sudan grass and oats pasture for fattening pigs; the role of the components of the vitamin B complex in the nutrition of herbivorous animals; hegari stored in trench silos as a feed for fattening beef cattle; comparisons of linseed meal and cottonseed meal for beef cattle and lambs; blackstrap molasses as a substitute for hegari in beef cattle rations; comparisons of hegari and corn for laying hens; growing turkeys under semi-confined conditions; rough rice and no mash v. mash feeding of laying hens; vitamin A requirements for fattening beef cattle; relation of various protein supplements to utilization of carotene by beef animals; cottonseed meal v. peanut meal as protein supplements for fattening steers; hegari, red top, alfalfa, sorghums, and cottonseed meal for fattening beef cattle; maintenance of sheep and cattle on bitterweed ranges; and the nutritive value and control of bitterweed.

**Animal husbandry in India**, A. OLVER (*Nature [London]*, 149 (1942), No. 3783, pp. 489-491).—A brief summary is given of livestock conditions in India with special reference to cattle production and the sacred nature of cows.

**Availability to rats of phosphorus in red clover hays of widely varying phosphorus content**, D. E. WILLIAMS, F. L. MACLEOD, and E. MORRELL. (Tenn. Expt. Sta. et al.). (*Jour. Nutr.*, 23 (1942), No. 5, pp. 501-511).—Analysis of the high and low phosphorus red clover hays used in preceding studies (E. S. R., 84, p. 657) indicated that the higher iron and aluminum contents of the low phosphorus samples are sufficient to be a possible disturbing factor in the utilization of phosphorus by the formation of insoluble phosphates. It seems evident that they may interfere with growth and bone development in the rat. Phosphorus supplements with ash from the red clover low phosphorus samples were less available than with ash from high phosphorus samples. It thus seems clear that other minerals may modify the utilization of phosphorus by the rat from the high and low phosphorus hays.

**Sweetpotato plant increasingly used as livestock feed**, H. W. BENNETT (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, pp. 1, 7, 8).—Studies are noted which have shown that sweetpotatoes in many forms may be profitably fed to different types of livestock.

**Commercial feeding stuffs**, L. S. WALKER and E. F. BOYCE (*Vermont Sta. Bul.* 487 (1942), pp. 43).—The usual report (E. S. R., 87, p. 834) of 1,598 samples of feeds of 660 brands drawn from dealers' stocks during December 1941 is presented. The 50 samples of feeds failing to comply with their specifications are also indicated.

**Velvetbeans, cottonseed meal, and peanut meal as protein feeds for fattening steers in the Coastal Plain area**, E. W. McCOMAS, J. R. DOUGLAS, and B. L. SOUTHWELL. (Coop. Ga. Coastal Plain Expt. Sta.). (*U. S. Dept. Agr.*,

*Tech. Bul. 831 (1942), pp. 12, figs. 6*).—In four experiments of 126–140 days' duration, lots of steers fattened on rations of ear corn in the husk and peanut straw with velvetbeans as the protein supplement made average daily gains of 2.11 lb. and required less corn and peanut straw per unit of gain than other similar groups with cottonseed meal or peanut meal in place of the velvetbeans. This supplement produced steers that regularly commanded the best selling prices. Cottonseed meal produced more rapid gains than peanut meal, but the latter supplement produced steers of better quality. Each test was conducted with lots of about 12 steers with the supplements balanced to furnish equal amounts of protein.

**Cottonseed cake equal to corn in fattening ration, and may be used in large amounts**, A. E. CULLISON (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, p. 7).—Continuing the studies of large amounts of cottonseed cake for fattening calves (E. S. R., 83, p. 805), the results of two tests with four lots of heifers and steers with approximately 8, 6, 4, and 2 lb. per head daily as supplements to corn produced average daily gains of nearly 2 lb. in 170- and 142-day tests. The small differences between the lots were not considered significant.

**Dried citrus pulp in beef cattle fattening rations**, J. M. JONES, R. A. HALL, E. M. NEAL, and J. H. JONES (*Texas Sta. Bul. 613 (1942), pp. 20, figs. 4*).—In three trials over about 150 days with 3 lots of 8–10 Hereford steers each, dried citrus pulp consisting almost entirely of grapefruit peel, rag, and seed replaced about 25 percent of the ear corn chop with husks in a ration including cottonseed meal and hegari silage. Practically equal gains were produced with slightly higher finish on the citrus pulp than with corn. Replacing about half of the ear corn with citrus pulp was less palatable, decreased feed consumption, gains, and finish, and had a slight laxative effect. When gains were adjusted to agree with the therms per 100 lb. practically the same results were obtained for ear corn chop with husks and for the citrus pulp. No effect on the color of the fat in the carcass was noted.

**"Stringy" wool and copper deficiency in Western Australia**, H. W. BENNETTS (*Jour. Dept. Agr. West. Austral.*, 2. ser., 19 (1942), No. 1, pp. 7–13, figs. 5).—Evidence is presented that stringy wool is indicative of copper deficiency. The condition shown in three fleeces with a copper-deficient ration was eliminated in three others by drenching the ewes three times weekly so that the copper intake was equivalent to 15 mg. daily.

**Reindeer compared with domestic animals in relation to fattening, sex, and increase**, S. HADWEN (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 308–311, figs. 2).

**Pig feeding trials, 1938** ([*Irish Free State*] *Dept. Agr. Jour.*, 37 (1940), No. 1, pp. 71–74).—A summary of pig feeding experiments at 30 centers in which bulky rations of 40 parts corn meal, 20 oats, 30 pollard, and 10 parts bran were compared with a concentrated ration of 70 parts corn meal and 30 parts pollard for feeding pigs from about 12 weeks of age to bacon weight showed practically no differences in the rate of gain. Both rations proved satisfactory and showed that a wide range of home-grown cereals and their byproducts was efficient and suitable for fattening pigs and producing a better type of carcass for conversion into bacon than a ration mainly of corn. There were combined results with 168 pigs on each ration and gradings of 120 carcasses from pigs on the bulky ration and 117 carcasses on the concentrated ration.

**Cottonseed meal in large quantities for pigs**, P. G. BEDENBAUGH (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, p. 5).—In a test with 7 lots of 10 pigs each self-fed yellow or white corn with cottonseed meal, treated in one experiment with 3.4 percent ferrous sulfate, there were produced by the latter treat-

ment average daily gains of 1.48 lb. The group of pigs receiving 85 parts corn with equal parts of cottonseed meal and tankage made average daily gains of over 2 lb. per head. Because of illness or death individual pigs had to be removed from all lots except the control.

**Fish meal for growing and fattening pigs, W. L. ROBISON** (*Ohio Sta. Bmo. Bul.* 217 (1942), pp. 117-123).—In several experiments with approximately 40 50-lb. pigs fed in dry lot and on pasture during several successive years it was found that the gains produced with corn and fish meal were made approximately as rapidly as with corn, tankage, linseed meal, alfalfa, and minerals. When fish meal or liver meal was added to corn and trio protein mixture average gains were increased. In a comparison of menhaden and white fish meal as supplements to corn for dry lot feeding the menhaden fish meal proved superior both in gains produced and feed consumed. A summary is presented of fish meal experiments elsewhere.

**Deficiency symptoms in growing pigs fed a peanut ration, W. G. KIBK and R. M. CROWN** (*Florida Sta. Bul.* 372 (1942), pp. 52, figs. 8).—In a preliminary trial of 140 days' duration four lots of four pigs approximating 60 lb. each were fed on peanuts, with and without supplements of calcium carbonate and cod-liver oil available in one half of the lots. The utilization of peanuts for gains and the poor growth resulting indicated that they were not satisfactory, but the addition of 2 gm. of sodium chloride per head daily to half of the pigs restored appetites and thrifty appearance quickly. Satisfactory gains of nearly 1 lb. per head per day were made during the final 48-day period. The breaking strength and specific gravity of the femurs and humeri were slightly decreased by supplementing the ration with calcium carbonate, but the combination of calcium carbonate and cod-liver oil proved most efficient. The breaking strength of the bone was improved by the inclusion of salt in the ration. The calcium and phosphorus composition of the fat-free bones were not appreciably affected by the different rations fed although total ash was increased by the mineral supplements. The results were compared with those of check pigs on pasture. Further experiments with groups of two pigs individually fed similar rations showed that the 2 gm. of salt daily with or without cod-liver oil seemed necessary to provide stimulus for growth needed during the first 14 weeks of the feeding period. Gains of practically 1 lb. per head daily were produced with supplements of salt and calcium carbonate to the peanut ration. Chemical composition and breaking strength of the bones indicated that the rations influenced the total ash and thereby the total calcium, phosphorus, and carbon dioxide in the dried fat-free bone, but did not affect the amount and ratio of calcium and phosphorus found.

**Studies on the vitamin B complex in the nutrition of the dog, A. E. SCHAEFER, J. M. McKIBBIN, and C. A. ELVEHJEM.** (*Wis. Expt. Sta.*). (*Jour. Nutr.*, 23 (1942), No. 5, pp. 491-500, figs. 2).—Continuing the studies of the vitamin B requirements of the dog (*E. S. R.*, 86, p. 229), no rapidly fatal deficiency appeared on purified rations supplemented with the synthetic vitamins thiamin, riboflavin, nicotinic acid, pyridoxin, pantothenic acid, and choline. When any one was left out of the diet symptoms of faulty growth and weight decline appeared in puppies in 3-6 weeks and in older dogs in 1-3 mo. Purification of washed casein by alcohol extraction was accompanied by loss of weight and some hair graying not due to pantothenic acid deficiency. Growth on the purified ration was increased by supplements of a liver extract which seemed to contain a factor synthesized in the intestine of the dog with the aid of nicotinic acid. The condition was not rectified by supplements of inositol,  $\beta$ -amino benzoic acid, and glutamine. The study led to indications of possible qualitative differences in the requirements of the dog and other animals.

**A calibration of the development of the chick under-improved conditions of incubation and the relationship of developmental rate to age of hen and hatchability record, J. K. NEEL (*Poultry Sci.*, 21 (1942), No. 4, pp. 294-300).**—The mean stage and range of development of eggs removed at 6-hr. intervals from 24 to 72 hr. showed there was an acceleration of growth as incubation continued with uniformity of rate attained at about 72 hr. During the period 24-48 hr. development was slightly more than half that occurring during the period 48-72 hr. The calibration was made on groups of about 25-30 eggs from Rhode Island Red hens which were laid only between 10 a. m. and 4 p. m. to exclude excessive brooding of eggs held in the oviduct overnight. Incubation began at 6 p. m. on the date of laying, and the egg temperature of 92° F. was attained before the timing period was started. High egg development rate was correlated with high percentage hatchability. Both rate of development and percentage hatchability decreased with advancing age of the hens from 2 to 4 yr.

**Backyard hatching and brooding of chicks, E. HOFFMAN (*New Jersey Stas. Hints to Poultrymen*, 29 (1942), No. 5, pp. 4).**—General directions for hatching, housing, and caring for the setting hen and her chicks.

**Blood values of hens fed a yeast-fermented mash supplemented adequate diet, C. J. HAMRE and J. T. MCHENRY. (Hawaii Expt. Sta.). (*Poultry Sci.*, 21 (1942), No. 4, pp. 333-339, fig. 1).**—The hematological elements and blood values of hens receiving yeast-fermented mash as a supplement to an adequate diet over 7 and 19 mo. did not differ significantly from values of birds receiving control diets. Notwithstanding the discordance of values reported in the literature, similar results were found with 39 hens fed the control and yeast-fermented rations. Hemoglobin and differential blood counts were tabulated. These counts may be considered normal for the chick.

**Broodiness and viability, T. C. BYERLY and C. W. KNOX. (U. S. D. A.). (*Poultry Sci.*, 21 (1942), No. 4, pp. 370-373, fig. 1).**—Tabulation of the broodiness and mortality in July to October for 5 yr. among 1,369 broody and 3,199 non-broody hens of the heavy breeds in the Beltsville Research Center flock showed that there was 9.1 percent mortality among the broody and 18.8 percent among those which were nonbroody. It was suggested that the lack of the broody mechanism with its consequent flooding of the laying hen with ♀ hormone may increase the mortality by increasing the incidence of neoplasms.

**Methods and rations for fattening poultry, IV-VI, H. S. GUTTERIDGE and J. B. O'NEIL (*Sci. Agr.*, 21 (1941), Nos. 9, pp. 517-521; 10, pp. 607-612; 11, pp. 711-716).**—In continuation of the series previously noted (E. S. R., 85, p. 654), three papers are presented.

**IV. The relative value of certain cereal grains, of bone meal, and of premixing of feeds (pp. 517-521).**—In 2-week periods of crate fattening roasters, Barred Plymouth Rock cockerels made similar gains on yellow corn and ground buckwheat. Both were superior to ground barley and ground oats when fed with 5 percent bonemeal. There was no beneficial effect from additions of the bonemeal either in quality or amount of fat. The grains were fed with fresh skim milk with premixing of the rations for half of the birds of each lot.

**V. The comparative effect of hulled oats and yellow corn, of skim milk and water, and of varying temperatures (pp. 607-612).**—Fattening of 144 cockerels at temperatures ranging from 23° to 70° F. showed that corn meal-fattened birds produced only 83.5 percent of the gains made by cockerels receiving coarsely ground hulled oats. However, corn meal proved equivalent to the oats for the production of fat and grading quality. The oat-fed birds, however, produced

whiter flesh. Skim milk was superior to water for mixing mash. Differences in the temperature did not seem to be an important factor.

VI. *The comparative economy of range rearing, crate fattening, and caponizing for production of roasters* (pp. 711-716).—A summary of the costs of producing poultry by different methods showed that crate feeding was most efficient for the production of the best finished birds. The least economical procedure was direct killing of cockerels off range. Caponizing at 5 ct. per bird gave results surpassed in economy only by crate fattening.

The effect of fibre and "bulk" in the dietary on the progress of chickens and on the prevention of feather picking and cannibalism, E. J. SHEEHY and E. M. BURKE ([*Irish Free State*] *Dept. Agr. Jour.*, 37 (1940), No. 1, pp. 42-70, pls. 6).—The tendency of chickens to look for extraneous material and to pick at the feathers of other chickens became less as the percentage of bran in the ration increased and consequently the fiber content was greater. Soaking before feeding wheat bran or oats did not alter the effect on the behavior of the chicks. Feather picking was largely checked by the addition of fiber or oats to a concentrated ration, but there was no further benefit above 6 percent. For rapid fattening the best results were obtained with about 5 percent fiber. Wheat bran containing the same fiber content proved superior to oats in the prevention of feather picking. Feather picking was inhibited by lawn clippings, mangels, and molasses beet pulp. The character of the droppings seemed to be modified by the fiber in the rations. Chickens may influence the bulk in their diet by litter consumption. In this study there were conducted 11 experiments with 2-4 groups of about 40-50 White Wyandottes in each, fed for 10 weeks in confinement on rations containing 2.7-8.9 percent fiber.

Observations on the stability of vitamin D, J. C. FRITZ, W. F. ARCHER, and D. K. BARKER (*Poultry Sci.*, 21 (1942), No. 4, pp. 361-369).—Hammond et al. (*E. S. R.*, 87, p. 262) found heat to interfere with the calcification induced by vitamin D, and further study of the stability of vitamin D showed the activity to be lost when many common ingredients were mixed with poultry feeds and stored. Among the destructive feeds were oystershell, dried milk products, crystalline sugars, washed sand, and other ingredients of poultry feeds. It seemed that the destruction of vitamin D resulted from air oxidation and that protection was offered by cereals, absorbent carriers, or gases. In the studies several sources of vitamin D were employed, and the destruction by milk solids was surprising. In connection with the investigation storage of vitamin D up to 11 mo. was ascertained in different mixtures. Preservation was only possible for more than 6 mo. in feeds containing soybeans or soybean meal, which presumably contain antioxidants.

Experiments on the storage of vitamin A by growing turkeys, T. H. JUKES. (Univ. Calif.). (*Poultry Sci.*, 21 (1942), No. 4, pp. 357-360).—In three experiments turkeys on a vitamin A-deficient diet were shown to store vitamin A fed as a supplement in the liver. The liver concentration ascertained 3 days after feeding one capsule containing 0.792 gm. of shark-liver oil was sufficiently greater than that found in the liver 8 days after feeding to indicate that about 30 percent of the dose was stored. Similar results were obtained in another experiment in which one and three shark-liver oil capsules were administered to turkeys with the deficient diet. After 30 days the livers contained sufficient vitamin A to show that the single massive doses protected the birds from the symptoms of A deficiency. In another experiment turkeys were found to die from vitamin A deficiency in an average of 37.6 days when no fish oil was given, but the survival time was increased to an average of 118.9 days when one capsule of the shark-liver oil was supplied.

## DAIRY FARMING—DAIRYING

[Abstracts of papers presented at the thirty-seventh annual meeting of the American Dairy Science Association] (*Jour. Dairy Sci.*, 25 (1942), No. 8, pp. 667-731).—Following are listed the titles and authors of papers pertaining either to dairy manufacturing or dairy production, presented at the annual meeting of the association (E. S. R., 85, p. 518) held at East Lansing, Mich., June 22-25, 1942: Present-Day Techniques of Artificial Insemination, by G. W. Trimberger (pp. 671-673) (Univ. Nebr.); Storing, Packaging, and Shipping Semen, by G. W. Salisbury (p. 673) (Cornell Univ.); Simple v. Complex Rations for Dairy Cattle, by C. F. Monroe and W. E. Krauss (pp. 673-674) (Ohio Expt. Sta.); Improving Dairy-Cattle Pastures, by W. B. Nevens (pp. 677-678) (Univ. Ill.); The Ability of Yearling Heifers to Withstand Cold Temperatures, by J. R. Dice (pp. 678-679) (N. Dak. Agr. Col.); Resting Maintenance Cost in Growing Dairy Cattle, by S. Brody, H. H. Kibler, and A. C. Ragsdale (p. 679) (Mo. Sta.); The Occurrence and Importance of Still-Unidentified Nutrients in Milk and Milk Products, by A. M. Hartman and C. A. Cary (pp. 679-680), and Hydroxyamino Acids of Milk Proteins, by B. H. Nicolet, L. A. Shinn, and L. J. Saidel (p. 680) (both U. S. D. A.); Utilization of Urea by Calves Less Than Four Months of Age, by J. K. Loosli, C. M. McCay, and L. A. Maynard (pp. 680-681) (Cornell Univ.); The Feeding of Korean Lespedeza Seed as a Protein Supplement for Milk Production, by H. A. Herman and A. C. Ragsdale (pp. 681-682), and The Biological Values of Lespedeza, Alfalfa, Corn, and Milk Proteins for Growing Dairy Heifers, by E. W. Swanson, H. A. Herman, and A. C. Ragsdale (pp. 682-683) (both Mo. Sta.); A Comparison of Acetic Acid, Fed as Triacetin, With Glucose as a Nutrient in Feeds, by T. B. McManus and C. B. Bender (pp. 683-684) (N. J. Stas.); Ruminal Gases in Normal and Bloat Animals, by T. M. Olson (pp. 684-685) (S. Dak. Sta.); Further Nutritional Studies on Calf Scours, by N. S. Lundquist and P. H. Phillips (p. 685) (Univ. Wis.); Factors Affecting the Vitamin A and D Potency of Alfalfa Hay, by G. C. Wallis (pp. 685-687) (S. Dak. Sta.); The Vitamin A and Carotene Content of the Blood Plasma of Calves From Birth to Four Months of Age, by L. A. Moore (p. 687) (Md. Sta.); Vitamin C in Dairy Cattle Nutrition, by G. C. Wallis (pp. 687-688) (S. Dak. Sta.); Carotene (Provitamin A) Requirements of Dairy Cattle for Conception, by A. H. Kuhlman and W. D. Gallup (pp. 688-689) (Okla. A. and M. Col.); The Relation of Nutrition to Breeding Performance in Dairy Bulls, by I. R. Jones, J. R. Haag, and R. W. Dougherty (pp. 689-690) (Oreg. Sta.); Some Preliminary Results of Feeding Chloretone to Bulls, by E. C. Scheidenhelm, A. L. Bortree, C. F. Huffman, and C. F. Clark (pp. 690-691) (Mich. State Col.); Effect of Amphyl on Bull Sperm, by H. O. Dunn, C. E. Shuart, and O. F. Garrett (pp. 691-692) (N. J. Stas.); The Relation of Morphology to Fertility in Bull Semen, by G. W. Trimberger and H. P. Davis (pp. 692-693) (Nebr. Sta.); Studies of Respiration Rate of Dairy Bull Spermatozoa, by R. E. Ely (pp. 693-694), and The Breeding Efficiency of Dairy Bulls Used Both Artificially and Naturally, by E. R. Berousek (pp. 694-695) (both Mo. Sta.); A Comparison of Artificial v. Natural Service in Heifers When Bred to the Same Sire, by C. E. Shuart, O. L. Lepard, and J. W. Bartlett (pp. 695-696) (N. J. Stas.); The Availability of Carotene in Alfalfa Hay as Compared With Carotene in Oil, by J. H. Hilton, J. W. Wilbur, R. J. Westfall, and S. M. Hauge (p. 696) (Purdue Univ.); The Cause of the Initiation of Lactation at Parturition, by J. Meites and C. W. Turner (pp. 696-697) (Mo. Sta.); Prehypophyseal Hormone (Mammogen) Control of Mammary Development, by E. T. Gomez (pp. 698-699) (U. S. D. A.); The

Effect of Adrenalectomy on the Lactogenic Hormone and Initiation on Lactation, by J. L. Trentin, J. Meites, and C. W. Turner (pp. 699-700), The Influence of Thyroxine Upon the Stimulation of Mammary Lobule-Alveolar Growth, by J. P. Mixner (p. 700), The Effect of Thyroxine on Rate of Growth and Efficiency of Weight Increment, by M. Koger and C. W. Turner (pp. 700-701), Growth and Energy Metabolism of Thyroidectomized Cattle, by S. Brody (p. 701), and The Effect of Thyrolactin on Milk Production, Metabolism, and Growth (pp. 701-702) and The Chemical Formation of Highly Active Thyroprotein (pp. 702-703), both by E. P. Reincke (all Mo. Sta.); Methods for Prolactin Assay Including Data on the Anterior Pituitary Prolactin Content of Dairy and Beef Cattle and Female Rabbits in Several Physiological Conditions, by S. R. Hall and B. H. Nicolet (pp. 703-704), An Intravenously Active Ovulating Factor in the Juice of Corn and Oat Plants, by J. T. Bradbury and R. E. Hodgson (pp. 704-705), and Further Evidence of the Existence and Specificity of an Orally Active Sex Maturity Factor(s) in Plant Juice Preparations, by E. T. Gomez (pp. 705-706) (all U. S. D. A.); Some Possibilities for the Use of Diethylstilbestrol in Dairy Cattle, by A. A. Lewis (pp. 706-707) (Mo. Sta.); The Influence of Ascorbic Acid on the Gonadotropic Hormone Content of the Male Rat Pituitary Gland, by R. P. Reece and E. J. Weatherby (pp. 707-708) (N. J. Stas.); Vitamin D, the Parathyroid Glands, and Calcium Metabolism, by I. L. Campbell (p. 708) (Mo. Sta.); Oxygen Uptake and CO<sub>2</sub> Elimination of the Bovine Mammary Gland, by W. E. Petersen and J. C. Shaw (pp. 708-709) (Univ. Minn.); The Enzymatic Hydrolysis of Diacetin by Bovine Mammary Gland Tissue, by P. L. Kelly (p. 709) (Ark. Sta.); The Effect of the Continuous Injection of Pitocin Upon Milk and Milk Fat Production, by C. B. Knodt and W. E. Petersen (pp. 709-710) (Univ. Minn.); The Incidence and Control of Milk Fever, by C. F. Monroe, W. E. Krauss, T. S. Sutton, and W. D. Pouden (pp. 710-711), and The Blood Picture in Normal and Milk Fever Cows, by W. E. Krauss, C. F. Monroe, R. G. Washburn, J. W. Hibbs, T. S. Sutton, and N. Van Denmark (pp. 711-712) (both Ohio Sta.); Nature of the Material in Mastitic Milk Responsible for the Whiteside Reaction, by H. O. Dunn, J. M. Murphy, and O. F. Garrett (pp. 712-713) (N. J. Stas.); The Value of Tyrothricin (Gramicidin) in a Herd Mastitis Control Program, by C. S. Bryan, R. E. Horwood, and C. F. Clark (p. 713) (Mich. Sta.); Experiences With Lactovaccine in the Control of Mastitis, by C. F. Clark, C. S. Bryan, and R. E. Horwood (pp. 713-714) and Mastitis and Herd Practices in the College Dairy Herd, by R. E. Horwood, C. F. Clark, and C. S. Bryan (pp. 714-715) (both Mich. State Col.); The Effect of Acidity and Temperature on the Growth of *Oospora luctis* Cultures, by E. R. Garrison (pp. 716-717), and Various Treatments Which Affect the Growth of Mold Mycelia in Cream and Resultant Butter, by J. E. Edmondson and W. H. E. Reid (pp. 717-718) (both Mo. Sta.); The Development of a Positive Phosphatase Test on Refrigerated Pasteurized Cream, by F. W. Barber and W. C. Frazier (p. 718) (Univ. Wis.); The Keeping Quality of Cream Pasteurized at 165° F. for 30 Minutes, Variously Treated, and Stored at 0° F., by E. S. Guthrie (pp. 718-719), and The Keeping Quality of Unsalted Butter Made From Sweet Cream Pasteurized at 165° F. for Thirty Minutes and Stored at 0° F. and 32° F., by C. N. Stark, E. S. Guthrie, and J. J. R. Campbell (p. 719) (both Cornell Univ.); Some Observations Concerning the Ascorbic Acid Content of Evaporated Milk, by D. V. Josephson and F. J. Dean (pp. 719-720) (Pa. Sta.); Control and Verification of Vitamin D in Milk, by M. J. Dorcas (pp. 720-721); A Voltammetric Method for Measuring the Concentration of Dissolved Oxygen in Dairy Products, by G. H. Hartman and O. F. Garrett (p. 721) (N. J. Stas.); Studies of the

**Mechanisms of Oxidized Flavor**, by W. C. Brown and F. C. Olson (pp. 721-722) (W. Va. Sta.); **Relation of Dissolved Oxygen to Certain Oxidation Reactions in Milk**, by G. H. Hartman and O. F. Garrett (pp. 722-723) (N. J. Stas.); **The Role of the Oxidase Producing Bacteria in the Development of Oxidized Flavor in Milk**, by J. F. Cone and C. J. Babcock (p. 723) (U. S. D. A.); **Bacteriological Studies on Creamery Water Supplies**, by R. T. Corley and B. W. Hammer (pp. 723-724) (Iowa Sta.); **Sensory Adaptation as a Factor in the Judging of Dairy Products for Flavor**, by S. T. Coulter (pp. 724-725) (Univ. Minn.); **A Quick, Colorimetric Method for Estimating the Quality of Butter**, by E. S. Guthrie and G. Knaysi (p. 725) (Cornell Univ.); **Forewarming Temperature of Plain Condensed Skimmilk and Properties of the Resulting Ice Cream**, by J. R. Clinch and J. H. Erb (pp. 725-726) (Ohio State Univ.); **Relation of Different Mix Compositions and Methods of Processing to the Texture, Structure, and Stability of Ice Cream**, by C. W. Decker and W. H. E. Reid (pp. 726-727) (Mo. Sta.); **The Gases Evolved by Cheddar and Limburger Cheese**, by F. L. Dorn and A. C. Dahlberg (p. 727) (N. Y. State Sta.); **The Preparation of Crystalline Rennin**, by C. L. Hankinson (pp. 727-728); **The Use of Rennet Paste in Romano-Type Cheese**, by C. A. Phillips, G. A. Richardson, and N. P. Tarassuk (pp. 728-729) (Univ. Calif.); **Studies Relating to the Canning of Pasteurized Milk Cheese**, by A. C. Dahlberg and J. C. Marquardt (p. 729) (N. Y. State Sta.); **Comparative Studies on Cheddar Cheese Prepared With Starter and With Certain Pure Cultures**, by D. D. Deane and T. G. Anderson (pp. 729-730) (Pa. State Col.); and **General Action in Cheese of an Enzyme Preparation From Chicken Stomach**, by F. J. Babel, G. F. Stewart, and B. W. Hammer (pp. 730-731) (Iowa Sta.).

[**Investigations in dairy production by the Missouri Station**] (*Missouri Sta. Bul.* 444 (1942), pp. 34-36, 37-38, 39, 42-43, 44, 45-46, 47).—Results are briefly reported by A. C. Ragsdale, H. A. Herman, N. P. Ralston, V. E. Peterson, C. W. Turner, E. P. Reineke, C. W. McIntyre, S. Brody, L. E. Washburn, E. R. Garrison, W. H. E. Reid, and W. S. Arbuckle of investigations on the influence of rations and management practices on the rate of growth and milk production of dairy heifers; factors influencing the solids-not-fat content of milk; precursors of milk constituents in the blood; the influence of roughage feeding on milk production; basal energy metabolism of lactating dairy cattle, goats, and rats; growth and metabolism of total and partial thyroidectomized dairy calves; growth, milk production, energy metabolism, and energetic efficiency of milk production in goats; the influence of fasting and refeeding on milk production, heat production, and respiratory quotient in dairy cattle and goats; fluorescent bacteria in dairy products; and the keeping quality of high serum solids ice cream.

[**Production of dairy cattle and dairy products by the Texas Station and cooperating agencies**] (*Texas Sta. Rpt.* 1941, pp. 26-29).—Brief results are presented by O. C. Copeland, G. S. Fraps, F. E. Hanson, C. N. Shepardson, A. L. Darnell, G. R. Fuller and W. S. Arbuckle on requirements of vitamin A for conception in dairy cattle; relation of temperature exposures to quality of southern short-cure Cheddar cheese; relation of manufacture and other conditions to quality of butter; dried citrus peel and pulp, dehydrated sweetpotato pulp, ground shelled corn, and high and low protein rations for lactating dairy cows; legume v. non-legume dry roughage for dairy cattle; milk substitute v. skim milk for dairy calves; and variations in the normal composition of milk produced in Texas.

**Adequate feeding highly important in dairies of State**, J. S. Moore (*Miss. Farm Res.* [Mississippi Sta.], 5 (1942), No. 8, p. 6).—Savings in feed effected by reducing the consumption of dairy cows were more than offset by the reduced value of the milk and products produced.

**Comparative palatability of some cereal pastures**, A. O. SHAW and F. W. ATKESON. (Kans. State Col.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 503-506).—Six cows having free access to equal areas of Balbo rye, common rye, wheat, and barley grazed an average of 52, 24, 18, and 6 percent of the time on these respective crops. The preference for Balbo rye and the dislike for barley was uniform for all cows.

**A comparison of legume hays for milk production**, C. C. HAYDEN (*Ohio Sta. Bul.* 631 (1942), pp. [1]+26, figs. 14).—Groups of three 7-11-month-old Holstein-Friesian heifers each were fed continuously on ground shelled corn with alfalfa, clover, and soybean hay, respectively. Four yr. or more results with each of the cows showed clover protein to be fully equal to alfalfa protein for milk production, but the differences were scarcely significant. During the first 10 mo. after calving the clover group consumed the most feed and the alfalfa group the least. Those on the clover hay required the least protein per unit of milk produced. The restricted rations are considered responsible for the excessive consumption of nutrients per unit of milk produced. Supplementing these rations with bonemeal at the rate of 2 oz. per head daily increased production about 600 lb. of milk and 20 lb. of fat per year. No single kind of legume roughage should be fed exclusively over long periods of time. No difficulties in reproduction during the four lactations were apparent, but the livers of the three alfalfa-fed cows and one soybean-fed cow were in bad condition when the animals were ultimately slaughtered. When rations were made more adequate after the completion of four lactations, the milk production was improved.

**The nutritive value of alfalfa hay.**—I, Cystine as a supplement to an all-alfalfa hay ration for milk production, C. F. HUFFMAN and C. W. DUNCAN. (Mich. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 507-515).—Employing a method for studying the deficiencies of alfalfa hay as previously reported (E. S. R., 80, p. 94), the addition of 20 gm. of *L*-cystine per day to an alfalfa hay ration for each of four cows did not increase milk production significantly, although tending to check the rapid decline in milk and fat production which was in progress on the alfalfa ration. The addition of 40 gm. of *L*-cystine per day to the ration of one cow produced a decrease in hay consumption and a sharp drop in milk and fat production but an increase in body weight. The replacement of part of the alfalfa hay with isocaloric amounts of corn significantly increased milk and fat production over the initial alfalfa feeding period and the subsequent cystine feeding period, thus indicating that cystine is not the first deficiency of an all-alfalfa hay ration.

**A statistical study of the influence of moisture and acidity on the palatability and fermentation losses of ensiled hay crops**, T. E. WOODWARD and J. B. SHEPHERD. (U. S. D. A.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 517-523).—Data obtained over a number of years on the palatability and fermentation losses in experimental lots of silage prepared from various grasses and legumes were subjected to statistical analysis. When compared on the basis of moisture content without reference to other treatment, the silages of relatively low moisture content (average 45 percent) were better in odor and palatability than those from comparable groups but of higher moisture content (average 70.6 percent). Losses in dry matter and protein were not significantly influenced by the moisture content, while preservation of carotene was significantly better in the high-moisture lots. Silages treated with molasses (average pH 4.36) were significantly more palatable than comparable lots prepared without molasses (average pH 4.76). There was little difference in the loss of nutrients in the treated and untreated lots. Silages treated with hydrochloric and sulfuric acids (average pH 3.66) were less palatable than un-

treated silages from the same crops (average pH 5.18). High acidity favored the conservation of nutrients in the silo, the difference being highly significant in the case of carotene but of doubtful significance for dry matter and protein. Practical recommendations are drawn from these findings.

**Studies on the chemical composition of the blood of dairy cattle.—III, The normal concentration of inorganic phosphorus in the whole blood of dairy cattle and factors affecting it, A. H. VANLANDINGHAM, H. O. HENDERSON, and G. A. BOWLING. (W. Va. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 537-548, figs. 2).—**Continuing this series of investigations (E. S. R., 76, p. 681), inorganic phosphorus was determined in over 600 composite samples of whole blood from cows and heifers in normal states of health and nutrition, using a previously described method for preparing the composite samples (E. S. R., 68, p. 809). Under the nutritive conditions employed, age was found to be the most important factor affecting the inorganic phosphorus of the blood. In general, the concentration increased up to 7 or 8 mo. of age and then gradually declined with advancing age. Pregnant heifers showed a lower concentration than unbred heifers of approximately the same age. There was no significant change during the first lactation, but there was a strong tendency for cows to show low values during the late weeks of the second gestation and the first 2 or 3 mo. of the second lactation. A similar trend was also followed near the end of the third gestation and for a month or more at the beginning of the third lactation. Season of the year or the fact that heifers were confined to the barn continuously or permitted to run outside in favorable weather had no apparent effect on inorganic phosphorus of the blood. However, for cows in the first lactation the concentration tended to be lower during the winter and early spring than during the summer and early fall.

**Blind halves in a goat's udder, C. W. TURNER and E. R. BEROUSEK. (Mo. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 549-555, figs. 3).—**This case history concerns a milk goat which failed to give milk after parturition. Examination revealed that both udder halves were blind, although the gland tissue was capable of secreting milk. It is indicated that the condition is probably due to an inherited or developmental defect rather than to the development of an overgrowth of connective tissue caused from mastitic infection.

**Seventy years of selection for conformation in dairy cattle, A. A. LEWIS. (Univ. Mo.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 489-501).—**A detailed analysis of the breeding involved in 5,180 cases of Commended and Highly Commended Jersey Island cattle.

**Factors affecting the passage of liquids into the rumen of the dairy calf.—II, Elevation of the head as milk is consumed, G. H. WISE, G. W. ANDERSON, and P. G. MILLER. (S. C. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 529-536, figs. 2).—**Continuing this series (E. S. R., 82, p. 240), information gained in anatomical studies and feeding experiments is presented. From a study of the relationship of the various organs in the young calf, it is concluded that "from a purely anatomical viewpoint it is difficult to relate the positions of the head and neck of the calf to the functioning of the esophageal groove." Repeated observations were made on the frequency with which milk entered the rumen when calves consumed milk from a rubber nipple and from an open pail, both at the floor level and from an elevated position (pail adjusted to bring the poll on a level with the withers). It was found that, irrespective of the feeder level, milk seldom entered the rumen when consumed from a nipple but frequently entered when consumed from an open pail. Apparently the transmission of stimuli regulating the esophageal groove is unaffected by the positions of the head and neck.

**The nutrition of calves: A review**, E. S. SAVAGE and C. M. McCAY. (Cornell Univ.). (*Jour. Dairy Sci.*, 25 (1942), No. 7, pp. 595-650).—A comprehensive review, with 280 references to the literature.

**Carotene in calf nutrition**, H. A. KEENER, S. I. BECHDEL, N. B. GUERRANT, and W. T. S. THORP. (Pa. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 7, pp. 571-583, figs. 3).—Continuing this line of investigation (E. S. R., 83, p. 99), data are presented to indicate that the minimum carotene requirement for growth and well-being of dairy calves is dependent upon environmental temperature. Within a temperature range of 50°-70° F., about 12  $\mu$ g. of carotene per pound of body weight daily appeared adequate, which essentially confirms earlier findings at the Pennsylvania Station, but during severe winter weather the minimum requirement increased to more than double this amount. The observed decline in blood carotene and blood vitamin A values during cold weather substantiated this increased requirement, and the severity of the gross and microscopic pathology agreed closely with the degree of deficiency observed before the calves were slaughtered. It is suggested that such histopathological changes may exist in calves raised in regions where roughage of poor quality is fed, and that these conditions may affect the productive and reproductive efficiency of the dairy cattle of such regions.

[Investigations of dairy manufacturing by the Nebraska Station] (*Nebraska Sta. Rpt.* [1941] pp. 55, 57-58).—Brief results are presented by L. K. Crowe, P. A. Downs, and C. H. Sanders on investigations on the characteristics of ice cream and ice cream mixes from several sources; and milk quality as affected by the individual cow.

**A method for surface area measurement of milk bottles**, W. D. BATEN and P. S. LUCAS. (Mich. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 8, pp. 663-665, fig. 1).—The approximate area of the outer and inner surface of a milk bottle was calculated by dividing the bottle into small sections, as described, each section representing a frustum of a cone whose surface may be calculated by formulas presented. The combined outside and inside surface area of a quart bottle of the design used in this study was 200.4 sq. in., which was 1.62 times greater than that of a pint bottle and 2.43 times greater than that of a half-pint bottle.

**Effect of homogenization on the curd tension, digestibility, and keeping quality of milk**, C. J. BABCOCK (*U. S. Dept. Agr., Tech. Bul.* 832 (1942), pp. 24, fig. 1).—A study was made of the effects of various conditions including pressure of homogenization, temperature, and other conditions on the curd tension and keeping quality of milk. The pressure of 2,500 lb. was found to give the maximum reduction in curd tension. Higher temperatures lowered the curd tension except when homogenization followed pasteurization. Homogenization at the pasteurizing temperature caused a slightly higher curd tension than homogenization at temperatures either below or above pasteurization. Two stages of homogenizers gave the same reduction in curd tension as single-stage homogenizers. Mixing homogenized soft-curd milk with unhomogenized milk lowered the theoretical curd tension only slightly for the mixture. Boiled milk and homogenized milk were more readily but not more completely digested than raw milk. It seemed quite evident that homogenized milk formed smaller curds than unhomogenized milk in the presence of artificial gastric juice in digestion in vitro. About 10 times as much copper was required to produce oxidized flavor in homogenized milk as in similar milk before homogenization. However, homogenized milk required only approximately half as long exposure to sunlight as unhomogenized milk to produce a sunlight-induced oxidized flavor. Homogenized and unhomogenized milk were equal in keeping quality when

stored at low temperature. No significant differences between the two milks were noted from the bacteriological standpoint or in rate of development of acid.

**Clean and cold milk**, R. S. BREED (*New York State Sta. Cir. 93, rev. (1942), pp. 4, figs. 4*).—A revision (E. S. R., 57, p. 668) of directions for producing clean milk and keeping it free from dirt and bacterial contamination.

**Influence of a film yeast, *Candida krusei*, on the heat resistance of certain lactic acid bacteria grown in symbiosis with it**, H. J. PEPPLER and W. C. FRAZIER. (Wis. Expt. Sta.). (*Jour. Bact.*, 43 (1942), No. 2, pp. 181-191, figs. 3).—A more detailed report of research previously noted (E. S. R., 85, p. 662).

**Observations on the rate of growth of *Oospora lactis***, H. B. MORRISON and H. W. HILL. (Ky. Expt. Sta.). (*Jour. Bact.*, 43 (1942), No. 2, p. 271).—When spores of *O. lactis* were streaked on standard agar and incubated at room temperature (70°-75° F.), the average time required for 10 colonies to produce 100 $\mu$ , 500 $\mu$ , and 1,000 $\mu$  of mycelia was 10.71, 14.21, and 15.28 hr., respectively. At 58° comparable lengths were attained in 44.3, 59.0, and 65.7 hr., respectively. However, after the mycelium had reached a length of 600 $\mu$  growth was practically as rapid at 58° as at 70°-75°.

**Control of mold in farm cream supply** (*Arkansas Sta. Bul. 417 (1942), pp. 9-10*).—Studies by T. J. Claydon and L. B. Schweiger showed that the mold counts of experimental butter were generally proportional to the mold content of the cream, which might be modified by a variety of conditions.

**The evaluation of flavor defects of butter, cheese, milk, and ice cream as designated by dairy products judges**, G. M. TROUT, P. A. DOWNS, M. J. MACK, E. L. FOUTS, and C. J. BABCOCK (*Jour. Dairy Sci.*, 25 (1942), No. 7, pp. 557-569).—Another detailed report by the committee of the American Dairy Science Association on judging dairy products (E. S. R., 82, p. 675) presents results of the flavor scoring of butter, cheese, milk, and ice cream by 47 trained judges and a panel of 5 selected judges for each product.

**Methods for manufacturing acid-precipitated casein from skim milk**, revised by E. O. WHITTIER (*U. S. Dept. Agr. Cir. 279, rev. (1942), pp. 30, figs. 6*).—This is a revision of an earlier edition (E. S. R., 70, p. 524). General directions are presented for the manufacture of acid-precipitated casein of high grade. The establishment of a suitable plant for this purpose is described. Fundamental steps in the manufacture and likelihood of defects are pointed out.

**The use of ultraviolet rays in the cheese factory and storage room**, F. R. SMITH. (Univ. Calif.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 525-528).—Six 15-w. low-pressure mercury-vapor lamps, when placed in a cheese-curing room approximately 15 by 12 by 11 ft. in size, with forced-air circulation, failed to show any control of the undesirable surface-mold formation in the room. Small-scale, carefully controlled experiments confirmed this finding. Direct irradiation of the cheese surface, both before and after paraffining, with a lamp 10 in. from the cheese failed to prevent mold growth on the cheese surface.

**A study of the coliform group in ice cream**, H. J. FOURNELLE and H. MACY. (Minn. Expt. Sta.). (*Jour. Dairy Sci.*, 25 (1942), No. 6, pp. 475-487, fig. 1).—Examination of 69 samples of factory-packed ice cream showed a range in coliform counts (in terms of most probable numbers) from 0 to 9,180 per cubic centimeter, and in 80 scoop or dipper samples a range from 0 to 101,000. It is indicated on the basis of these findings that factory-packed ice cream should contain less than 10 coliform organisms per cubic centimeter. Predominating species in the factory-packed and scoop samples, respectively, were *Aerobacter cloacae* 29.5 and 88.2 percent, *A. aerogenes* 23.8 and 18.0, *Escherichia freundii* 27.8

and 28.1, *E. coli* 5.3 and 1.1, and *E. coli neapolitana* 3.1 and 5.6 percent. Non-coliform species isolated from these samples constituted 9.7 and 6.8 percent of the total number in the respective samples.

## VETERINARY MEDICINE

**Keeping livestock healthy: Yearbook of Agriculture 1942** (*U. S. Dept. Agr. Yearbook 1942*, pp. XIII+[1]+1276, *figs.* 196).—This volume is the seventh in this series (*E. S. R.*, 86, p. 293). Following a foreword by C. R. Wickard, and a summary by G. Hambidge (pp. 1–107), the volume is subdivided into nine parts, as follows:

**Part 1. *Fundamentals of disease and insect control.***—Losses Caused by Animal Diseases and Parasites, by J. R. Mohler, A. E. Wight, W. M. MacKellar, and F. C. Bishopp (pp. 109–116); Causes of Disease, by H. W. Schoening, B. Schwartz, W. T. Huffman, and L. L. Madsen (pp. 117–137); Protective Mechanisms Against Disease, by A. Elchhorn, M. P. Sarles, and N. R. Ellis (pp. 138–154); The Endocrine Glands in Health and Disease, by A. H. Frank (pp. 155–166); The Relation of Genetics to Disease, by H. C. McPhee (pp. 167–174); Artificial Insemination and Disease Control, by A. H. Frank and R. W. Phillips (pp. 175–178); Disinfection and Disinfectants, by F. W. Tilley (pp. 179–187); How Research Aids in Disease Control, by J. R. Mohler (pp. 188–202); Origin and Spread of Important Insect Pests of Animals, by H. H. Stage and J. A. Hyslop (pp. 203–208); Regulatory Activities in Animal-Disease Control, by A. W. Miller, S. O. Fladness, A. E. Wight, D. I. Skidmore, E. C. Joss, and H. E. Moskey (pp. 209–226); and Fighting Disease With Knowledge, by D. S. Burch (pp. 227–235).

**Part 2. *Important general diseases common to several species.***—Tuberculosis and Its Eradication, by A. E. Wight, E. Lash, H. M. O'Rear, and A. B. Crawford (pp. 237–249); Anthrax, by C. D. Stein (pp. 250–262); Foot-and-Mouth Disease, by J. R. Mohler and J. Traum (pp. 263–275) (coop. Univ. Calif.); Parasites and Insects Affecting Livestock, by B. Schwartz and F. C. Bishopp (pp. 276–294); Bacterial Infections and Parasites Common to Man and Animals, by G. W. Stiles and J. T. Lucker (pp. 295–312); The Screwworm and Blowfly Problem, by E. C. Cushing and D. C. Farman (pp. 313–322); Nutritional Diseases of Farm Animals, by L. L. Madsen (pp. 323–353); and Plants Poisonous to Livestock, by W. T. Huffman and J. F. Couch (pp. 354–373).

**Part 3. *Common diseases and parasites of horses and mules.***—Equine Encephalomyelitis, by L. T. Giltner and M. S. Shahan (pp. 375–391); Equine Infectious Anemia, or Swamp Fever, by C. D. Stein (pp. 392–401); Periodic Ophthalmia of Horses, by L. O. Mott and H. R. Seibold (pp. 402–408); Glanders (pp. 409–412) and Dourine (pp. 413–416), both by T. W. Cole; Miscellaneous Diseases of Equines, by L. O. Mott, M. S. Shahan, L. T. Giltner, and A. H. Frank (pp. 417–458); Internal Parasites of Horses and Mules, by A. O. Foster (pp. 459–475); Mange in Equines, by M. Imes (pp. 476–481); Horse Bots and Their Control, by F. C. Bishopp and B. Schwartz (pp. 482–491); and Some Insect Pests of Horses and Mules, by F. C. Bishopp (pp. 492–500).

**PART 4. *Diseases and parasites of cattle.***—Brucellosis of Cattle, by E. Lash and H. M. O'Rear (pp. 501–511); Johne's Disease, by B. T. Simms, W. M. Mohler, and H. W. Johnson (pp. 512–517); Bovine Mastitis, by W. T. Miller (pp. 518–522); Blackleg, by W. M. Mohler (pp. 523–525); Shipping Fever, or Hemorrhagic Septicemia, by C. D. Stein (pp. 526–532); Milk Fever (pp. 533–536) and Paint Poisoning in Cattle (pp. 642–644), both by L. T. Giltner; Miscellaneous Diseases of Cattle, by G. T. Creech, R. L. Knudson, and O. L. Osteen (pp. 537–564); Cattle

Coccidiosis, by D. C. Boughton (pp. 565-571); Cattle Tick Fever, by W. M. MacKellar (pp. 572-578); Anaplasmosis—a disease of cattle, by G. W. Stiles (pp. 579-587); Cattle Scab and Its Control, by R. Snyder (pp. 588-592); Tapeworm and Roundworm Parasites of Cattle, by D. A. Porter (pp. 593-604); Bovine Genital Trichomoniasis, by G. Dikmans (pp. 605-611); Cattle Grubs, or Heel Flies, by E. W. Laake, F. C. Bishopp, and R. W. Wells (pp. 612-619); The Stablefly, by F. C. Bishopp and E. W. Laake (pp. 620-625); The Horn Fly, by W. G. Bruce (pp. 626-630); Cattle Lice, by O. G. Babcock and E. C. Cushing (pp. 631-635); Cattle Injuries Caused by Ingesting Foreign Objects, by L. T. Hiltner and J. A. Patton (pp. 636-641); and Nutritional Diseases of Cattle, by L. L. Madsen (pp. 645-672).

Part 5. *Diseases and parasites of swine*.—Hog Cholera, by C. N. McBryde (pp. 673-685); Swine Erysipelas, by H. W. Schoening, C. G. Grey, and O. L. Osteen (pp. 686-694); Enteritis of Swine (pp. 695-702) and Swine Influenza (pp. 703-713), both by C. N. Dale; Miscellaneous Diseases of Swine, by G. T. Creech (pp. 714-728); Brucellosis (Infectious Abortion) in Swine, by A. Eichhorn (pp. 729-733); Mange of Swine, by M. Imes (pp. 734-740); Hog Lice, by O. G. Babcock and E. C. Cushing (pp. 741-744); Internal Parasites of Swine, by L. A. Spindler (pp. 745-786); Trichinosis, by B. Schwartz (pp. 787-802); Salt Tolerance and Salt Poisoning of Swine, by N. R. Ellis (pp. 803-809); and Nutritional Diseases of Swine, by L. L. Madsen (pp. 810-827).

Part 6. *Diseases and parasites of sheep and goats*.—Foot Rot of Sheep (pp. 829-834); Sore Mouth of Sheep and Goats (pp. 835-838); Miscellaneous Diseases of Sheep and Goats (pp. 839-858), and Pregnancy Disease of Sheep (pp. 923-926), all by M. S. Shahan; Internal Parasites of Sheep and Goats, by G. Dikmans and D. A. Shorb (pp. 859-903); Sheep Scab and Its Control, by A. W. Miller (pp. 904-911); Sheep Ticks, by M. Imes and O. G. Babcock (pp. 912-916); Goat Lice, by O. G. Babcock and E. C. Cushing (pp. 917-922); and Lung Disease of Sheep, by G. T. Creech (pp. 927-929).

Part 7. *Common diseases and parasites of poultry*.—Pullorum Disease (pp. 931-943), Fowl Pox (Diphtheria) (pp. 977-986), and Miscellaneous Diseases of Poultry (pp. 993-1006), all by H. Bunya; Fowl Paralysis and Other Forms of the Avian Leukosis Complex, by C. A. Brandly, N. F. Waters, and W. J. Hall (pp. 944-962); Respiratory Diseases of Chickens and Turkeys, by W. J. Hall (pp. 963-976); Psittacosis, by K. F. Meyer (pp. 987-992) (coop. Univ. Calif.); Internal Parasites of Poultry, by E. E. Wehr and J. F. Christensen (pp. 1007-1040); Coccidiosis of the Chicken, by J. F. Christensen and E. A. Allen (pp. 1041-1047); Poultry Lice and Their Control (pp. 1048-1054); Poultry Mites (pp. 1055-1061); The Fowl Tick (pp. 1062-1067), and The Pigeon Fly (pp. 1072-1074), all by F. C. Bishopp; Bedbugs as Pests of Poultry, by E. A. Back and F. C. Bishopp (pp. 1068-1071); and Nutritional Diseases of Poultry, by H. W. Titus (pp. 1075-1107).

Part 8. *Common diseases and parasites of dogs and cats*.—Rabies and Its Control, by H. W. Schoening (pp. 1109-1123); Distemper of Dogs (pp. 1124-1129), Feline Enteritis (pp. 1130-1133), Miscellaneous Diseases of Dogs and Cats (pp. 1134-1149), Running Fits (Fright Disease) (pp. 1193-1195), and Nonparasitic Skin Diseases of Dogs and Cats (pp. 1196-1202), all by C. D. Stein; Internal Parasites of Dogs and Cats, by E. W. Price and P. D. Harwood (pp. 1150-1173); Mange of Dogs, by E. W. Price and F. C. Bishopp (pp. 1174-1179); Ticks Affecting Dogs, by F. C. Bishopp and C. N. Smith (pp. 1180-1187); Fleas, by F. C. Bishopp (pp. 1188-1192); and Nutritional Diseases of Dogs and Cats, by I. P. Earle (pp. 1203-1215).

**Part 9. Wildlife diseases and parasites.**—Diseases of Wildlife and Their Relationship to Domestic Livestock (pp. 1217-1225), Diseases of Farm-Raised Game Birds (pp. 1226-1231), and Diseases of Fur Animals (pp. 1232-1238), all by J. E. Shillinger.

Many of the contributions include references to the literature cited.

[**Work in animal pathology and parasitology by the Missouri Station**] (*Missouri Sta. Bul.* 444 (1942), pp. 46-47, 88-92).—Reports of progress (E. S. R., 87, p. 108) of work by H. A. Herman, R. G. McCarty, F. J. Olney, A. J. Durant, H. C. McDougale, C. Elder, and O. S. Crisler are given on the effect of sulfanilamide on udder streptococci of dairy cows; leucosis in fowls; heat therapy for blackhead disease in turkeys; cecal ablation for the control of blackhead in turkeys; fowl paralysis; pathology and comparative damage done by stomach, nodular, and tapeworms in sheep; transmission of Bang's abortion infection from swine to cattle under pasture conditions; toxemia in sheep; comparative results obtained with the tube agglutination and rapid or plate tests on low reacting sera in Bang's disease testing; low agglutination reactions in unbred virgin gilts; and a study of cattle that consistently give low titer reactions to the Bang agglutination test.

[**Work with animal diseases by the Nebraska Station**] (*Nebraska Sta. Rpt.* [1941], pp. 65-68).—The progress (E. S. R., 86, p. 87) of work with anti-swine-erysipelas serum, by L. Van Es and J. F. Olney, and hog cholera immunity is briefly reported upon.

[**Work in animal pathology and parasitology by the Texas Station**]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 91-94, 94-95, 110-112, 156-159).—Reports of progress (E. S. R., 86, p. 243) of work at the station and substations by H. Schmidt, R. D. Turk, O. C. Copeland, C. N. Shepardson, F. P. Mathews, A. L. Darnell, P. L. Piercy, C. A. Woodhouse, J. J. Reid, J. B. Boughton, and W. T. Hardy are given on infectious bovine abortion, loco weed poisoning, jimmies in sheep and goats, poisonous plants in the Davis Mountains, mastitis investigations, a new disease of cattle characterized by a nervous disorder, hemoglobinuria, photosensitization of animals manifested by widespread inflammation of the skin, anaplasmosis in cattle, the relationship of the Gulf Coast tick to screwworm infestation in livestock and methods for its control, keratitis of cattle, investigation of gastrointestinal parasites in cattle, soremouth (contagious ecthyma) of sheep and goats, stomach worms (*Haemonchus contortus*) of sheep and goats, hard yellow livers of sheep and cattle, sporadic bovine encephalomyelitis, infectious enterotoxemia (milk colic) of lambs, and feeding trials to determine toxicity of *Acacia berlandieri* and other suspected plants.

**Studies on the nature of Anaplasma**, J. C. LOTZE and M. J. YIENGST. (U. S. D. A.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 312-320, figs. 17).—"The order and regularity of the occurrence of the different-sized and morphologic types of anaplasms in the course of anaplasmosis suggest that the anaplasma is a parasite which invades the erythrocyte, undergoes a period of growth, and eventually undergoes multiple division resulting in the production of eight small, spherical bodies in each anaplasma. The rapid disappearance of the large, irregular-shaped anaplasms from the blood stream of the host animal suggests that anaplasms are in some way responsible for the destruction of the erythrocytes containing them. Evidence from tabulations of infected erythrocytes based on the size of the anaplasms indicates that an infected erythrocyte does not remain in the blood stream of the host longer than 3 to 4 days. The occurrence of a certain extra-erythrocytic body during the anaplasma phase of the disease and the attachment of this structure to mature erythrocytes only, usually in a mar-

ginal position on the erythrocytes, suggests that this form constitutes the stage of the parasite which enters the erythrocyte and develops into the anaplasma."

**Phenol as a preservative for equine encephalomyelitis brain tissue,** R. GWATKIN (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), No. 7, pp. 191-196).—In the experimental work reported the encephalomyelitis virus was found to be active in the brains of two guinea pigs, the skinned heads of which had been stored in 1 percent phenolsaline, one at room temperature and one in the refrigerator, for 6 days. Brains from normal guinea pig heads stored for 3 and 4 days at 37° C. in phenolglycerine and phenolsaline solutions were innocuous for guinea pigs by intracerebral injection. The controls in glycerine and saline solutions were putrid at that time. There was some suggestion of lowered virus activity in the higher dilutions of brain suspension exposed to 1 percent phenol for 2 and 5 days, as manifested by delay in the death of injected animals. Intracerebral injections of 0.2 cc. of brain suspension containing 1 percent phenol caused the death of several guinea pigs. Replacements which received the same dose all lived. Two halves of a guinea pig brain preserved in glycerine and phenolglycerine solutions revealed no appreciable difference in virulence after 6 days at room temperature. The unskinned heads of two gophers in buffered glycerine solution, with and without phenol, both became putrid at 37°. Phenol in a concentration of 0.5 percent did not prevent the development of bacteria in brains when the heads were held for 4 days at 37°. Ice is considered to be the best method of preserving brains or heads for examination for the presence of equine encephalomyelitis virus, but if this is not obtainable these experiments suggest that 1 percent phenol might safely be added to buffered glycerine solution or saline for the preservation during transport of skinned heads of small animals and birds or for brains or portions of brains of large animals.

**John's disease in Arkansas** (*Arkansas Sta. Bul.* 417 (1942), pp. 10-12).—A brief account of work by Eveleth and Gifford with this disease in Arkansas, where it was discovered in sheep (*E. S. R.*, 87, p. 716).

**Infectious laryngotracheitis, its diagnosis and control,** C. H. WEAVER (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), No. 4, pp. 107-115, figs. 5).

**Further studies on the histology of the bovine kidney,** R. F. LANGHAM, R. T. INGLE, and E. T. HALLEMAN. (*Mich. Expt. Sta.*). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 260-267, figs. 9).—A report of further work (*E. S. R.*, 81, p. 713).

**The toxicity of foliage of *Aleurites fordii* for cattle,** M. W. EMMEL, D. A. SANDERS, and L. E. SWANSON. (*Fla. Expt. Sta.*). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 785, pp. 136-137).—Report is made of the loss from a herd of 44 well-fed purebred Hereford and Aberdeen-Angus cattle of 14 that died as a result of eating the foliage from branches of the tung oil tree (*A. fordii*) that had been discarded in their pasture. Two heifers force-fed macerated tung leaves (1.25 and 1.75 lb., respectively) and 1 cow which voluntarily ate picked foliage developed symptoms of poisoning. The outstanding symptoms of poisoning by tung tree leaves in cattle consisted of hemorrhagic diarrhea which usually became more or less watery, loss of appetite, listlessness, unthriftiness, and emaciation. Symptoms occurred 3 to 5 days after exposure and 1 animal lingered 3 weeks before dying. The most pronounced post-mortem lesions were hemorrhagic gastroenteritis and passive congestion of the visceral organs. Granular degeneration with small scattered areas of necrosis were predominant in the tissues of the visceral organs, particularly of the liver, kidneys, and intestines.

**Incidence of gastrointestinal nematodes of cattle in the southeastern United States,** D. A. PORTER. (*U. S. D. A.*). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 304-307, 308).—Report is made of partial or complete examinations of

the abomasum, small intestine, and large intestine of 84 cattle, ranging in age from 1 to 18 mo., from Alabama, Georgia, Florida, Mississippi, and Louisiana. In some instances only the stomach was examined and in others only the intestine. Fifteen species of nematodes representing 10 different genera were recovered. The numbers of specimens were counted or estimated in most cases. The percentage incidence of the various species was: *Cooperia punctata* 91, *Haemonchus contortus* 83, *Ostertagia ostertagi* 74, *Bunostomum phlebotomum* 62, *Oesophagostomum radiatum* 59, *Trichostrongylus axei* 47, *Trichuris* spp. (*T. ovis* and *T. discolor*) 44, *C. pectinata* 32, *Strongyloides papillosus* 21, *H. similis* 18, *Nematodirus helvetianus* 15, *C. oncophora* 11, *Trichostrongylus colubriformis* 9, and *Capillaria longipes* 7.

**Sporadic bovine encephalomyelitis: Filtration of the causal agent, T. W. STEARNS and S. H. McNUTT.** (Iowa State Col.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 253-257.)—Report is made of the results of studies on the filtration of the agent of sporadic bovine encephalomyelitis. Of 34 filtration trials with Berkefeld N or V candles, 15 filtrates were found to contain sufficient agent to infect guinea pigs, 3 were questionable, and the remainder were negative. Assays in chick embryos before and after filtration indicated an almost complete loss of the causal agent during filtration. Assays of unfiltered material killed embryos in dilutions as high as 1:1,000,000,000. Evidence is presented that the addition of suspensions of liver and spleen of the normal guinea pig to filtrates increases the possibility of infecting guinea pigs with filtrates of the causal agent.

**The relation of flies (*Musca domestica* Linnaeus) to the transmission of bovine mastitis, H. E. EWING, JR.** (Univ. Del.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 295-299.)—In transmission experiments, the details of which are given in tables, it was possible for the housefly to carry *Streptococcus agalactiae* externally and internally. This organism and pathogenic staphylococci were found at the external surfaces of the teat sphincters in nearly all of the mastitic animals examined. It was considered unlikely, however, that the houseflies trapped in the dairy barn and studied in the investigation would have been important as agents for the transmission of bovine mastitis.

**Homogenized sulfanilamide-in-oil intramammary injections in bovine mastitis, J. C. KAKVAS, C. C. PALMER, J. R. HAY, and E. S. BIDDLE.** (Univ. Del.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 274-284, fig. 1.)—Report is made of the chemotherapeutic properties of sulfanilamide when administered directly into the bovine mammary gland for the treatment of streptococcal and staphylococcal mastitis. Light liquid petrolatum was found to be a suitable vehicle for incorporating and administering the drug. Description is given of a method for the preparation of the homogenized sulfanilamide and the procedure for intramammary injections.

"In streptococcal mastitis the dosage recommended for an average size udder is 40 cc. of the homogenized product given daily for 4 days. If the infection persists the treatment should be repeated and the daily dose may be increased to 80 cc. with safety. This applies both to lactating and nonlactating cows. In staphylococcal mastitis the dose recommended is 80 cc. of the product given daily for 4 days and repeated if indicated. The homogenized sulfanilamide as used in these experiments was well tolerated and readily absorbed by the mammary gland. It can be used in acute, subclinical, and chronic forms of mastitis. No contraindications have been found. There was no decrease in milk production during or after treatment. One hundred and three cows were treated for streptococcal mastitis by intramammary injections with homogenized sulfanilamide. One hundred of these were infected with *Streptococcus agalactiae* and 3 were infected with *S. uberis*. Based on bacteriological findings,

cures were effected in 92 cows (89.3 percent) and partial or no improvement in 11 cows (10.7 percent). Breaking down the results into quarters treated, of the total 265 quarters, 251 (94.7 percent) were cured and 14 (5.3 percent) were not cured. In acute and chronic mastitis caused by pathogenic staphylococci, promising results were obtained in preliminary trials from intramammary use of homogenized sulfanilamide." Sulfathiazole similarly prepared was found capable of destroying the infection within the udder, but was objectionable owing to the formation of plugs which temporarily occlude the teat duct.

A list of 24 references to the literature is included.

**The eradication of streptococcic mastitis by treatment with tyrothricin,** F. E. MARTIN (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 784, pp. 23-25).—In a herd of 71 cows 49 were found to be infected in 130 quarters with long chain streptococci, diagnosis having been made by the incubated smear technic. Treatment consisted in the instillation of tyrothricin into the quarter and repeated as indicated, the administration having been made during all stages of lactation. Of 130 infected quarters 90 percent were cured, requiring an average of 2.3 treatments per quarter. The reactions from tyrothricin in an oil emulsion were slight when small doses were employed.

**Calfhood vaccination in a brucellosis control program in certified dairies,** C. W. BONYNGE (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 785, pp. 120-123).

**The use of sulfonamides in the treatment of calf diphtheria,** J. FARQUHARSON (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 785, pp. 88-92, fig. 1).—The statistical, clinical review of a series of 76 cases of calf diphtheria presented emphasizes the excellent results obtained from sulfonamide therapy. The author has found sulfapyridine to be the drug of choice in the treatment of calf diphtheria in which *Actinomyces necrophorus* is either the primary or secondary agent.

**Studies on sheep, with the demonstration of Pasteurella localized in the central nervous system,** H. E. BIESTER, L. H. SCHWARTZ, and R. A. PACKER. (Iowa State Col.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 268-273, figs. 7).—Report is made of the recovery of *Pasteurella* organisms during an epizootic among sheep which manifested clinical symptoms characteristic of a central nervous disturbance. The organisms were recovered from the brain of experimentally inoculated animals and in one case by direct inoculation of a bacteriologic medium with a suspension of infectious brain material. One or more nutritional factors were believed to be contributory in the course of the disease. The pathology of the brain was distinct from that associated with ovine listeriosis. The organisms recovered were identical to those of *P. multocida* group II as classified by Rosenbusch and Merchant (E. S. R., 80, p. 822).

**Tularaemia in sheep,** R. GWATKIN, R. H. PAINTER, and I. W. MOYNIHAN (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), No. 6, pp. 163-168, figs. 2).—The occurrence of tularemia in a band of 850 yearling ewes in southern Alberta, in which 24 died and 5 or 6 seriously affected animals recovered, is reported upon. All the ewes examined were heavily infested with the Rocky Mountain spotted fever tick *Dermacentor andersoni* Stiles. The tularemia organism (*Pasteurella tularensis*) was recovered from 1 sheep on autopsy, from engorged ticks taken from it, and also from engorged ticks taken from another sheep which had been ill for 10 days and was recovering. Serum of this animal showed complete agglutination in 1:400, almost complete in 1:800, and partial in 1:1,600. The outbreak lasted only 5 days, and its cessation coincided with disappearance of ticks, which earlier were reported to have been unusually heavy.

**Phenothiazine-medicated pellets for range sheep**, E. C. McCULLOCH. (Wash. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 785, pp. 114-119, fig. 1).—The author has found that phenothiazine-medicated pellets afford a practical, convenient, and reasonably efficacious method of treating range sheep infested with *Haemonchus contortus* and *Trichostrongylus colubriformis* in the abomasum. For the individual medication of sheep with phenothiazine or for the preparation of phenothiazine suspensions, a mixture of 5 parts of phenothiazine with 4 parts of molasses forms a convenient and practical mass.

**Tests with nicotinic acid for the prevention of infectious swine enteritis**, B. H. EDGINGTON, W. L. ROBISON, W. BURROUGHS, and R. M. BETHKE. (Ohio Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 785, pp. 103-108).—The data presented led to the conclusion that the protective value of nicotinic acid against *Salmonella choleraesuis* infection is not sufficient to encourage its use as a specific preventive or curative measure for this type of bacterial infection of swine.

**The in vitro neutralization of hog-cholera virus with hog-cholera antiserum**, H. C. H. KERNKAMP and M. H. ROEKE. (Minn. Expt. Sta.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 300-303).—The results of experiments, reported in tables, have shown that an in vitro neutralization of hog cholera virus by hog cholera antiserum does occur. When mixtures of virus and serum were incubated for 1 hr. at 37.5° C. it required approximately five times as much antiserum as virus to effect a neutralization, whereas when incubated for a longer period (5 hr.) about an equal amount of antiserum and virus resulted in neutralization.

**Swine erysipelas**, L. VAN ES and C. B. McGRATH (*Nebraska Sta. Res. Bul.* 128 (1942), pp. 43, figs. 5).—A revision of Research Bulletin 84 (E. S. R., 76, p. 251).

**Ascorbic acid in certain body fluids of horses**, B. J. ERRINGTON, W. S. HONGKISS, and E. P. JAYNE. (Ky. Expt. Sta.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 242-247).—The results of ascorbic acid analyses of the blood plasma, semen, spinal fluid, and the aqueous and vitreous humors of horses are reported upon, the details being given in tables. They indicate that horses do not assimilate ascorbic acid when it is administered by mouth. No correlation was observed between the ascorbic acid content of the blood plasma and that of the other fluids examined. There is a tendency for a decrease in the ascorbic acid content of the spinal fluid and the eye fluids in local inflammatory processes. In cases of periodic ophthalmia there was a decrease in the ascorbic acid of the aqueous humor of 58.5 percent from the average normal.

**Whitebrush (*Lippia ligustrina*) poisoning in horses**, F. P. MATHEWS. (Tex. Expt. Sta. and U. S. D. A.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 784, pp. 35-38, figs. 2).—An investigation of losses in horses that have for many years occurred in various parts of Texas, particularly in Val Verde, Kinney, and Uvalde Counties and were attributed to the grazing on white brush, led to feeding experiments in which two horses that browsed upon this plant suffered from the toxic effects and later succumbed. The symptoms consisted of emaciation, leg weakness, and incoordination. A calf that was kept in the same enclosure for 56 days developed the same emaciation but no other evidence of toxic effects. Two sheep and a goat kept in the enclosure for 79 days suffered no ill effects.

**Significance of inclusion bodies of distemper**, W. WISNICKY and L. WIPF. (Wis. Expt. Sta.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 285-288, figs. 5).—It was found that distemper inclusion bodies provide an invaluable aid in diagnosing distemper, although there are conditions when the presence of several

kinds of inclusionlike bodies may confuse the diagnosis. The necessity for basing the diagnosis on history, clinical picture, post-mortem gross appearance, and the presence of characteristic inclusion bodies is emphasized.

**Interspecies transmission of avian leucosis in embryos**, M. POLLARD and W. J. HALL. (U. S. D. A.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 247-252, figs. 6).—The virulence of the leucosis agent was little affected by passage into turkey, guinea fowl, quail, and pheasant embryos. The reason for its marked exacerbation when passed successfully through two series of duck embryos is as yet speculative. The postinoculation period in quail embryos was relatively short, but this might be attributed to the small size of the embryo, the dosages for all of these species being between 0.05 to 0.1 cc. of "leucotic" blood. "Zigzag" passages from the chick embryo to the turkey embryo and then back to the chick embryo, even when repeated several times, induced no marked alteration in the character of the leucotic response. There was no attenuation of virulence when passed through turkeys as reported by K. Jármai.<sup>1</sup> The disease has been transferred in ovo from the chick to the turkey and from the turkey to the duck, guinea fowl, and quail. It has similarly been transferred from chicks to pheasants and from the latter species to quail and from chicks to guinea fowls and from the latter to pheasants. It has been transferred through three generations in turkey embryos, two in ducks, and two in the guinea fowl embryos. Leucosis was induced in 22.8 percent of 57 turkey poults and in 1 pheasant chick which were inoculated.

**Vinylite-resin-corrosion preparations in the study of the avian leucosis complex**, G. E. COTTRAL. (U. S. D. A.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 227-234, figs. 4).—A description is given of the technic for using vinylite resin to prepare corrosion casts of the vascular systems of organs of the domestic fowl.

**Serial passage of lymphomatosis-osteopetrosis in chickens**, C. A. BRANDLY, N. M. NELSON, and G. E. COTTRAL. (U. S. D. A.). (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 289-295, figs. 4).—Report is made of work in which six serial passages were accomplished in chickens with the strain 3 agent of lymphomatosis-osteopetrosis.

**Respiratory-nervous disorder in eight-months old pullets**, D. E. STOVER (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 239-241, figs. 4).—Report is made of a disorder in 70 percent of a flock of 750 birds, of which 6 succumbed. The symptoms were blueness of the comb, droopiness, inappetence, and a tendency for many of the birds to remain on the roosts. Egg production dropped from 64 to 17 percent, and a number of soft-shelled eggs were laid.

**Laying hens poisoned by calcium oxide (quicklime)**, G. W. STILES. (U. S. D. A.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 784, pp. 20-23, figs. 2).—The loss of about 20 percent of a flock of 90 hens was shown in experimental work to have been due to the consumption of an overdose of lumpy quicklime spread over the drop boards and in the litter. As a means of prevention it is recommended that quicklime be used only in a finely powdered form well spread over the premises. Recovery in sick fowls was hastened after they received dilute vinegar treatment.

**Possible irritating effects from dusting baby chicks and growing and adult fowls with hypochlorite powders**, S. M. COSTIGAN (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 235-239, figs. 3).—It was found that dusting with hypochlorite powders chicks affected with infectious bronchitis or older birds with bronchitis, laryngotracheitis, or coryza did not cause more severe inflammation than that produced by the infective agents. Pullorum-infected chicks whose lungs were

<sup>1</sup> Arch. Wiss. u. Prakt. Tierheilk., 70 (1935), No. 1, pp. 32-70.

involved were not adversely affected by the dusting, as was shown by the higher mortality in the control birds.

**The relationship of infectious omphalitis of poults and impetigo staphylogenes in man,** R. B. WILLIAMS and L. L. DAINES (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 784, pp. 26-27, 28).—Report is made of an investigation of the 20- to 30-percent loss of poults that occurred at a hatchery operating forced-air type incubators with a combined capacity of 43,000 turkey eggs. The findings are said to be in agreement with those of Volkmar (E. S. R., 62, p. 566) and Brandly (E. S. R., 68, p. 534). It is concluded that the infection originated within the hatchery and that the etiological agent was a strain of *Staphylococcus aureus*. The endemic occurrence of impetigo and sore throats among men employed in the hatchery and the brooding houses, the isolation of a strain of *S. aureus* routinely from the coagulated heart blood of the poults, the isolation of a similar organism from an employee working as a herder of young turkeys, and the necessity for operators to work within the incubators furnished evidence that this organism was the cause of the loss.

**Intestinal cultures for detecting salmonellosis in young turkeys,** J. J. POSELL (*Amer. Jour. Vet. Res.*, 3 (1942), No. 8, pp. 257-259).—Of 100 lots totaling 366 young turkeys that were cultured, and the isolations of *Salmonella* organisms from the intestines compared to those from other organs, 40 lots and 112 birds were positive. Eleven species of *Salmonella* other than *S. pullorum* were isolated. Pullorum disease was not detected by intestinal cultures and missed by the remaining cultures in any one lot. Paratyphoid infection was detected by intestinal cultures and missed by the remaining cultures in one-third of the lots. It is concluded that instances in which paratyphoid organisms are recovered solely from the intestinal tracts may represent true infections. Routine examination of young turkeys should include intestinal cultures.

## AGRICULTURAL ENGINEERING

**[Agricultural engineering investigations by the Missouri Station]** (*Missouri Sta. Bul.* 444 (1942), pp. 16-17, 18, 19, 20).—These included experiments to show cost of various methods of handling cornstalks for conversion into artificial manure, by J. C. Wooley and R. Beasley; on the proper size, depth, and spacing of tile drains for Missouri soils, by Wooley; on the use of electricity in the brooding of chicks, by M. M. Jones; and on combine harvesters in Missouri, by Jones, Beasley, and L. E. Hightower.

**[Agricultural engineering investigations by the Nebraska Station].** (Partly coop. U. S. D. A.). (*Nebraska Sta. Rpt.* [1941], pp. 68-73, 82).—Studies of electric power on Nebraska farms are noted by E. E. Brackett and F. D. Yung; methods of cooling milk on the farm and their effect on quality, by H. P. Davis and P. A. Downs; mechanical equipment needed for the eradication of bindweed, and mechanical equipment, power, and labor required in Nebraska for the production of corn, both by C. W. Smith; adaptation of insulated electric brooders in uninsulated poultry houses, by Yung and F. E. Mussehl; pig brooders, by Yung; an evaporative egg cooler, an insulated water-cooled egg storage cabinet, and a fruit and vegetable dehydrator, all by Brackett, Yung, Davis, Downs, and Mussehl; and pump irrigation, by H. E. Weakly.

**[Agricultural engineering investigations by the Texas Station]** (*Texas Sta. Rpt.* 1941, pp. 6-8, 43-44).—Mechanical harvesting of cotton is reported upon by H. P. Smith, D. T. Killough, D. L. Jones, and M. H. Byrom; efficiency in distribution and placement of cottonseed and fertilizer, and atmospheric ex-

posure of wire and fencing, both by Smith and Byrom; garlic drying, by Smith, Byrom, and G. E. Altstatt; and land use in relation to sedimentation in reservoirs in the Trinity River Basin, by [A. N.] Garin and L. P. Gabbard (coop. U. S. D. A.).

**Methods for determining permeability of water-bearing materials, with special reference to discharging-well methods**, L. K. WENZEL (*U. S. Geol. Survey, Water-Supply Paper 887 (1942), pp. VI+192, pls. 6, figs. 17*).—This report outlines the general methods for determining permeability and includes some of the more widely used variations of each. It includes a section on direct laboratory methods and a bibliography of literature on permeability and laminar flow, by V. C. Fishel, and a list of organizations in the United States that make permeability tests.

Four pumping tests to determine the permeability of water-bearing materials were made in Nebraska, in connection with an investigation of the ground-water resources of the State by the Federal Geological Survey in cooperation with the conservation and survey division of the University of Nebraska. Observations on the fluctuations of the water level in many observation wells gave information on the behavior of the water level in the vicinity of discharging wells. The Federal Geological Survey in cooperation with the Kansas Geological Survey made a similar pumping test in the Arkansas River Valley, near Wichita, Kans., in 1937. The permeability of the water-bearing materials at the location of each of the five tests was computed by several of the discharging-well formulas outlined. The permeabilities so determined for any one test agree within about 5 percent. Descriptions of the pumping tests and of the permeability computations are included, together with records of the draw-down of the water level in observation wells in the tested areas in Nebraska.

**Water levels and artesian pressure in observation wells in the United States in 1940, parts 1-6**, O. E. MEINZER, L. K. WENZEL, ET AL. (*U. S. Geol. Survey, Water-Supply Papers 906 (1942), pp. III+226, figs. 10; 907 (1942), pp. IV+120, figs. 9; 908 (1942), pp. IV+288, figs. 7; 909 (1941), pp. III+208, figs. 7; 910 (1941), pp. [3]+184, fig. 1; 911 (1941), pp. IV+240, figs. 15*).—This series of records was published in the form of one volume per year up to 1939 (E. S. R., 85, p. 542), but an increase in the number of observation wells and the quantity of water level pressure data available have so far increased as to make it advisable to subdivide the 1940 records here noted into six volumes, dealing respectively with the Northeastern, Southeastern, North Central, South Central, and the Northwestern States, and with the Southwestern States and the Territory of Hawaii.

**Surface water supply of the United States, 1940, parts 4, 6, 7, 10**, G. L. PARKER et al. (*U. S. Geol. Survey, Water-Supply Papers 894 (1941), pp. V+213, pl. 1; 896 (1942), pp. VIII+457, pl. 1; 897 (1941), pp. VI+349, pl. 1; 900 (1941), pp. IV+125, pl. 1*).—These papers record measurements of stream flow for the year ended September 30, 1940, No. 894 covering St. Lawrence River Basin, No. 896 the Missouri River Basin, No. 897 the lower Mississippi River Basin, and No. 900 the Great Basin.

**Water resources for rice irrigation** (*Arkansas Sta. Bul. 417 (1942), pp. 6-7*).—This brief discussion of studies by K. Engler indicates that the use of surface water in quantities sufficient to diminish the decline of ground-water level in neighboring wells is in some instances possible, and that there are some other advantages in the use of surface water for rice irrigation.

**Control of microorganisms by ultraviolet irradiation**, H. STIERLI. U. S. D. A.). (*Agr. Engin., 23 (1942), No. 8, pp. 262-265, figs. 6*).—Hot cathode and cold electrode germicidal lamps were used in tests on commercial hydrocoolers.

Although a relatively large number of lamps were used and two methods of placement (in air above the water or immersion directly in the water) were tried, no satisfactory control of micro-organisms was obtained. In both cases, but especially with the immersed lamp, the low temperatures necessary for precooling sharply reduce the ultraviolet output and life. Immersed operation may be improved by enclosing the lamp in a special ultraviolet-transmitting glass. At this time it seems impractical to use ultraviolet radiation for control of micro-organisms in precooling water because of the large number of germicidal lamps necessary for the production of sufficient ultraviolet intensity.

**Relation of drainage to the victory program of agriculture, J. G. SUTTON.** (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 8, pp. 249-250, 252, figs. 2).—The author calls attention to the damage done during the preceding war, and not yet fully repaired, by the plowing up and subsequent wind erosion of large areas of the plains. Much of the increased production needed in the present war can be carried out with suitable drainage measures on lands now too wet for use and within the limits of an expenditure which will make this an important contribution to the war effort. It is important, however, that the scope of drainage which should be carried on as a war measure be specifically defined to avoid criticism that the drainage of swamps and undertaking of large new projects entails.

**The relation of water management to grassland farming, C. L. HAMILTON.** (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 8, pp. 245-246, 248, fig. 1).—The author finds, in part, that without some degree of grassland farming a lasting solution for many of the water problems in agriculture becomes impractical. Permanent vegetative cover is often the only profitable solution for acute water erosion wastage. In other instances profitable grass or crop production is dependent upon drainage, runoff diversion, moisture retention, or supplemental irrigation or other water-corrective measures. The success of one practice usually depends upon the other. Mechanical measures frequently fail if not supported by proper vegetal measures. Similarly vegetative measures fail when mechanical aids are ill-suited or inadequate.

**The relation of grassland farming to soil and water conservation, F. G. BELL.** (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 8, pp. 247-248).—Pointing out a confusion in the use of the term "grassland farming," the author defines such a farming system as one involving the use of grass as the major production element in the cropping system or a method of farming in which grasslands are considered as the basic unit of land use on the farm, the definition in either form being understood not to exclude entirely the growing of cultivated crops. The value of such a system from the viewpoint of soil and water conservation is taken as generally accepted. This discussion is concerned mainly with the economic problems involved. It is concluded, in part, that when the maximum capabilities of grass, as a crop, are understood and effectively used, it may be hard to justify, on either a conservation or economic basis, any other type of land use for the very large acreage of land on which an erosion hazard exists.

**Machinery in Britain's food production campaign, C. I. C. BOSANQUET** (*Agr. Engin.*, 23 (1942), No. 8, pp. 260-261).—Use of farming machinery on an increasing scale has made possible in England a 50-percent increase in the acreage of arable land and a food production increase of about 30 percent. One of the striking facts brought out in this summary of the current British agricultural situation is that the agricultural machinery supplied from the United States produces in the first 12 mo. between 7 and 10 times the combined weight of the equipment itself and of the fuel and oil consumed in its use in

human food. Use of Government-owned machinery for the working of land which does not justify owner-purchase of machinery (mainly because the land now tilled will be returned to grass after the war) is one of the features of the current agricultural situation noted.

**A method of estimating the minimum farm equipment requirements for 1943.** J. B. DAVIDSON. (Iowa State Col.). (*Agr. Engin.*, 23 (1942), No. 8, pp. 251-252, fig. 1).—The 1943 farm equipment requirement estimates must be related specifically to the production objectives for that year. Though not established at the time of writing, these objectives may be expected to include (1) increase in the volume of certain crops (the 1942 objectives having been increased from 88 percent for wheat to 255 percent for peanuts above the production of 1941), and (2) an increase in the acreage of certain new crops, especially new oil and fiber crops. Estimates for the tooling of these increases are considered under the headings repairs, replacement of machines, machines needed for new crops, machines needed for increased production other than that of new crops, equipment needed to counterbalance labor shortages, tractor requirements, and farm equipment needed for export.

**Rubber-tired equipment of principal farm machines.** A. P. BRODELL and R. A. PIKE (*U. S. Dept. Agr., Bur. Agr. Econ. and Agr. Market. Serv.*, 1942, *F. M.* 29, pp. [2]+7).—"Crop correspondents in February 1941 supplied information relative to the age, type, rubber-tired equipment, fuel consumed, and work performed by their tractors. They estimated the number of tractors of different type on farms in their locality, the extent of use of rubber tires on general-purpose and standard-wheel tractors; the percentage of farmers owning combines, grain binders, mowers, and manure spreaders; and the proportion of these machines that were equipped with rubber tires. Usable returns were received from more than 25,000 crop correspondents who reported on machines for their locality and on more than 17,000 tractors on their own farms. The reports provided complete information as to the age and type of tractor and extent of use of rubber tires for more than 13,000 tractors." The information on the use of rubber tires on tractors and some other farm machines is summarized.

**Farm tractors: Type, size, age, and life.** A. P. BRODELL and R. A. PIKE (*U. S. Dept. Agr., Bur. Agr. Econ. and Agr. Market. Serv.*, 1942, *F. M.* 30, pp. [2]+15, fig. 1).—This report summarizes the information on types, size, age, and life of farm tractors collected from crop correspondents as noted above.

**The drying of young grasses for feed.** N. O. BELT (*Agr. Engin.*, 23 (1942), No. 8, pp. 257-259, 261, figs. 4).—High-temperature drying is held more economical than the low-temperature method, producing as good a product or perhaps better. Future developments in driers for forage crops will be on this principle. Coke or coal may be used as a fuel for driers, but gas or oil is preferred for simplicity of operation and regulation of temperature. Cutting and loading machines for handling grasses and forage crops should be further developed. The Redpath harvester was found outstanding in this work and was used to replace the Wilder cut lift combine at Foxden Farm, but it could be further perfected for cutting short grass and the cost reduced by improved design and production methods. Bagging, balling, and storage of dehydrated crops are held to need study and improvement, as do growing, fertilizing, and developing the most suitable grasses and clovers to be used for drying. It is believed very likely that the quality and yields obtained by the application of large amounts of fertilizers would justify the cost. Work so far has shown that dried immature pasture herbage makes a feed of superior quality, and that it can be grown and dried on a farm scale. Further progress is being delayed by the lack of more suitable equipment, which is an engineering problem.

**A continuous soil pasteurizer**, J. R. TAVERNETTI. (Univ. Calif.). (*Agr. Engin.*, 23 (1942), No. 8, pp. 255-256, 261, figs. 4).—The soil passes from a hopper, having approximately a 5-cu. ft. capacity and provided with agitators, into a 6-ft. length of 4-in. iron pipe around which are wound two 2,500-w. flexible metal-sheathed heating elements. The elements are approximately  $\frac{1}{8}$  in. in diameter and 19 ft. long and are wound spirally with about 2 in. between turns. There is a sheet metal casing over the heating elements and the spaces between turns are filled with metal filings. The entire heater is insulated with 4-6 in. of mineral wool. A screw conveyor of 4-in. diameter with a  $4\frac{1}{2}$ -in. pitch and 8 ft. long extends through the pipe and a semicircular trough in the bottom of the hopper. It is driven by means of a chain and sprocket from a speed reducer, which in turn is driven by a  $\frac{1}{8}$ -hp. electric motor. A thermostat connected in series with the heating units has its sensitive element against the pipe.

The average rate of pasteurizing was approximately 5 cu. ft. of loose soil per hour, or 1 cu. ft. per 1,000 w. of heating capacity. The moisture content of the soil was found an important factor in the proper operation of the machine. The most satisfactory combination of mechanical operation and pasteurizing was obtained when the soil was moist enough not to be dusty but not too wet to crumble readily after being squeezed in the hand. The desirable percentage of moisture varied from as low as 3 or 4 percent with pure sand to as high as 25 or 30 percent with soils containing considerable organic material.

**Gearing farm structures to the war effort**, D. G. CARTER. (Univ. Ill.). (*Agr. Engin.*, 23 (1942), No. 8, pp. 253-254).—As factors favoring new structures and repairing, the author recognizes (1) relatively high farm income; (2) elimination of much of the competition for this income; (3) continuous change in farm building needs; (4) inadequacy of present structures; (5) the cumulative excess of depreciation over structural and reparative expenditure estimated at \$1,720,000,000 for the past 20 yr.; (6) the wartime emphasis on production, conservation, and labor saving; (7) increased interest on the part of the farmer himself and of the manufacturer, dealer, and the general public; and (8) availability of much noncritical material for farm building. The limitations and restrictions are held to be less of a hindrance with respect to farm building than these have been generally assumed to be. Wartime opportunities for the agricultural engineer to be of increased service in planning and in leadership are considered to be many. Examples are given. A wartime program for farm building advancement is briefly outlined.

**Factors affecting temperatures in Southern farmhouses**, J. W. SIMONS and F. B. LANHAM. (Coop. Univ. Ga.). (*U. S. Dept. Agr., Tech. Bul.* 822 (1942), pp. 78, figs. 46).—Detailed studies of air and surface temperatures and conditions affecting them in cheap farmhouses of from one to four rooms are reported for both summer and winter. In relatively new frame construction with lapped weatherboarding on the exterior and beaded ceiling lumber on the interior, reducing infiltration of air through walls and around windows and doors to a minimum reduced fuel consumption as much as 30 percent with wind velocities up to 9.7 miles per hour. In like construction 3 yr. old, having lapped weatherboarding without paper or sheathing on the exterior and beaded ceiling lumber on the interior, fuel consumption increases approximately 56 percent with an increase in wind velocity from 3.0 to 9.7 m. p. h. Cottonseed hulls  $3\frac{5}{8}$  in. in depth used as ceiling insulation will reduce fuel consumption approximately 25 percent at low wind velocities when used in like construction in three-room houses, and from 18 to 27 percent at wind velocities ranging from 3 to 9

m. p. h. in the types of construction employed in the one-room houses. In a one-room metal house fuel consumption was decreased approximately 50 percent by wall and ceiling insulation of cottonseed hulls. The use of curtain walls to close the spaces between foundation piers reduced fuel consumption from 12 to 20 percent in wood-frame construction as used in the three-room houses with cottonseed-hull ceiling insulation and provision made for reducing air infiltration to a minimum through walls and around doors and windows. With wind velocities up to 9.7 m. p. h., a total fuel saving of as high as 47.8 percent may be obtained by insulating the ceiling of the three-room house with cottonseed hulls (3% in. deep), installing effective wind barriers in the walls and around windows and doors, and providing curtain walls between the foundation piers. Concrete-slab floors laid over gravel fills on the ground maintain more uniform and higher temperatures than wood floors on piers.

Reducing the entrance of solar radiation through window and door openings was found of prime importance in any attempt to maintain lower summer temperatures in low-cost farmhouses. Three coats of white paint on the exterior of wood-frame construction resulted in a small reduction in the average interior wall surface temperature during the day. Air-temperature reduction at the 42-in. level was negligible from the use of ceiling insulation with windows and doors open.

Numerous other measures studied were of little effect in such structures.

### AGRICULTURAL ECONOMICS

[Investigations in agricultural economics by the Missouri Station, 1939]. (Partly coop. U. S. D. A.). (*Missouri Sta. Bul.* 444 (1942), pp. 14-16, 39-40, 71).—Results not previously noted are reported as follows: (1) Brief findings by C. H. Hammar and E. S. Troelston as to the decrease from 1927 to the period 1933-38 in farm land values in 13 counties, farm mortgages and foreclosures on lands of different soil types, and the success of Missouri farmers with investments in farm real estate; (2) brief statements by Hammar and N. Clough as to sales turn-over and the types, conditions, etc., of farm buildings in 5 areas studied; (3) findings by B. H. Frame as to financial returns, crop yields, livestock sales, etc., on 59 farms in the Big Creek watershed in the northern part of Harrison County, Mo., and the southern part of Ringgold and Decatur Counties, Iowa; (4) table by Frame showing the relation between crop equipment investment and crop acres in 1937 on 69 Harrison County farms; (5) some records as to cost of seeding, yields of pastures and legumes, costs of silage, etc., on the Hatch Farm of the station, by A. C. Ragsdale and C. W. McIntyre; and (6) table by H. L. Kempster showing by years 1933-38 the average farm price of poultry feeds, average farm price of eggs, pounds of feed 122 eggs would purchase, and the egg: feed ratio.

[Investigations in agricultural economics by the Ohio Station], J. I. FALCONER (*Ohio Sta. Bimo. Bul.* 217 (1942), pp. 145-146).—The table of index numbers of production, prices, and income (E. S. R., 87, p. 584) is brought down through April 1942. Tables show the estimated total tons of different kinds of commercial feeds reaching the retail trade in Ohio in 1929, 1932, 1937, 1939, 1940, and 1941, and the sales by years 1929-41.

[Investigations in farm and ranch economics by the Texas Station]. (Partly coop. U. S. D. A.). (*Texas Sta. Rpt.* 1941, pp. 40-43).—In addition to findings previously noted, results for studies are reported by W. E. Paulson on the marketing of turkeys, showing the grades, average weights, and prices received for 27,317 birds sold in the 1940 Thanksgiving market, and on the

average margins on grain and supply business of grain elevators, and the percentages of members and directors of cooperative elevator associations that were tenants; by L. P. Gabbard and E. J. Hervey as to inequalities of tax assessments and delinquencies in San Saba County and as to the trend of taxes in representative counties of the State; by H. C. Bradshaw, Hervey, and Gabbard as to savings in local governmental purchasing in four counties resulting from using specifications, centralized purchasing, competitive bidding, etc.; and by J. Motheral and Gabbard as to landlord supervision of the operation of rented land in eastern Texas, the Gulf coast area, and the Panhandle area, the increase from 1939 in the use of written leases, and the changes in farm population during 1940.

**Statistical investigation of a sample survey for obtaining farm facts,** R. J. JESSEN. (Coop. U. S. D. A. et al.). (*Iowa Sta. Res. Bul.* 304 (1942), pp. 104, figs. 2).—Methods of sampling farm facts in Iowa are presented and discussed.

**War and farm work,** R. C. TETRO and M. R. COOPER (*U. S. Dept. Agr., Misc. Pub.* 492 (1942), pp. 12+21, figs. 11).—This discussion is prepared from land-grant college publications and suggestions contributed by farm management specialists of the Bureau of Agricultural Economics. It takes up the farm timetable, fitting the family to the farm, working with neighbors and others, machines and labor saving, and hired labor in their relations to the war needs.

**Rationing: A selected list of references,** A. M. HANNAY (*U. S. Dept. Agr. Libr. List* 3 (1942), pp. 60).—Included are 286 annotated references on rationing during the present war with a few references to World War I. The references are grouped as general and by countries.

**Effects of crop acreage control features of AAA on feed production in 11 Midwest States,** T. W. SCHULTZ and O. H. BROWNLEE (*Iowa Sta. Res. Bul.* 298 (1942), pp. 673-696).—The authors estimate that the production of corn in the Midwest in 1938-40 was about the same as in 1928-30 and that the production of corn without crop control would have been only slightly larger than that actually harvested.

**Controlling corn and hog supplies and prices,** G. SHEPHERD (*U. S. Dept. Agr., Tech. Bul.* 826 (1942), pp. 82, figs. 22).—The location of the heavy corn-producing areas of the United States, the production of hogs, the fluctuation in production and demand for corn and hogs, etc., are discussed. One part of the bulletin deals with the problems of controlling the corn supply and another with controlling the demand for hogs. In the first part, the development of the A. A. A. Ever-Normal Granary program; the size of stabilization stocks; prices, costs, and incomes; and geographical corn loan-rate structure are discussed. The second part deals with whether the demand for hogs can be controlled, the effect of hog-corn prices on hog production, the procedure for meeting changes in the demand for hogs, how the price of hogs may be changed, and whether a controlled system is better than an open-market system.

Some of the findings and conclusions were: "Practically complete stabilization for all emergencies over the last 75 yr., except for the one period from 1933-36, could have been attained with storage stocks not exceeding a billion bushels at any time. A program for the future could get along very well with storage stocks of 700 or 800 million bushels, if hybrid corn reduces the effects of drought and if control of production is effective. . . . If the storage stocks for the country as a whole equaled, for example, 25 percent of the average production of corn, then the stocks in each State should equal 25 percent of the average production of corn in that State, multiplied in each case by a figure representing the severity of fluctuations in corn production in the State. In addition,

the corn should be stored as far north as possible, in order to keep down damage by insects. . . . The corn-storage program would disturb corn-storage practices and relative livestock production in different parts of the Corn Belt less if the existing flat loan rate were replaced by a system of geographical differentials corresponding to average corn-price differentials over the last 15 or 20 yr. An alternative system could be based on average prices at terminal markets and freight rates to those markets. . . . It would be possible to make the stabilization program finance itself, from a banker point of view, by stopping short of complete stabilization and setting the loan rate each year a few cents below the price at which an average crop would sell. The price would then rise enough from large-crop years to short-crop years to cover the costs of storage. But as stabilizing supplies of corn increases gross incomes to farmers from the sale (or feeding) of corn, and also reduces the costs of producing, processing, and distributing livestock, perhaps it would be better to go all the way to complete stabilization. If farmers retained the benefits from this stabilization of supplies, it would seem that they should bear the costs. If, however, production expanded and the benefits were passed on to consumers in the form of more goods at lower prices, it would seem that the costs should be charged to them. It would be well in any case to include a 'life-saver' clause in the formula for determining the loan rate, so that the rate would be reduced automatically if the storage stocks exceeded half a billion bushels or some similar figure. . . .

"Demand cannot be controlled (except to a very limited extent, perhaps 1 or 2 percent, by surplus-disposal programs) without stabilizing the whole economy. Until that is accomplished, the only feasible way to deal with fluctuations in demand for hogs is to meet them with corresponding fluctuations in production of hogs. That will require a more farsighted control of hog production than the open market has afforded in the past, for (1) pork is perishable, and large supplies sell at low prices even though short supplies and high prices may be imminent a few months later, (2) producers respond much more to present prices than to prospective prices, and (3) the decision to increase or reduce the number of hogs going to market must be made at least a year in advance of the time when the market supplies of finished hogs are needed. The hog market can be made more farsighted by Government forecasts of the requirements for pork and lard a year or more in the future, implemented by a guaranteed price for hogs that will call forth the production needed. Risks of financial losses are involved, but they could be minimized if the Government guaranteed only 90 percent of the estimated price, and disposed of any unforeseen surpluses to low-income groups of consumers."

An interpretation of 'parity prices' for Pacific coast egg producers, H. E. ERDMAN and G. B. ALCORN (*California Sta. Mimeog. Rpt. 81 (1942), pp. [2]+44, figs. 18*).—The data are presented and discussed under the following headings: Meaning of the parity figure, the monthly farm prices, index of prices paid by farmers, comparative costs of egg production, feed:egg ratios as indicators of the position of the poultry industry, nature and significance of base period, price ceilings, and regional differences.

Land-use experience in Callaway County, Missouri, A. M. MEYERS, JR., and C. H. HAMMAR. (Coop. U. S. D. A.). (*Missouri Sta. Res. Bul. 346 (1942), pp. 56, figs. 19*).—The purpose of this study was "to formulate general conclusions regarding adapted types of land uses in Callaway County. The conclusions are significant to other areas in northeastern Missouri which are characterized by similar problems. These conclusions were derived from a method of analysis in which the county was first subdivided into 33 fairly homogeneous land areas.

The land of each area was then described in terms of its basic characteristics, agronomic adaptations, and present condition with respect to conservation. Because many of these land areas were similar, they were grouped into eight area groups or classes. Farmers' land-use experience, interpreted mainly from records of the Agricultural Adjustment Administration and a survey of farm buildings, was then appraised for each land-area class. Conclusions as to adapted uses of the land in each area class were then drawn by correlating the information regarding the agronomic use capabilities of the land with farmers' experience in using it." The importance of and trends in agriculture in the county, the climate and land resources of the county, and the eight land areas are described. The differences in agriculture—land in farms, type of farming, land-use pattern, size of farms, etc.—are discussed by land-area classes. The relation of character of farm buildings and type of land to farm size and farm land use and of idle land and abandoned buildings to type of land are analyzed and discussed. An appendix includes descriptions of the sources of data and methods of procedure used in obtaining and analyzing the data.

**Economic aspects of recreational land use in the Lake of the Ozarks area,** J. R. SNIPE and C. H. HAMMAR (*Missouri Sta. Bul.* 448 (1942), pp. 54, figs. 15).—The natural environment of the area and types of recreational facilities found in it and the utilization of the area for recreation are described and discussed. Analysis was made of some economic aspects of land use and recreation in the area, including the changes in the tax base, the importance of the Bagnell Dam and submerged land in the tax base, the valuation of recreational property, the recreational investment, and expenditures by groups stopping at commercial resorts by summer residents and by transient visitors. In 1928, when most of the real estate consisted of valley farms and their adjoining rough lands, the assessed valuation for the area included in this study was \$2,962,385, and the taxes levied were \$44,358. In 1939 the assessed valuation was \$9,073,065 and the taxes levied \$133,957. Of the total valuation 5.02 percent was commercial recreational real estate, 5.47 percent noncommercial recreational real estate, 6.73 percent undeveloped recreational land, 11.87 percent nonrecreational real estate, and 70.91 percent submerged land and the Bagnell Dam.

**Farming new land in the Yazoo-Mississippi Delta: Problems of small, family-sized farms in the backwater area,** P. S. McCOMAS, T. MULLINS, and E. L. LANGSFORD (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1942, *F. M.* 35, pp. [4]+46, figs. 3).—This report, which deals with the Yazoo backwater area of the Yazoo-Mississippi Delta of Mississippi, "contains a description of the area and an analysis of its suitability for farming, a consideration of some of the problems confronting new-land settlers, and suggestions for improving the economic condition of new settlers. Major emphasis has been placed upon the operation of family-sized farms of which 5,000 to 6,000 can be developed in this new area."

**Increasing incomes and conserving resources on cotton-corn farms in Marion County, Alabama,** B. T. LANHAM, JR., and W. F. LAGBONE. (*Coop. U. S. D. A.*). (*Alabama Sta. Bul.* 256 (1942), pp. [2]+23, figs. 5).—The physical factors, farm trends, size of farms, and labor supply and requirements in the county are briefly described. Tables and charts are included and discussed showing for representative one-mule, two-mule, and three-mule farms the land use and crop production, livestock numbers and production, usual monthly distribution of man labor and mule work, cash receipts and expenses, summary of farm business and family labor returns, value of family living, etc., under the present farming system and under an alternate system with improved crop, livestock, and woodland practices and increased acreages in crops due to clearing woodlands and putting idle croplands into use.

Of the farms in the county, 3.3 percent had no mules, 32.3 operated with one mule, 45.6 with two mules, 10.7 with three mules, and 8.1 percent with over three mules. "One-mule units average 22 acres of cropland, two-mule units 35, and three-mule units 53. Most one- and two-mule units are worked by the operator and his family labor; whereas, most three-mule units are worked by the operator and his family plus the additional labor of one sharecropper family." "Net cash incomes (1935-39 prices and usual yields) for representative one-mule farms are \$102, and for representative two-mule farms \$176. The net cash incomes resulting from the alternative systems are \$186 and \$422, respectively, for the one- and two-mule farms."

**Farm organization and financial returns in the lower Powder River Valley, Baker County, Oregon.** G. B. DAVIS and D. C. MUMFORD. (Coop. U. S. D. A. et al.). (*Oregon Sta. Bul.* 406 (1942), pp. 56, figs. 10).—Data for the year ended May 31, 1939, were obtained during the summer of 1939 for 61 irrigated farms and ranches in the Keating area and for 19 dry-land farms in the Sparta area. The location, topography, soils, climate, economic development, etc., are described, and for each area analysis is made of the farm organization—type and size of farms, cropping system, livestock program, etc.—the distribution of investment, the receipts, expenses, labor income, credit situation, etc. For the Keating area the beef cattle, range sheep, dairy farm, and miscellaneous farm livestock practices are described in some detail, and the reasons for variations in income on the different types of farms are discussed.

[Effect of reorganization and price changes on farm income] (*Arkansas Sta. Bul.* 417 (1942), pp. 42-44, fig. 1).—The possibilities for obtaining increased returns from farms in the Coastal Plains area and in central and northern Arkansas through reorganization are briefly discussed.

**Why some farmers are more successful than others.** J. J. VERNON. (Coop. U. S. D. A.). (*Virginia Sta. Bul.* 341 (1942), pp. 19, figs. 7).—The important facts and conclusions in Technical Bulletin 71 (E. S. R., 86, p. 694), are presented.

**A general appraisal of the livestock industry in the Southeastern States.** W. K. McPHERSON (*Alabama Sta. Bul.* 257 (1942), pp. 32, figs. 14).—The trends from 1924 through 1939 in amounts of feeding stuffs and livestock products and in numbers of livestock on farms, the location of the livestock enterprises, and the possibilities of expanding the livestock industry in the area—Virginia, West Virginia, North Carolina, South Carolina, Georgia, Florida, Kentucky, Tennessee, Alabama, and Mississippi—are discussed. Charts show, for each State, the 10 States combined, and the United States, the indexes (1924-39) for production of all feeding stuffs, production of concentrate feeding stuffs, harvested forage feeding stuffs, pasture forage feeding stuffs, and major classes of livestock products, and amount of livestock on farms. Maps of the area show the total animal units, total feed units, number of swine, grain feed units, number of cattle, harvested forage feed units, and pasture feed units per square mile, and the number of feed units per animal unit, all by counties for 1940.

"Since farmers have been required to curtail the acreage planted to cotton, they have increased the production of feedstuffs. The most significant shifts have taken place in the States in which cotton is the major source of farm income and in Florida. . . . In the Southeastern States as a whole, increases in the production of harvested forage feedstuffs are greatest, followed closely by the production of concentrates during the period studied. The production of pasture forage did not increase significantly. . . . The production of livestock products has increased in all of the Southeastern States during the

period from 1925 through 1940. . . . Farmers in the cotton-producing States increased their livestock populations significantly during the past 10 yr. . . . Some increases in the production of livestock products can be expected as farmers learn and put into use better breeding and feeding practices, but any material increase in the production of livestock or livestock products in the Southeastern States will be dependent upon the ability of the farmers to increase the production of feedstuffs. Since most of the land suitable for cultivation is now being farmed, increases in the production of feedstuffs must, for the most part, come through an increase in the per-acre yields."

**Forest grazing and beef cattle production in the Coastal Plain of North Carolina: Results of a survey of 100 cattle producing farms, H. H. BISWELL and J. E. FOSTER.** (Coop. U. S. D. A. et al.). (*North Carolina Sta. Bul.* 334 (1942), pp. 22, figs. 9).—One hundred farmers distributed throughout the area were interviewed by the authors, the specific objectives of the survey being to investigate the present use made of forest lands for grazing and the extent of the different forage types and the possibilities of expanding and improving the use of forest lands for grazing; the number, distribution, quality, and condition of beef cattle; the methods employed in feeding, breeding, handling, and marketing; the use made of tame pastures; and the chief problems in combining beef and timber production in this area. The material is presented under the following headings: Operators' plans regarding forest lands; extent to which forest lands are being used for grazing; forage types; browse and poisonous plants; forest fires; beef cattle—size of herds, breeding, management, condition, breeding season, feeding, and mineral deficiencies, diseases, and parasites; and tame pastures.

Forest lands and tame pastures each furnished about 29 percent of the year-long feed of beef cattle in the area. Ninety-two of the 100 farmers interviewed were grazing forest lands. The use of forest lands for grazing and the number of beef cattle have increased considerably in recent years, and there appears to be opportunity for greater expansion as many forest areas with nutritious native forage are not used at present. "The development of better practices and the proper correlation of the grazing of forest lands with that of tame pastures, field crops and feed, together with improved livestock and livestock management, afford a possibility of deriving greater returns from these lands than from the growing of timber alone."

**Livestock and forestry enterprises on farms in the Ozark region, W. T. WILSON and J. W. REID** (*Arkansas Sta. Bul.* 419 (1942), pp. 50, figs. 15).—Records for the crop year 1937 were obtained in May, June, and July 1938 by personal interview for 200 farms in the limestone region in north central Arkansas. "Data were collected for a relatively complete farm management analysis of the livestock and forestry enterprises, including farm organization, production methods and practices, receipts and expenses by enterprises, and other factors contributing to comparative success or failure." The region and the pasture, timberland, and crop management in the area are described.

The average size of farm was 294 acres, with 156 acres in forest land, 73 in open pasture, 48 in crops, and 17 acres in farmstead, waste, and idle land. The average number of livestock per farm was: Work stock 3.6, cattle 19.6, sheep 16.1, goats 11.8, hogs 13, and hens 57.2. The total investment was \$4,937 per farm. The average cash income for all farms was \$486, and the average net family income was \$895. Value of family living obtained from the farm averaged \$288. There was a tendency for incomes to increase as the size of farm increased. Acreage in timberland was an unimportant factor affecting income.

"When the farms were grouped by size, those with the higher percentage of land in pasture produced the higher labor income per farm up to the 400-acre group. As the number of animal units of all livestock increased, the labor income increased. Since cattle comprised about 57 percent of the total animal units, the effect of cattle on income was shown by the fact that the greater the number of cattle the higher the labor income. The principal factors for the success of the most profitable over the least profitable farms were: Larger total acreage, one and one-half times more livestock, higher crop yields, more legumes and pasture, 0.71 more returns from livestock and livestock products per animal unit, 2.15 more returns per acre of crops, and 6.47 more receipts per acre of forest land. The most profitable farms were organized for the production of livestock by balancing feed crops pasture, and livestock numbers."

**Input-output relationships in milk production.** E. JENSEN, J. W. KLEIN, E. RAUCHENSTEIN, T. E. WOODWARD, and R. H. SMITH (*U. S. Dept. Agr., Tech. Bul. 815 (1942), pp [2]+88, figs. 21*).—Two series of experiments were conducted at the Delaware, Indiana, Maryland, Michigan, Mississippi, New Jersey, New York State, Pennsylvania, South Dakota, and Virginia Experiment Stations. In the series I experiments, "cows were fed rations computed in what might be called the scientific way—strictly according to an accepted feeding standard, either the Haecker standard or the Morrison standard. All animals were fed maintenance rations according to their weight, but production rations varied from 30 percent below to 30 percent above the standard level. The differences in rates of feeding were designed to represent conditions where some herds continuously were fed more than the requirements called for per pound of milk in contrast to other herds that continuously were fed less than requirements. Therefore, if cows on the experiment in the heavy-fed groups responded to the feeding above standard requirements with increased production of milk, the production ration was increased." In the series II experiments, "the feeding as practiced by practical dairymen was approached more closely. Only one check group was fed according to the Haecker standard; the other groups were fed roughage at liberty, but the grain ration was varied in proportion to milk produced, so as to feed different groups 1:2, 1:3, 1:4, and 1:6 (1 lb. of grain for every 2 lb. of 4-percent milk, etc.). At two stations the cows in one group were fed only roughage. Except for some of the groups fed at standard the allowance of roughage was in no case curtailed, even if this meant that when cows were dry or giving only a small quantity of milk, they received more feed than was called for by the requirements of the feeding standard used. In this series some of the herds were barn-fed throughout the year; others were on pasture during the summer. Altogether, 157 yearly records were obtained of cows fed according to the series I method, and 210 according to the series II method."

In addition, five of the stations continued the work for a third year during which 87 cows were fed all the grain they would eat for most of the lactation period. "At four of the stations, the level of feeding was based on the Haecker standard; at the other six, on the ratio of grain to milk during lactation. At seven stations, these groups of cows were fed at six or more levels; at two stations, five levels; and at one station, two levels."

Some of the results and applications of the study were: "It was found that in the herds used for experiments, 15 to 20 percent more milk was obtained from the cows at high levels of feeding than from cows fed at standard, and 45 percent more than from cows fed at 70-80 percent of standard. The law of diminishing physical output applies to milk production. There was a consistent stepping up of production with every increase in grain allowance, but the additional milk produced for each additional unit of feed decreased. . . . The re-

sponse to increased feed was less at the high levels than at the low levels—0.6 lb. of 4-percent fat-corrected milk for each additional pound of digestible nutrients at the highest level and 1.7 lb. at the lowest level. At normal feeding levels the additional output for an additional unit of feed was much smaller than the average output per unit of feed consumed above maintenance. On an average, cows returned about 3 lb. of milk per pound of digestible nutrients consumed above maintenance; but for each additional pound of total digestible nutrient added to a normal ration an increase of only about 1.0–1.5 lb. of 4-percent milk was obtained. At low feeding levels this additional return was greater. At higher feeding levels it was even smaller. At two stations a group of cows fed roughage alone produced 80 percent as much as a comparable group fed grain at the rate of 1 lb. for each 6 lb. of milk in addition to all the roughage they would eat. . . .

"It is not possible by increased feeding to stimulate the milk production of cows of low inherent productivity as much as the production of cows of high inherent productivity. But it was found that at the same percentages of the standard production requirements, the low and high producing cows gave about the same additional amounts of milk for 1 additional pound of feed. With an increase in feeding level, cows reached a higher peak of production and maintained consistently higher production during the lactation period. . . . There was a fairly consistent increase in body weight as the feeding level increased. The difference in weight between cows fed at the lowest and highest levels was over 100 lb. . . . Feeding at different levels had no influence on the fat percentage of the milk. . . . The input-output relationships determined, if applied on a national scale, show that large additional quantities of feed grains can be converted into milk with only a small loss in efficiency. . . . The most profitable level of feeding is not fixed. It ranges all the way from no grain at all to more than 5,000 lb. of concentrates per year for cows capable of high production, depending upon prices of feed and milk. This means that the feeding standards may be profitably exceeded when the relationship between prices of feed and milk is favorable."

**Seasonal variation in production in the New York milkshed, and its relation to production-adjustment plans, A. J. POLLARD.** (Coop. U. S. D. A. et al.) ([*New York*] *Cornell Sta. Bul.* 783 (1942), pp. 62, figs. 8).—The purposes of this study were "first, to measure the differences in seasonal and in total deliveries of milk by various groups of producers in the New York milkshed, and in the butterfat content of milk delivered by these groups; and, second, to determine how the price returns to these different groups would be affected by certain modifications in the method of paying producers, designed to adjust the supply of milk either seasonally or annually." The analysis of the seasonal variations in production had for its purpose "to show, for a representative sample of dairies throughout the milkshed, (1) the relative number and monthly output of dairies having different patterns of seasonal production, and (2) the relationship between seasonality of deliveries and such factors as size of dairies, butterfat content of the milk, location in the milkshed, and market outlet." The study of production adjustments had for its purposes "to show how the price returns to producers with different patterns of seasonal production and in different locations in the milkshed vary under a market-wide pooling plan without a production-adjustment feature, and to show how these price returns would be affected by the use of any one of three types of production-adjustment plans."

Records of the quantity and butterfat content of milk delivered by 3,000 inspected dairies to 82 plants from July 1938 to June 1939 were analyzed. A sample of 229 uninspected dairies delivering milk to condensers and cheese factories was also obtained. The author summarizes the findings, in part, as follows:

"With respect to the seasonal variations of milk deliveries by dairies inspected for the New York market, this analysis has brought out the following points: A majority of the producers make their peak deliveries of milk in the second quarter of the year, but many producers make their largest deliveries at other times. Nearly half of the producers make their smallest deliveries of milk in the fourth quarter of the year. Most of the others make their smallest deliveries in either the first quarter or the third quarter. At all times of the year, the bulk of the milk supply for New York is contributed by producers whose largest deliveries are made in the spring and summer months. There are wide differences among the several districts of the milkshed as to the proportions of dairies with different patterns of seasonal production. In general, a relatively high proportion of the producers in the areas far from New York have uneven summer dairies (that is, their largest deliveries of milk are made in the second or the third quarter, their smallest deliveries are made in the first or the fourth quarter, and the ratio of the deliveries in their low quarter to the deliveries in their high quarter is less than 70 percent). In the areas near New York, a relatively high proportion of the producers have even or winter dairies (that is, the ratio of the deliveries in their low quarter to the deliveries in their high quarter is 70 percent or more, or their largest deliveries are made in the first or the fourth quarter and their smallest deliveries are made in the second or the third quarter). The proportions of even dairies and winter dairies appear to be somewhat higher among the members of large cooperatives than among the members of local cooperatives or the unorganized producers. There appears to be little, if any, relation of the size of dairies and the butterfat content of the milk to seasonal variations in milk deliveries.

"With respect to the analysis of the several payment plans studied, the following points have been noted: The variation in computed price returns to groups of producers with different seasonal patterns of production was surprisingly small under any of the plans for which analyses were made. The production-adjustment plans changed somewhat the annual returns to the various groups of producers, but the greatest change was only 4 percent. Application of the base-rating plan caused the greatest change in price returns. By modifying the base period, even greater effects on returns could be obtained. Each of the plans used in this study benefited the even producers whose largest deliveries were made in the third quarter of the year, and under three of the four forms of payment the summer producers received slight benefit. Each of the four forms of payment resulted in lower returns to the winter and spring producers."

**Reducing truck mileage in retail milk delivery**, J. A. HITCHCOCK (*Vermont Sta. Bul.* 491 (1942), pp. 12, figs. 3).—The findings are reported for a study in Burlington and Winooski, Vt., of the refrigeration facilities of stores and homes, the savings that would result from the delivery of milk only on alternate days, and the possibilities of consolidating milk delivery routes. Some of the findings were:

The average daily purchases of milk and weekly purchases of cream were 1.9 qt. and 0.65 pt., respectively, of which 18 and 32 percent, respectively, were purchased at stores. "Approximately nine-tenths of the storekeepers of the two cities, handling a little more than nine-tenths of the milk and cream sold through stores, stated that they had the facilities necessary to handle their receipts on an every-other-day delivery basis, though some indicated that such a scheme would be inconvenient." Seventy-five percent of the homes had mechanical refrigerators, 21 percent ice refrigerators, and 4 percent no refrigerators. "On the basis of a study of truck travel in a sample area it is estimated that at least four-fifths of the present truck mileage in house-door

delivery of milk is unnecessary. However, a complete consolidation of routes would require a very drastic reorganization of the milk distribution system, and probably could not be accomplished except by the establishment of a monopoly of the business in the hands of one agency."

**Production credit in Florida citrus and vegetable areas, J. W. REITZ** (*Florida Sta. Bul. 367 (1942), pp. 102, figs. 3*).—"This study is primarily concerned with borrowing operations of growers who obtained operating capital in the 1937-38 season, together with a consideration of the problems and policies of various agencies providing funds. . . . To obtain data for this study 1,000 citrus and vegetable growers were interviewed, 389 of whom borrowed for production purposes. Of 653 citrus growers interviewed 25.3 percent borrowed for production purposes as compared with 47.1 and 71.8 percent, respectively, for 102 citrus-truck and 245 truck growers. Records covering receipts, expenses, and borrowing operations as well as other information pertaining to the farm business were taken only from those growers and farmers who borrowed for production purposes during the 1937-38 crop season. Thus there are included in the study 165 citrus, 48 citrus-truck, and 176 truck records. Information on practices and policies were obtained from 151 lending agencies including commercial banks, production credit associations, shippers, brokers and commission firms, cooperative marketing associations, direct government agencies, and merchants." The sources of cash loans, the cost of such loans by source, the cost for secured and unsecured loans and according to term and size, the variation in terms by source of loans, security requirements, relation of equity in business to security requirements, life insurance as security, and budgeting and repayments of loans are discussed. The size and purpose of merchant loans, the cost of merchant credit, and secured merchant loans and their relation to term and cost are also discussed. Other subjects dealt with are installment credit, miscellaneous credit problems of growers, loans unpaid, lending operations of cash credit agencies and merchants, and credit practices and policies of merchants.

Some of the findings were: The 398 growers obtained \$917,193 in production loans, of which 72.1 percent was advanced by cash lending agencies. The average size of loan was \$1,815 and \$724, respectively, for cash lending agencies and merchants. "Citrus producers who borrowed obtained 40.5 percent of their cash expenses as compared to 48.6 percent for truck growers. Production credit associations furnished 35.2 percent, cooperative marketing associations, including the Growers Loan and Guaranty Company, 27.2 percent, banks 16.1 percent, and independent marketing agencies 14.3 percent of the cash credit obtained by 301 of the 389 growers who borrowed from cash sources. The remaining 7.2 percent was furnished by direct Government agencies." The average interest rate on cash loans was 5.3 percent, varying from 6.9 charged by banks to 5 percent charged by production credit associations. "When costs such as inspection and legal fees are included the effective interest rate on all loans was 5.9 percent. The effective rate for the Growers Loan and Guaranty Company was 7.2, banks 7.1, Florida Citrus Production Credit Association 6.6, local production credit associations 6.0, independent shippers 6.0, and cooperatives 5.4 percent." Approximately 75 percent of the cash loans were secured, but only 26.4 of the merchant loans. Eighty-three percent of the merchant credit was for fertilizers, 7.5 for seed, and 9.8 for spray and dust, grove care, and miscellaneous purposes. The effective interest rate was 22.8 percent on fertilizer loans and 7.7 percent on other types of merchant credit. Citrus growers obtained fertilizer credit at an effective rate of 13 percent as compared with 24.3 percent for truck growers.

Seventy-two of the 389 borrowers expressed dissatisfaction with the credit system. "Banks reported that 0.2 percent of their loans to growers were normally charged off. The respective figures for production credit associations, cooperatives, and independent shippers were 0.3, 1.3, and 5.0 percent." The normal losses on advances reported by different types of merchant firms were: Hardware and machinery 7.3, fertilizer 4.5, and general farm supplies 4.7 percent.

**Use of credit by cotton farmers, Hardeman County, Tennessee, 1940.** W. S. ROWAN and B. H. LUEBKE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 136 (1942), pp. III+34, figs. 35*).—"This study was undertaken to analyze the use of farm credit in cotton type-of-farming areas where the credit system has been geared to a one-crop system." Farm credit schedules were obtained from 51 farms. The area and the sample farms are described. The data are analyzed and discussed under the headings of amount and distribution of credit, real estate loans, and short-term credit—cash loans, merchant credit, open book accounts, and installment credit.

The average debt for farmers in the survey was \$570 per farm. One-third had no indebtedness, and nearly 50 percent no debt or less than \$100. The ratio of indebtedness to value of real estate, equipment, and livestock was 19 percent for the farms having indebtedness. Of credit, 75.6 percent was real estate mortgages, 14.9 chattel mortgages, 4.5 installment credit, 2.9 personal notes, and 2.1 percent open accounts. Nearly 62 percent of the real estate loans were incurred to buy farms. The average interest rates were: Real estate loans 4.7 percent, short-term cash loans 9.2, open accounts 11.5, and installment credit 12 percent on the original balance and 23 percent on the average unpaid balance.

**Farm credit agencies in a cotton county, 1940.** W. S. ROWAN and B. H. LUEBKE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 137 [1942], pp. III+19, figs. 8*).—"This second report on the study noted above discusses and analyzes the lending agencies operating in the county. The order of importance was commercial banks 32.4 percent, Federal land bank 31.5, individuals 15.8, Farm Security Administration 7.2, merchants 6, Production Credit Association 4.5, insurance companies 1.6, and emergency and crop loans 1 percent.

**Estimation of income tax revenue and incidence.** C. G. HILDBETH (*Iowa Sta. Res. Bul. 300 (1942), pp. 777-822, figs. 2*).—"This is an evaluation of a method of estimating the yields and incidence of various possible types of income tax—that of dividing the population into income brackets and estimating the number of people and average tax in each bracket.

**Organization and operation of New Mexico cooperative cotton gin associations.** R. P. CALLAWAY (*New Mexico Sta. Bul. 293 (1942), pp. 35, figs. 3*).—"The data upon which this study was based were obtained largely from the financial reports and records of these associations. The number and the location of cooperative gins, membership and number of patrons, volume of cotton ginned, etc., are described. Analysis is made of the sources of capital, capital investment, assets and liabilities, members' equities, and of operating results from 1938-39 to 1940-41. More detailed analysis is made for the 1940-41 season of the volume of business, sources of income, expenses of ginning, relation of volume ginned to net income from ginning, and distribution of earnings.

During the 1940-41 season 15 cooperative associations operated 18 of the active gins in the State and did nearly 60 percent of the total ginning. The average capital investment per association was over \$40,000. Members' equities for all the associations were 77 percent of the value of all assets. The net income of 8 identical associations, 1938-39 through 1940-41, averaged \$2.34 per 500-lb. bale, of which less than one-third was derived from ginning proper.

Patronage dividends averaged \$1.99 per bale, of which \$1.23 was paid in cash and 76 ct. credited to patronage equity accounts or issued as certificates. In 1940-41 nearly 40 percent of both the gross and net incomes came from the sale of cottonseed, 23 percent of the gross and 3 percent of the net income from bale cotton sales, and 18 percent of the gross and 32 percent of the net income from ginning and sterilization. The net income per \$1 of sales was for bale cotton 1.7 ct., cottonseed 12.4 ct., ginning 21.7 ct. per \$1 of revenue; handling bagging and ties 22 ct. per \$1 of sales and 31 ct. per pattern. Ginning expenses (13 associations) averaged \$3.21 per 500-lb. bale in 1940-41. Of the net income, 82.5 percent was used for patronage dividends, 9.5 percent credited to surplus, 5 percent for interest payments, and the remainder for dividends on stock, reserves, donations, and bad debts.

**Cotton marketing practices in selected local markets in Louisiana, H. W. LITTLE and R. A. BALLINGER** (*Louisiana Sta. Bul.* 345 (1942), pp. 27, figs. 2).—Information related to the 1940-41 cotton marketing season was collected by personal interviews from 184 cotton growers and 52 cotton buyers in 8 markets in the northern and central parts of Louisiana. The average production of cotton per grower, the market outlets used by growers, the factors related to the choice of outlets, marketing practices of growers, their knowledge of quality and market conditions, and the practices of local cotton buyers are analyzed and discussed. Some of the findings and conclusions were that "30 percent of the producers had no knowledge of the quality of their cotton when they sold it and another 25 percent knew only what the buyer told them concerning the grade and staple length of their bales. . . . While nearly one-half of the producers had available current information concerning the price of futures and the spot prices of middling  $1\frac{5}{16}$ -in. cotton, only 7 percent had access to information regarding premiums and discounts for various grades and staple lengths." Nearly 50 percent of the total volume of purchases in the local markets studied were made by independent buyers, over 40 percent by salaried buyers, and about 10 percent by persons buying on commission. "Practically all buyers at least made an attempt to determine the grade and staple length of a bale of cotton before purchasing it. However, it seems probable that a considerable proportion were not able to do this very accurately. About three out of every five local buyers interviewed had no means of checking their work against official grade standards or staple types. Most of the other buyers had access to the standards for only a few of the more common grades and staple lengths."

**Marketing central Oregon and Klamath Basin late-crop potatoes, D. B. DELOACH and G. R. SITTON** (*Oregon Sta. Bul.* 400 (1941), pp. 36, figs. 3).—"The purpose of the study was to determine the extent the marketing methods affected the quality of the product offered to the consumer and the manner in which the marketing methods influenced the character of consumer demand and the cost of marketing." Information was obtained by survey from 67 retail stores in the San Francisco Bay area, 65 in Portland, 25 in Eugene, and 17 in Salem, Oreg. A representative sample of each grade of Oregon potatoes handled by each store was graded by an inspector of the Oregon State Department of Agriculture. The production of and market for late potatoes are described. The San Francisco Bay area potato market, the markets of the three Oregon cities, and potato sales to governmental agencies are discussed, as well as the quality deterioration after shipping point inspection, the efforts to maintain quality, and marketing methods and marketing costs.

"Breakage, light greening, dry rot, and soft rot were found in a high percentage of the samples of potatoes taken in the several markets surveyed. A combina-

tion of these defects that developed after shipping point inspection was of sufficient importance to cause 65.1 percent of the samples from the San Francisco Bay markets to be below the grade designated on the original container. Comparable percentages for Portland, Salem, and Eugene were 47.6, 36.8, and 22.2, respectively. . . . The principal causes for deterioration in quality were rough handling that resulted in an excessive amount of broken and shattered potatoes, improper storage (temperature, air circulation, and stacking) that caused dry rot and soft rot, and improper display in the retail stores in which potatoes were exposed to light for too long a time that resulted in light greening. . . . The authors feel that, exclusive of waste from deterioration, the cost of marketing potatoes is not out of line with the cost of the services rendered by the dealers. Hand-to-mouth buying by the urban consumers has increased the costs of marketing by shifting risks and financing to the producer or to the middleman."

**Operating practices on the farmers' section of the French Market in New Orleans, Louisiana,** W. R. DANIEL and R. A. BALLINGER (*Louisiana Sta. Bul. 347 (1941), pp. 26, fig. 1*).—The use made of the market, the value of loads sold, time spent on the market by growers, types of buyers preferred, Government market reports and inspection service, truck-jobbers' sales on the market, the operations of buyers, etc., are discussed.

Analysis of the value of produce handled is made in tables showing the number of loads of different commodities offered on the market in 1939 and the percentages of each commodity coming from different districts. Some possible ways of improving the services of the market are suggested.

Nearly 85 percent of the 1,776 individuals qualified to sell on the market in 1939 operated farms in the 10 parishes surrounding New Orleans. The average area devoted to fruits and vegetables was 28.5 acres. The market was the sole outlet for fruits and vegetables for over 1,000 farmers, about 60 percent of the total number using the market. Less than 11 percent of the farmers sold as much as 50 percent of their produce elsewhere.

**The Baton Rouge City Abattoir: Relation to the retail meat supply, production and marketing problems of farmers,** J. M. BAKER (*Louisiana Sta. Bul. 351 (1942), pp. 20, fig. 1*).—The purpose of this bulletin "is to ascertain the extent to which the Baton Rouge abattoir has achieved the objectives for which it was established, to show its relation to the retail meat supply and to the local livestock industry, to give information which would help to determine whether the plant should be continued in operation, and to show the advantage of uniting the operation of the abattoir with other marketing units needed by the farmers. . . . Information was obtained from 46 local meat dealers concerning the sources of their meat supply and their opinions of the value of the Baton Rouge City Abattoir to the meat trade, the farmer, and the consumer. . . . Data concerning the operation of the city abattoir were obtained from the manager of the abattoir and from records on file at the city hall. Personal interviews with managers of abattoirs and with local meat dealers were used as a means of obtaining information from them." The volume and kinds of livestock slaughtered, the cash earnings and expenses, amount and sources of the earnings and the operating costs, the use of the abattoir by retail meat dealers, the sanitary condition, and the need for the abattoir and of a cooperative or quasi-cooperative farmers' market, with a number of activities, including the city abattoir, are discussed.

**Cooperative manufacture and distribution of fertilizer by small regional dry-mix plants,** J. H. LISTER (*U. S. Dept. Agr., Farm Credit Admin. Cir. 126 (1941), pp. [4]+102, figs. 10*).—The rise, present development, and methods of

operation of the Farmers' Cooperative Fertilizer Purchasers, Inc., Kenbridge, Va., the Tennessee Valley Fertilizer Cooperative, Decatur, Ala., and the Central Farmers' Cooperative, Inc., Selma, Ala., are discussed. Analysis is made for each of the sales, costs of materials, operating expenses, gross operating income, departmental operations, unit costs of operation, distribution of income, and financial condition. Appendixes include the articles of incorporation and bylaws of the three associations.

"These three regional-type associations have provided an economical fertilizer service for their members by making available at reasonable cost fertilizer of good quality adapted to the needs of the areas served."

**Corn futures: Volume of trading, open contracts, and prices from January 2, 1936, to December 30, 1939** (*U. S. Dept. Agr., Statist. Bul. 74* (1941), pp. 151, fig. 1).—This bulletin is the fourth (*E. S. R.*, 77, p. 718) presenting corn futures data on volumes of trading, open contracts, and prices published by the Commodity Exchange Administration, formerly the Grain Futures Administration. "All statistical data presented in this bulletin on volume of trading and open contracts have been compiled from reports furnished the Commodity Exchange Administration by the clearing members and the clearing associations of the exchanges. The price data are from the official quotations of the Chicago Board of Trade for transactions in 'round lots' of 5,000 bu. or multiples thereof. In a few instances these quotations have been supplemented by data secured from brokerage houses."

**World corn production and trade**, H. H. CONRAD (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Foreign Agr. Rpt. 5* (1942), pp. [2]+49, figs. 19).—This review of world corn production and trade covers the period 1925-39 and is limited as far as possible to corn as a grain. Statistics are presented and discussed on world production and trade. The position that corn occupies in the economy, before the outbreak of World War II, of the countries in North America, South America, Europe, Africa, Asia, and Oceania is described and discussed.

"During the first 5 yr. of the period the United States accounted for about 55 percent of the total world outturn, but during 1935-39 the combined production of the other countries averaged slightly above the United States crop. International trading in corn was considerably stimulated during the period, particularly in Asiatic countries. Exports from Indo-China and Manchuria were expanded, and Japan became an increasingly important import market. The increased world demand for corn resulted largely from its high value as livestock feed, but the utilization of this grain for human food accounted for a sizable share of the world consumption, especially by native farmers of Africa, South America, and Asia. Furthermore, in the latter part of the period the mixing of corn flour with wheat flour was required in several countries as a means of stretching wheat supplies."

**"New World" wheat agreement**, G. P. BOALS (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Agr. in Americas*, 2 (1942), No. 8, pp. 148-150, figs. 2).—A brief statement of some of the provisions of the agreements signed by Argentina, Canada, the United States, Australia, and Great Britain and announced July 2, 1942.

**Foreign Agriculture, [June-September 1942]** (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Foreign Agr.*, 6 (1942), Nos. 6, pp. [2]+209-253, figs. 15; 7, pp. [2]+255-298, figs. 5; 8, pp. [2]+299-320; 9, pp. [2]+321-342).—Included are articles as follows: No. 6, British Food Administration, by M. Ogdon (pp. 209-226) (see p. 130), and Venezuela's Agricultural Problem, by K. H. Wylie (pp. 227-253); No. 7, North Caucasus—A Russian Granary, by L. Volin (pp. 255-264); The Food Supply of India, by W. I. Ladejinski, (pp. 265-281),

United States-Peruvian Reciprocal Trade Agreement, by L. C. Nolan (pp. 282-294), and Wartime Farm Labor Supply in the United Kingdom, by M. E. Long (pp. 295-298); No. 8, Continental Europe's Prewar Food Balance, by J. H. Richter (pp. 299-312), and Yerba Maté, by L. C. Nolan and J. L. Wooster (pp. 313-319); and No. 9, International Agreements for the Control of Farm Surpluses, by L. A. Wheeler (pp. 321-325), Wartime Distribution of Agricultural Machinery in the United Kingdom, by M. E. Long (pp. 326-328), and Australian Wheat Stabilization, by M. E. Wright (pp. 329-339). Notes are included on pages 340-341 on The International Wheat Agreement, United States and Canada Collaborate in Harvest Work, and The Second Inter-American Conference of Agriculture.

**Crops and Markets, [May and July 1942]** (*U. S. Dept. Agr., Crops and Markets*, 19 (1942), Nos. 5, pp. 105-128, figs. 2; 6, pp. 129-164, figs. 2).—Each number includes general crop reports, reports on specific crops, reports of farm labor wages, prices received by farmers for farm products, stocks of grains on farms, etc., and market reports for cotton, dairy and poultry products, feed, grain, and livestock and livestock products.

**Prices of farm products in Iowa, 1851-1940**, N. V. STRAND (*Iowa Sta. Res. Bul.* 303 (1942), pp. 905-998, figs. 26).—This is a local farm price series for Iowa, beginning with 1850.

## RURAL SOCIOLOGY

**Statistics of family composition in selected areas of the United States, 1934-36.—X, Los Angeles, California** (*Fed. Security Agency, Social Security Bd., Bur. Res. and Statis. Mem.* 45 (1942), pp. XXVIII+308).—Data are presented from the study of family composition in the United States, based on the National Health Survey, made in 1935-36 by the United States Public Health Service.

**The rural population resources of Missouri**, C. E. LIVELY and R. B. ALMACK (*Missouri Sta. Bul.* 444 (1942), p. 75).—In this study the authors found that the State of Missouri could use little more than half of the farm-reared males in the occupation of farming without increasing the number of farms and farmers. The proportion varied from two-thirds in the northwestern section to two-fifths in the Ozark area.

**Adjustment of population to rural resources in Missouri**, C. E. LIVELY. (Univ. Mo.). (*Jour. Land and Pub. Util. Econ.*, 18 (1942), No. 1, pp. 67-76, figs. 2).—The author discusses the relationship of population and land in the State. Included are trends in population growth, population fertility in relation to growth, population movements, rural resources, migratory labor, and the relation of health to population.

**Beaverdam: A rural community in transition**, A. D. EDWARDS (*Virginia Sta. Bul.* 340 (1942), pp. 64, figs. 12).—This report describes a rural community in central Virginia. Some topics presented are the economic base of the community and population trends and living conditions in the community. Also discussed are community organization, changing functions of local government, and the role of Negroes in the life of the community.

**Comparison of representation in administrative agencies with natural neighborhoods and communities, Roane County, Tenn.**, C. E. ALLRED, H. J. BONSER, and L. S. STITH (*Tennessee Sta., Agr. Econ. and Rural Sociol., Dept. Monog.* 138 (1942), pp. [3]+47, figs. 29).—This is an analysis of 52 white and 2 Negro natural neighborhoods in the county.

**"Members of committees and boards and the county officials are concentrated in the towns. Agricultural representation is unequally distributed. . . . Women would be expected to furnish a more important share of the leadership and**

representation in the county. There is a concentration of representatives along the highways and at other accessible locations."

**Reorganization of public welfare in Michigan**, E. B. HARPER and D. L. GIBSON (*Michigan Sta. Spec. Bul.* 318 (1942), pp. [1]+80, figs. 5).—This is a study of a major local institution, public poor relief, in the process of adjusting to changed conditions. The investigation centered around four sample counties shortly before reorganization took place and was aimed at discovering the condition factors as well as the nature and degree of the adjustment that actually occurred.

By way of practical application of the findings, it is concluded that welfare reorganization in Michigan must be viewed as a continuous process, to be effective must be based upon public opinion in the local community, and, finally, where the emergence of new problems and conditions and the demands for efficiency indicate the need for change, must be preceded by community re-education. Efforts at intellectual instruction should be directed particularly at changing emotional beliefs and popular ideas and at demonstrating the relation of the new program to obvious local needs and accepted values. In addition it should be aimed specifically at rural elements in the population and based on a thorough knowledge of rural social psychology and customs.

**Zoning land for recreation**, G. S. WEHRWEIN and H. A. JOHNSON. (Univ. Wis.). (*Jour. Land and Pub. Util. Econ.*, 18 (1942), No. 1, pp. 47-57).—This is a stock taking of 10 yr. of the recreational use of land in Oneida County, Wis.

**Parent-adolescent adjustment, its measurement and significance**, L. H. STORR. (Nebr. Expt. Sta.). (*Character and Personality*, 10 (1941), No. 2, pp. 140-150).—In an extension of the author's study (E. S. R., 85, p. 267), a new family life questionnaire of 150 items was constructed with particular reference to such matters as the degree of mutual confidence between the parents and their adolescent children, the amount of family cooperation and joint activity, and the extent of good fellowship, congeniality, and companionship within the family group. This questionnaire, which could be answered in terms of three responses—F (frequently), O (occasionally), and R (rarely or never)—together with other scales and questionnaires, was administered to 490 young people between 13 and 20 yr. of age, with a mean of 15.4 yr., and about evenly divided as to sex, living on farms and in small farm communities in a single county in the State and attending small community high schools. The methods used in the analysis of the material are described, with a discussion of the significance and interpretation of the findings.

"The significance of this study lies in its emphasis on the importance of the individual parent-child relationship. It stresses the fact that every child in the family occupies a unique position and assumes a unique role in family interaction, and that slight original differences in temperament or motivation soon become important differences, as roles are assumed and practiced in the daily contacts of family and social life. Because of these differences, the same general family situation might constitute very different effective environments to different children in the family. Hence, it is quite important that the parent make a study of, and gain insight into the unique individual problem of each child, if he is to be successful in achieving happy and helpful relationships with all his children."

## AGRICULTURAL AND HOME ECONOMICS EDUCATION

**Supervised practice in vocational agriculture in Iowa**, H. P. SWEANY and J. A. STARRAK (*Iowa Sta. Bul.* P29, n. ser. (1941), pp. 32, figs. 3).—"This bulletin presents the findings of an investigation, the major purposes of which were

(1) to identify the chief factors which apparently contribute to the success of the more effective programs of supervised farm practice now in existence in Iowa, and (2) to ascertain the methods employed by the instructors in the development and maintenance of their programs. Twenty-four of the 128 high schools in Iowa offering courses in vocational agriculture during the school year 1937-38 were selected because of the relatively high quality of their supervised farming programs. The specific technics employed by the instructors in these selected schools in the organization and supervision of the respective supervised farm-practice programs were investigated in considerable detail."

Some of the more important findings were: "Three of the four commonly recognized types of supervised farming practice are represented in the programs of the 24 departments investigated, i. e., the productive enterprise project, the improvement project, and the supplementary farm practice. The fourth type, placement for farm experience, is apparently nonexistent in these programs." Of the 17 objectives of supervised farming programs scored by teachers, the 5 receiving the highest scores were "to establish boys in farming, to improve farming methods used on the individual home farm and in the community as a whole, to develop an interest in farming as an occupation, to provide a means of earning for the boys, to develop methods of economical production."

Parents were the greatest single source of financial aid in establishing the projects, and intelligent cooperation of parents was considered an important factor in the success of the programs. Twenty-three of the 24 departments included in the investigation had Future Farmer chapters. Only 51 percent of the boys had complete control over the management of their projects. Long-time planning of the program is essential if the objective "establishment in farming" is to be realized. Instructors made frequent use of class time and activities in planning and promoting the programs of their students. "The purposes for which the instructors most frequently visited the boys on their home farms were as follows: (1) To encourage the boy and increase his interest, (2) to teach some important principle or technic, (3) to assist with the discovery and solution of problems encountered, and (4) to check upon methods being used in the projects. The practices most frequently employed by instructors to develop and maintain interest in supervised farming programs were as follows: (1) Project tours, (2) showing at fairs, (3) promotion through ranks of Future Farmer chapters, (4) news items in local papers." Considerable cooperation in marketing products and buying seed and breeding stock and also in their production were reported.

**Farm market outlets for home industries** (*Arkansas Sta. Bul.* 417 (1942), pp. 13-14).—A brief report of a study by I. C. Wilson on reasons for success or failure of home demonstration club, farmers' curb, and handicraft markets in the State.

**The impact of war on experiment station research in home economics**, S. L. SMITH. (U. S. D. A.). (*Jour. Home Econ.*, 34 (1942), No. 7, pp. 447-453).—A paper presented before the research department of the American Home Economics Association at its 1942 convention.

**Introduction to meteorology**, S. PETERSSSEN (*New York and London: McGraw-Hill Book Co.*, 1941, pp. IX+236, figs. 142).—Intended for students without previous acquaintance with the subject, this text was written in response to a demand for a nontechnical book to serve the many short and elementary courses in meteorology already in progress in the United States.

**Plant biology**, P. WEATHERWAX (*Philadelphia and London: W. B. Saunders Co.*, 1942, pp. VI+455, figs. 182).—This book has been prepared in an attempt to present a college course providing the cultural values expected of an intro-

duction to a science and at the same time serving as a satisfactory groundwork for more technical advanced courses in botany.

### FOODS—HUMAN NUTRITION

[Foods and nutrition research by the Texas Station] (*Texas Sta. Rpt. 1941*, pp. 24-25, 85-87).—This is a progress report (E. S. R., 86, p. 267) of studies, some of which have been noted elsewhere, on variations in the vitamin content of foods, by G. S. Fraps, W. W. Meinke, and A. R. Kemmerer; the chemical and physical factors responsible for tendering meat during cooking, by S. Cover; processing of canned meat, by Cover, H. Schmidt, and R. D. Turk; and the mineral composition of vegetables grown in representative regions of Texas and the relation of variation in mineral content to the probable nutritive value, by J. Whitacre [et al.] (Coop. U. S. D. A. et al.).

The forty-sixth report on food products and the thirty-fourth report on drug products, 1941, E. M. BAILEY ET AL. (*Connecticut [New Haven] Sta. Bul. 460 (1942)*, pp. 423-456).—This annual report (E. S. R., 86, p. 550), summarizing the results of regulatory examinations for the calendar year 1941, includes data on the lead content of milk, the ascorbic acid content of rose hips (0.17 mg. per gram for *Rosa multiflora*; 1.4-6.0 mg. per gram for *R. rugosa*), and an abstract of a paper by H. J. Fisher on Sugar and Its Substitutes.

[Meat studies of the Missouri Station] (*Missouri Sta. Bul. 444 (1942)*, p. 63).—This progress report (E. S. R., 83, p. 269) for the year ended June 30, 1939, includes studies by J. A. Cline, M. C. Hayes, and R. Staggs on the relation of U. S. grades of beef to the palatability of porterhouse steaks and the effect of constant oven temperatures upon the palatability and cooking losses of commercially cured hams.

Digestion characteristics of various types of milk compared with human milk, F. J. DOAN and J. L. DIZIKES (*Pennsylvania Sta. Bul. 428 (1942)*, pp. [1]+18, figs. 5).—The curd characteristics and digestibility of different types of milk were determined by an in vitro method based on that of Doan and Flora (E. S. R., 81, p. 736), but modified (1) to eliminate the tryptic digestion, (2) to provide for carrying out the digestion with artificial gastric juice in thin-walled rubber tubes subjected to a definite rhythmic squeezing action simulating peristalsis, and (3) to provide for gradual lowering of the pH during the digestion period to conform with what is known to occur in the infant stomach. The various curd-size fractions present in the milk at zero digestion time and after the first, second, and third hour of digestion were hardened to prevent breakup by treatment with formaldehyde and were then separated by a series of screens and a filter paper. The amounts of the various sized curds were determined, not by weighing, since this was shown to introduce errors due to variable protein hydration, but by nitrogen determination. The procedure is described in detail, and the digestion apparatus is described and illustrated. The results of digestibility analyses on a number of different types of milk are presented as a bar graph which makes it possible to visualize the curd characteristics and progressive changes during digestion and to compare one type of milk with another, as well as with breast milk utilized as a standard of comparison. Lactic acid milk or buttermilk (pH 4.5 or lower), evaporated milk, and superheated soft-curd milk were found to exhibit excellent digestibility characteristics and are considered particularly suitable for artificial feeding of infants. Next to these and in descending order of suitability for infant use were lactic acid milk (pH 5.4-5.7), boiled milk, homogenized milk, metaphosphate-treated milk, chocolate milk, trypsin-treated milk, and goat's

milk, the last four being only slightly more digestible than ordinary milk. Milk treated with locust bean gum was detrimentally affected.

**More milk for more children** (*U. S. Dept. Agr., Misc. Pub. 493 (1942), pp. 8, figs. 9*).—An informational publication regarding the purpose, operation, the requirements, etc., of the school milk program of the Agricultural Marketing Administration.

**Butter and margarine**, R. M. LEVERTON. (*Univ. Nebr.*). (*Jour. Home Econ.*, 34 (1942), No. 4, pp. 240-241).—Food value for the money expended (in the present illustration 25 ct.) is calculated for butter, fortified margarine, and other foods. At the prices listed and as far as vitamin A is concerned, it is pointed out that green, thin-leaved vegetables, such as chard, and yellow vegetables, such as carrots, are more economical sources of vitamin A than either butter or margarine, and that the two latter may be equally economical, depending on their relative vitamin A potency and their relative cost.

**Wheat in national diets**, M. K. BENNETT (*Wheat Studies, Food Res. Inst. [Stanford Univ.], 18 (1941), No. 2, pp. 35-76, figs. 6*).—This study presents a statistical investigation of the place of wheat in the national diet of 52 nations (1933-38) and changes in the position of wheat between 1923-28 and 1933-38. The population of the 52 nations constituted some 88 percent of the world total in 1935. Calories from cereals and potatoes constituted as little as 30 percent of the total food calories in some countries and as much as 90 percent in others. The relative importance of this group of foods was largely determined by income status so that the ratio of cereal-potato calories to total food calories was in itself a rough index of income status and a rougher index of quality of diet. Wheat contributed less than 5 percent of the total food calories in several countries, mostly oriental or tropical, and as much as from 40 to 50 percent in others. In the United States and some 17 other countries, wheat dominated among the cereal-potato foods, furnishing over half—even up to 75 percent in some nations, including the United States—of the cereal-potato calories. In other countries rice, rye, or corn was dominant. The interrelated factors of climate, food preference, and income status seemed to explain these preferences. Changes in national per capita disappearance of wheat flour from 1923-38 to 1933-38 were in some instances of large magnitude and usually difficult to explain. They did not tend toward equalization of divergent levels.

**Why enrichment of flour?** A. E. TAYLOR (*Wheat Studies, Food Res. Inst. [Stanford Univ.], 18 (1941), No. 3, pp. 75-108, fig. 1*).—This paper "is devoted to a discussion of the background of the problem of enrichment or fortification of foods with vitamins and minerals and the reasons which have prompted our Government to take a formal step in enrichment of wheat flour by permitting the addition of specified amounts of thiamin, nicotinic acid, riboflavin, and iron."

**Milk solids and enrichment—an experimental enquiry**, H. H. MITCHELL, T. S. HAMILTON, and J. B. SHIELDS. (*Univ. Ill.*). (*Bakers Digest*, 16 (1942), No. 9, pp. 185-186, 199, figs. 3; also essentially in *Milk Plant Mo.*, 31 (1942), No. 6, pp. 24-29, figs. 3).—This address gives the findings of a biological comparison of nine breads, each fed as the sole diet except for a supplement of cod-liver oil, to young growing rats that were observed for growth response and analyzed to determine their storage of minerals and vitamins. The breads, prepared according to specifications, were designed to compare the nutritive quality of milk breads (white bread, enriched white bread, and whole-wheat bread, each made with 6 percent milk solids) with the nutritive quality of enriched white bread and whole-wheat bread.

"The presence of milk solids in the bread formula, or of added calcium salts, brought about a more complete calcification of the bones. Milk solids in bread, as compared to enriched bread, induced a greater store of riboflavin in the body.

Whole-wheat bread behaved similarly. Milk solids, although contributing very little niacin to a bread formula, seemed to improve the retention within the animal body of niacin added as such to the bread. Although containing more iron than unenriched milk-solids bread, neither enriched bread nor whole-wheat bread induced a greater concentration of hemoglobin in blood. The thiamin content of rats raised on unenriched milk-solids bread was distinctly less than that of rats raised on whole-wheat or enriched breads." It is concluded that the best breads contain both the enriching elements and milk solids.

**Home canning of fruits, vegetables, and meats**, L. STANLEY, M. STEINBARGER, and D. SHANK (*U. S. Dept. Agr., Farmer's Bul. 1762, rev. (1942), pp. [2] + 48*).—This revision of the publication noted previously (*E. S. R.*, 76, p. 419) is directed toward meeting the limitations imposed by present restrictions of supplies. Specifically it advises that pressure canners be shared, notes the war-time types of glass jars and bottles available, emphasizes the need for using jars on hand and for reusing screw bands, and outlines adaptations toward adjusting to the sugar allowance under the rationing system. In the latter case it is suggested that fruits be canned in their own juice or in thin or medium sirup or even in water. It is pointed out that honey may be used to replace up to one-half and corn sirup up to one-third of the sugar called for in canning.

**The use of calcium chloride in the home canning of whole tomatoes**, Z. I. KERTESZ (*New York State Sta. Cir. 195 (1942), pp. 3, fig. 1*).—Since recent tests (*E. S. R.*, 83, p. 302) have shown that this treatment causes a much better retention of the firmness and shape of the tomatoes, the application of this procedure to the home canning of tomatoes is recommended, particularly late in the season when the tomatoes mature and soften and tend to fall apart during processing. In the procedure described whole tomatoes are prepared for canning in the usual manner and placed in quart jars. Before the tomato juice is added to the jar, 1 teaspoonful of a  $\text{CaCl}_2$  solution containing  $2\frac{1}{4}$  oz. of anhydrous  $\text{CaCl}_2$  in 1 pt. of water is added. The jar is then filled with tomato juice and processed. This amount of  $\text{CaCl}_2$ , about 10 gr. per quart jar, approximates the proportion (0.07 percent) permitted under the food laws if declared. When the process is used with small Italian-type tomatoes which are just ripe, the tomatoes usually retain enough of their firmness to be used in winter salads.

**Canning with a pressure cooker**, H. CHARLEY and R. D. NOERS (*West Virginia Sta. Cir. WS 7 (1942), pp. [8], fig. 1*).—This nontechnical leaflet for housewives describes pressure cookers of different types and gives general directions for their use, with a time table and specific directions for canning several nonacid foods.

**Home preparation and preservation of fruit and vegetable juices**, D. K. TRESSLER and C. S. PEDERSON (*New York State Sta. Cir. 194 (1942), pp. 20, figs. 9*).—Two types of juices are considered, namely, cloudy or natural juice prepared by pressing the ground or crushed fruit in coarse cloths, and pulpy juice prepared by forcing pulp and juice of the fruit through a corrosion-resistant metal screen. For preparing the cloudy juice, three types of presses are described and illustrated, these being (1) the screw (barrel) press available in several sizes, (2) the nutcracker type press for small quantities, and (3) a press utilizing an ordinary hydraulic automobile jack and other materials usually available on the farm. Construction details and dimensions are given for the latter press, with approximate capacity of 1 bu. of fruit. For preparation of pulpy juice the tapered press or extractor, electrically or hand-operated, and the centrifugal extractor are described. The latter press serves for making small amounts of juice for immediate consumption from the more solid vegetables and fruits. The general principles of preparation, including hot or cold

extraction, and of preservation by freezing or heat sterilization (pasteurization) are discussed. Particular emphasis is given to the necessity for rapid and prompt handling through all procedures. Detailed directions are given for making and preserving apple, grape, cherry, raspberry, plum, and blended-fruit juices; and tomato juice (and blends), sauerkraut, rhubarb, carrot, celery, beet, and turnip juices.

**Drying foods for victory meals** (*U. S. Dept. Agr., Farmer's Bul. 1918 (1942), pp. 11+14, figs. 3*).—This publication, bringing together information to date on methods for home drying of fruits and vegetables, stresses the importance of this method of preservation as a wartime measure for conserving sugar, metals, rubber, and other materials. Consideration is given to the importance of speed in the process, the kinds of fruits and vegetables to dry, general directions concerning preparation for drying, equipment for steaming, methods of drying, containers and conditions for storage, and preparation for table use. Specific instructions on how to dry individual foods are given for 10 fruits and 13 vegetables.

**Food from the garden**, H. V. TAYLOR, J. C. DRUMMOND, and M. PYKE (*Nature [London], 148 (1941), No. 3763, pp. 712-714*).—This report is based on records for 1940 of crop yields obtained by seasons from 98 vegetable gardens planted according to the cropping scheme issued by the Ministry of Agriculture (Great Britain) in 1939. Quantities of vitamins A and C furnished by these crops were estimated by seasons. A fairly even supply of vegetables was secured, with the larger quantities available during the winter months. It appeared probable that the vitamin C requirement and a substantial proportion of the needs for vitamin A for a family of five would be supplied throughout the year with crop yields such as those obtained in the present test of the cropping scheme.

**Food investigations in Canada** (*Nature [London], 149 (1942), No. 3766, pp. 27-28*).—This is a summary of the research program at the food laboratories of the National Research Council of Canada as affected by the war. Brief progress reports are included on poultry, eggs, pork, and bacon.

**British Food Administration**, M. OGDON (*U. S. Dept. Agr., Foreign Agr. Relat., Foreign Agr., 6 (1942), No. 6, pp. 209-226*).—This report discusses the functions and organization of the Ministry of Food, Great Britain, and the decentralization of some of its activities by the formation of divisional food offices; acquisition and control of supplies, including control of agricultural production and supplies, commodity marketing schemes for milk control and for the control of the oil and fat industry; consumer price control; developments in method of food rationing, including points rationing scheme, differential rationing for heavy workers, consumer supplies in air raids, social aspects of rationing, and education and enforcement. Numerous references are given as footnotes and literature citations.

**Biological symposia, VII**, edited by J. CATTELL (*Lancaster, Pa.: Jaques Cattell Press, 1942, vol. 7, pp. VIII+322, pl. 1, figs. [84]*).—This symposium (edited by H. Klüver) deals with Visual Mechanisms. The sections on The Photochemistry of Visual Purple, by A. C. Krause (pp. 23-41); Visual Systems and the Vitamins A, by G. Wald (pp. 43-71); and Anoxia in Relation to the Visual System, by E. Gellhorn (pp. 73-85) (Univ. Ill.) are of particular interest.

**Nutrition in national defense**, F. G. BOUDREAU (*Amer. Jour. Pub. Health, 31 (1941), No. 9, pp. 977-983*).—This is a summary of the papers and discussion of the round table on nutrition in national defense at the 1941 conference of the Milbank Memorial Fund.

**The selection of foods for between-meal feeding in industry**, H. H. HAGGARD and L. A. GREENBERG (*Jour. Amer. Dietet. Assoc., 17 (1941), No. 8, pp.*

753-758).—Earlier recommendations of the authors that food for between-meal feeding in industry need fulfill only two requirements—(1) that it supply carbohydrate (not less than 30 mg.) and (2) that it put no burden on digestion—have been supplemented by a third requirement—(3) that it contain both minerals and vitamins. Canned natural fruit juices are considered to fulfill these requirements and to have the advantage of being easily served in the factory. To determine the relative values of different fruit juices in raising the blood sugar, six adult male subjects were given 225 cc. of the fruit juice in question. The concentration of sugar in the blood was determined at half-hour intervals for 4 hr. Three series of determinations were made on each of the six subjects. The average basal concentration was 96 mg. percent, and the average increase above this level for the different fruit juices amounted to 81 mg. percent for pineapple juice, 53 for unsweetened orange juice, 76 for sweetened orange juice, 49 for unsweetened grapefruit juice, 72 for sweetened grapefruit juice, and only 22 mg. percent for tomato juice. In comparison, the increase in blood sugar following the ingestion of 30 gm. of dextrose in 225 cc. of water was 88 mg. percent.

**Nutrition in relation to pregnancy and lactation,** J. E. BECKER, H. J. BICKERSTAFF, and N. J. EASTMAN (*Amer. Jour. Pub. Health*, 31 (1941), No. 12, pp. 1263-1270).—In this paper, presented at the 1941 meeting of the American Public Health Association, the authors consider in some detail the daily allowances for specific nutrients during the latter half of pregnancy and lactation adopted by the committee on food and nutrition of the National Research Council and review the literature on which these allowances were presumably based. The need for sound dietary advice and practices throughout these periods is emphasized, with the comment that "the taking of a detailed dietary history several times during pregnancy, followed by suggestions and help in the making of necessary changes, would seem as important a procedure in the management of pregnancy as the physical examination and medical history."

**Hospital diets** (*War Dept. [U. S.], Tech. Man. No. 8-500, pp. 309*).—This manual, prepared in the interest of standardizing the construction of menus and the preparation of diets in military hospitals, is intended to simplify the problems of ordering and preparing diets suitable for average patients under normal conditions and for specific cases. The diets, designed to meet the normal requirements of station or hospital, are compiled from various sources. No attempt is made to discuss diets in detail. The several chapters deal with the normal diet and its modifications; therapeutic and special diets; instruction pamphlet data for patients; and menus. The appendix presents tables on food composition, weights and measures, liver recipes, and recipes for diabetics.

**Anthropometric and orthopedic examinations: A technique for use with children,** M. P. BAUM and V. S. VICKERS (*Child Develpmt.*, 12 (1941), No. 4, pp. 339-345).—The methods followed in the department of child hygiene of the Harvard School of Public Health in taking body measurements and in making observations of posture of infants and children are described, with emphasis on the recognition and handling of the psychological problems of children. These are discussed in four age groups—young infants, older infants from 15 to 24 mo., children from 2 yr. to those in the third or fourth grade of school, and older children. The order in which body measurements are taken is listed, and the measurements included are described briefly.

**Mass studies in human nutrition: Nutritional status of children in a college community,** P. B. MACK, J. M. SMITH, C. H. LOGAN, A. T. O'BRIEN, A. H. STEWART, and P. DODDS. (*Pa. State Col. et al.*). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 2, pp. 69-78, figs. 24).—The results of a study by the methods described previously (E. S. R., 82, p. 130) of the nutritional status of a group of 147 intermediate grade school children in a college community were compared

with those of a group of children of the same age in a small industrial city (E. S. R., 86, p. 858). As judged by physical examination, 20 percent of the children in the college community fell in the highest class as compared with none in the industrial community, 77.2 as compared with 30.8 percent in class 2, and 2.8 percent in class 3, and none in classes 4 and 5 as compared with 69.2 percent for the three lower classes combined. Similar differences, though varying in degree, were found in the results for the separate tests for various aspects of nutritional status. In weekly intakes of various foods by all income classes combined, the corresponding values for the college and industrial groups, respectively, were milk 4.2 and 2.8 qt., meat 8.9 and 3.3 servings, eggs 2.9 and 2.3 in addition to those used in cooking, citrus fruits 4.9 and 2.6 servings, other fruits 7.9 and 4.9, potatoes 6.9 and 5, green vegetables 4.9 and 4.1, yellow vegetables 2.8 and 1.7, and tomatoes 3.8 and 2.2 servings, and bread 27.3 and 48.3 slices, respectively. Comparing the food intakes of the same income groups, "there was a higher intake of these foods throughout all income groups of the college community which was believed to be associated with the greater community attention to nutrition problems in the former community. Even in this community, however, all children were not in optimum nutritional well-being, showing that even among more privileged families there is still room for improvement in the feeding of growing children."

**An assessment of the nutrition of a rural population in Tennessee, J. B. YOUMANS** (*Amer. Jour. Pub. Health*, 31 (1941), No. 7, pp. 704-708).—In the present investigation records of food consumption are obtained by field workers on a family and individual basis, using a week's inventory record for the family and three daily records per week for each individual. The assessment of the physical condition is based on a full medical history, a complete physical examination for signs of deficiency disease, and laboratory tests for detecting subclinical and latent as well as frank cases of deficiency. The laboratory tests for all of the subjects include "(1) a test of visual adaptation to dark using Hecht's adaptometer; (2) the concentration of vitamin C and that of inorganic phosphorus, calcium, and phosphatase in the blood; (3) the total serum protein, serum albumin, and globulin; and (4) the red cell count, hemoglobin, and hematocrit determination. In addition, vitamin B<sub>6</sub> excretion in the urine, the concentration of vitamin A in the blood, a bacteriologic test of free nicotinic acid in the blood, a measure of prothrombin concentration as an index of vitamin K deficiency, and a slit-lamp examination for evidence of riboflavin deficiency have been done on a large number of the subjects." Roentgenograms of the wrists and ankles for the customary clinical interpretation and for measurements of bone density with a photoelectric cell densitometer are also included.

The results to date show a high incidence of a deficiency of calories, protein deficiency among adults and older children, iron deficiency anemia among children and women, a high incidence (over 50 percent) of vitamin A deficiency, a 20 percent incidence of vitamin C deficiency, and low incidence of vitamin B<sub>1</sub> and vitamin D deficiency.

**The interrelation of calcium and fat utilization in the growing albino rat, C. E. FRENCH.** (*Pa. Expt. Sta.*). (*Jour. Nutr.*, 23 (1942), No. 4, pp. 375-384).—In the tests described young rats selected in sets of four from a litter were placed on an experimental regime involving a 4-day preliminary period and a 40-day period of excreta collection, following which the animals were sacrificed for analysis. Each rat of a set of litter mates was fed one of the four synthetic experimental rations. These were so prepared as to provide, when fed in equicaloric amounts, essentially the same contents of protein, salts, calcium, phosphorus, and vitamin supplements, but to contain, respectively, 5, 15, 28, and 45 percent of fat. The first three of these diets permitted excellent growth, and the calcium utilization decreased moderately and consistently in the order

of increasing fat content. Forty-five percent of fat in the diet resulted in less growth and in the excretion of a larger number of fecal pellets; on this diet the utilization of calcium decreased considerably as compared with the utilization on the other diets. The most efficient utilization of calcium was obtained from the diet containing 1 gm. of fat to 0.60 gm. of calcium; and the efficiency of the utilization of the calcium decreased in the order of the increase in the ratio of fat to calcium in the diets. The utilization of the calcium paralleled the acidity of the intestinal tract, the most efficient utilization accompanying the most acid reaction, which pH determinations showed to result from the 5-percent fat diet. The data are discussed in relation to various theories concerning the physiological relationship between fat and calcium.

**The effect of honey upon calcium retentions in infants,** E. M. KNOTT, C. F. SHUKERS, and F. W. SCHLUTZ (*Jour. Ped.*, 19 (1941), No. 4, pp. 485-494, figs. 3).—Calcium balance studies on 14 healthy male infants less than 6 mo. old were made for a total of 120 metabolism periods in which the infants received milk formulas employing different types of milk, varying levels of vitamin D, and either corn sirup or honey as the source of carbohydrate. Magnesium balance, as reported earlier (Ea S. R., 87, p. 596), was determined simultaneously in 89 of the metabolism periods involving 9 infants. Low calcium intakes tended to limit calcium retentions, but high intakes did not insure high retentions; the lowest calcium retentions occurred when 0.120 gm. of calcium per day was given with irradiated milk (and no additional vitamin D); retentions of calcium at low levels of vitamin D (up to 170 International Units per day) were higher with the evaporated milks, especially evaporated lactic acid milk, than with dried half-skim milk; but with high levels of vitamin D (from 680 to 1,000 I. U.) retentions were highest with the dried milk. In paired periods in which honey and corn sirup were used as sweetening agents in formulas given to the same infant, it was observed that calcium retentions were always higher with the formulas containing the honey. The increased retentions when honey was fed occurred both with low and with high intakes of vitamin D, and regardless of the type of milk fed or the use of lactic acid. It is concluded that honey is a type of carbohydrate well suited to the infant's needs and probably deserves a wider use in infant dietaries.

**The nutritional importance of choline,** W. H. GRIFFITH (*Jour. Nutr.*, 22 (1941), No. 3, pp. 239-253).—In this review the author discusses the relation of choline and of protein to liver lipides in older rats; of choline, cystine, and methionine to liver lipides in older rats; of choline to methylation of homocysteine, to hemorrhagic degeneration in young rats, to thiamin and other vitamins of the B complex, to phospholipid turnover in the liver, and to manganese in the prevention of perosis in birds; other effects of choline; relation of choline to unidentified dietary factors concerned with the metabolism and transport of lipides; and the daily requirement of choline in young rats. An extensive list of literature references is appended.

**The significance of choline as a dietary factor,** C. H. BEST (*Science*, 94 (1941), No. 2449, pp. 523-527).—An abbreviated version of a paper given at the University of Chicago fiftieth anniversary celebration, September 1941.

**Quantitative distribution of phosphorus and calcium in certain fruits and vegetables,** H. C. SHERMAN and M. S. RAGAN (*Jour. Nutr.*, 23 (1942), No. 3, pp. 283-292).—For most of the foods considered in this study, analyses were made of from 4 to 10 entirely separate specimens as obtained in city markets supplied from widely varied sources. In blackberries, currants, and raspberries, respectively, the seeds, constituting about 24, 17, and 15 percent of the weight of the fruit, showed about 6, 8, and 3 times as high a percentage of phosphorus as the flesh. The phosphorus content differed appreciably, therefore, depending upon

whether the edible portion was analyzed with or without the seeds. In the Flame Tokay grapes studied the percentage of phosphorus in the seeds was 3 times that in the flesh, but the seeds constituted so small a proportion (2.4 percent) of the whole fruit as scarcely to influence the average composition. Tomatoes, okra, and summer squash, with seed contents amounting, respectively, to about 3.5, 14, and 32 percent of the weight of the fruit, contained, respectively, about 15, 25, and 56 percent of their total phosphorus in the seeds. The phosphorus content of the edible portion, therefore, was measurably influenced by the inclusion or exclusion of the seeds. Pods and seeds of cowpeas and several varieties of beans, including samples at various stages of maturity, were analyzed for calcium and phosphorus. With increasing maturity, the seeds showed an increasing concentration of phosphorus and contained as high as from 90 to 97 percent of the total phosphorus, while the calcium concentration and content increased progressively in the pods. Separate analyses of the leaves, edible stems, and flower buds of broccoli showed a definite concentration of phosphorus in the flower buds and a still more pronounced concentration of calcium in the leaves. There was a well-marked concentration of calcium in the septa of oranges as compared to the reamed juice; the latter, even though containing the softer portions of the pulp, contained only 27 percent of the calcium of the edible portion.

**Potassium in animal nutrition**, E. ORENT-KEILES and E. V. MCCOLLUM (*Jour. Biol. Chem.*, 140 (1941), No. 2, pp. 337-352, fig. 1).—A diet adequate in all other respects but containing only 0.01 percent K was prepared from purified foodstuffs. Rats on this diet showed roughened and thinning fur, a striking alertness, and a marked pica; grew slower than normal but lost no weight; showed lower food consumption and different water intake than the controls; and showed disturbances in fertility and reproductive behavior, which were, however, possibly due to inanition rather than K deficiency. Metabolic studies of the balance of N, Ca, P, Mg, Na, K, and Cl indicated that in spite of the low K intake the deficient rats were in equilibrium with respect to this element. Mg storage was 2.5 times greater in the rats on the K-low diet, and the Cl balance in these rats was negative. Tissue analyses showed that in the K-deprived rats the K in the muscle was lowered and Na was increased, which was exactly the opposite of the control tissues. K was also lower in the heart and kidney.

**The effects of the substitution of bicarbonate for chloride in the diet of rats on growth, energy, and protein metabolism**, L. VORIS and E. J. THACKER. (Pa. Expt. Sta.). (*Jour. Nutr.*, 23 (1942), No. 4, pp. 365-374).—Paired feeding experiments were conducted with rats on a synthetic diet with normal chloride content (0.28 percent) and with rats on the same diet in which the chlorides of the salt mixture were replaced by equivalent quantities of the corresponding bicarbonates. The chloride-deficient ration contained 0.02 percent chloride and 0.49 percent bicarbonate. "In comparison with the rats receiving the normal chloride ration, the chloride-deficient rats showed depression of appetite, increased consumption of water, increased heat production, and diminished body gain of nitrogen and energy. There was a smaller percentage gain of water on the basis of fat-free tissue, and the ratio of water gained to protein gained was significantly lower with the chloride-deficient rats than with the normal controls. The prevailing deficiency of chloride ion did not affect the digestion and absorption of nutrient energy but did prominently affect its disposal within the bodies of the rats."

**Social implications of vitamins**, R. R. WILLIAMS (*Science*, 94 (1941), Nos. 2447, pp. 471-475; 2448, pp. 502-506).—An address given at the fiftieth anniversary celebration of the University of Chicago, September 22, 1941.

**[Vitamins studies of the Missouri Station]** (*Missouri Sta. Bul.* 444 (1942), pp. 7-10, fig. 1).—This progress report (E. S. R., 87, p. 145) for the year ended

June 30, 1939), includes, in addition to work noted from other sources (E. S. R., 85, p. 851; 86, p. 422), studies on cataract in rats and on the adequacy of a milk ration, both by A. G. Hogan, L. R. Richardson, J. G. Lee, and E. L. Powell.

**The effects of various vitamin supplements and of whole yeast on the digestion and absorption of the carbohydrate of a complete diet.** R. A. RUSSELL and E. S. NASSET (*Jour. Nutr.*, 22 (1941), No. 3, pp. 287-294, fig. 1).—In experiments conducted on adult dogs with jejunostomies, it was demonstrated that fresh yeast has a distinctly stimulatory effect on gastrointestinal motility, which is often but not always accompanied by increased rates of digestion and absorption of carbohydrate; that dried yeast and a 50-percent alcohol-soluble extract of dried yeast have no effect on motility but increase by about 20 percent the rate of digestion and absorption; and that of the pure vitamins of the B complex now available, thiamin, riboflavin, nicotinic acid, and pyridoxin given as supplements to an already adequate basal diet have no effect, but pantothenic acid as calcium pantothenate has a marked effect on the rate of digestion and absorption of carbohydrates. It is suggested that crystalline pantothenic acid may be responsible for at least part of the yeast effect.

**Absorption experiments with vitamin A.** G. A. LEPAGE and L. B. PETT (*Jour. Biol. Chem.*, 141 (1941), No. 3, pp. 747-761, figs. 4).—The absorption of orally administered vitamin A in doses of 10,000 International Units (three subjects) and of 300,000 I. U. (five subjects) was followed by determinations of the vitamin in the blood plasma at stated intervals for 24 hr. and in the feces at the end of the first, second, and third days. These experiments showed that the peak of concentration of vitamin A in the blood occurred on the smaller dosage at from 3 to 5 hr. and on the larger doses at 4 hr., but the highest proportion of the ingested dose accounted for as vitamin A in the blood was only 3.19 percent. In the same subject the amount recovered in the feces was 0.46 percent of the larger dose. Spectrographic investigation of the blood at 4 hr. and the feces for 3 days following the ingestion of 300,000 I. U. of vitamin A by three subjects revealed the presence of a substance the absorption curve of which showed a maximum at 275 m $\mu$ . Evidence was obtained that this substance, which was not present in control blood or control feces extracts or in the vitamin A concentrate used, is an oxidative product of vitamin A.

**Vitamin A in blood and its relation to body reserves.** P. C. LEONG (*Biochem. Jour.*, 35 (1941), No. 7, pp. 806-812, figs. 2).—Three young dogs were used as experimental animals in this investigation, which was divided into (1) a preliminary period of about 4 mo. (starting at 6 weeks of age), during which an adequate diet of known vitamin A content was given, (2) a dosing period of about 2½ mo. in which graded doses of vitamin A were administered and the content of the vitamin in the fasting blood was determined at intervals, and (3) a depletion period of about 16 mo. on a vitamin A-free diet. The total vitamin A intake during period 1 was 26,000 International Units and during the dosing period 56,000, 198,000, and 1,064,000 I. U., respectively.

The blood levels of vitamin A rose gradually during the dosing period and were proportional to the intake. As soon as the supplements were withdrawn the blood levels began to fall until zero levels were reached at 154, 138, and 168 days, respectively. Throughout the entire depletion period no signs of vitamin A deficiency were observed, and the dogs remained in a healthy condition. The female bore five young on the two hundred and seventy-sixth day of depletion, but her milk supply began to fail after about 3 weeks and three of the litter died in a short time. No vitamin A could be detected in their livers. At the end of the depletion period the blood of the three dogs was again examined for vitamin A and none was found. On autopsy the livers contained 70, 50, and 1,370 I. U. of vitamin A, respectively. These results are thought to

indicate that a low or negative A value for the blood of dogs cannot be taken to indicate that the vitamin A reserve is seriously depleted.

The results of the post-mortem examination are reported briefly in an appendix by H. F. Burn.

**Vitamin A deficiency and the nervous system, S. B. WOLBACH and O. A. BESSEY** (*Arch. Pathol.*, 32 (1941), No. 5, pp. 689-722, figs. 15).—The confusion concerning the relation of vitamin A deficiency to lesions of the central nervous system has been cleared by the discovery that if the deficiency occurs at a sufficiently early age it results in a disproportionate growth of the central nervous system with relation to the bony development and consequent mechanical injury to the brain, spinal cord, and nerve roots as a result of pressure. The detailed evidence reported in this paper, with numerous microphotographs of histological sections, is chiefly from experiments on white rats, but confirmatory experiments have been conducted on dogs. The epithelial changes in vitamin A deficiency are entirely unrelated to the presence or absence of the lesions of the nervous system, and the relation between the central nervous system and bone development is not altered in riboflavin and pyridoxin deficiency.

**Vitamin B complex and fat metabolism, J. C. FORBES** (*Jour. Nutr.*, 22 (1941), No. 4, pp. 359-364).—It is reported that in rats on a fat-free diet presumably adequate except for the B vitamins other than thiamin, which was administered as 0.2 mg. of thiamin chloride daily, the administration of either pyridoxin, riboflavin, or calcium pantothenate alone gave no increase in the concentration of neutral fat or cholesterol in the liver over that produced by thiamin alone; that the administration of both riboflavin and pyridoxin increased the neutral fat but not the cholesterol content of the liver; that the further addition of calcium pantothenate increased still further the neutral fat content and raised the content of cholesterol; and that nicotinic acid added to the other supplements produced a very striking increase in the liver cholesterol but not the neutral fat. Choline had a lipotropic action under all of the conditions studied, but the effect was less marked in the animals receiving nicotinic acid than in the other groups. Choline also reduced the amount of cholesterol in the liver but to a less extent in the presence of nicotinic acid.

**The effect of a vitamin B complex deficiency on gastric emptying and small intestinal motility, G. W. HEUBLEIN, W. D. THOMPSON, JR., and J. P. SCULLY** (*Amer. Jour. Roentgenol. and Radium Ther.*, 46 (1941), No. 6, pp. 866-875, figs. 10).—Roentgenographic observations on the dog on diets deficient in vitamin B complex and supplemented with vitamin B<sub>1</sub>, with and without nicotinic acid and riboflavin, are reported and illustrated. These indicate that early in the acute phase of a vitamin B complex deficiency there is a marked delay in the gastric motility and a moderate delay in the motility of the intestines. Other appearances, including atony which later becomes evident throughout the small intestine, more nearly resemble those observed in multiple vitamin deficiency in human adults. Another point of similarity is frequently the immediate partial emptying of the stomach but a delayed emptying time. Nicotinic acid and lactoflavin exerted little, if any, effect on the downward course of the B deficiency. The administration of vitamin B<sub>1</sub> caused a temporary return to normal motility, but complete restitution did not occur until whole yeast was given by mouth. In the opinion of the authors "the treatment of hypomotility of the gastrointestinal tract in vitamin B deficiency demands other factors contained in whole yeast that are not supplied in lactoflavin, thiamin hydrochloride, and nicotinic acid."

**The distribution of nicotinic acid in foods, L. J. TEPLEY, F. M. STRONG, and C. A. ELVEHJEM.** (*Wis. Expt. Sta.*). (*Jour. Nutr.*, 23 (1942), No. 4, pp. 417-423).—

The method of Snell and Wright (E. S. R., 87, p. 12) was found applicable to a wide variety of foods in the determination of nicotinic acid. Preliminary trials indicated that the nicotinic acid was stable to extraction by water, acid, or alkali. For most materials water extraction was satisfactory, but for complete extraction of cereals alkali or acid treatment was necessary. Recovery of nicotinic acid when added to a wide variety of materials ranged from 90 to 110 percent. In general, values obtained by the microbiological assay of dried meat samples agreed very well with those obtained earlier (E. S. R., 87, p. 150) by chemical analysis. The values obtained by the microbiological assay of food mixtures checked with the calculated values based on the assay of each component.

Data, expressed as milligrams percent, are reported for the nicotinic acid content of numerous fruits, vegetables, cereals, and miscellaneous materials. The values for fruits and vegetables, ranging from 0.10 to 2.18, fresh weight basis, indicated that these foods were not very good sources of nicotinic acid; on a dry weight basis carrots (14 mg. percent) and tomatoes (16.5 mg. percent) were the best of this group. Meats in general (15.7–45.5, dry basis), yeast (40–60), and peanut butter (18.6) were excellent sources; milk (0.08) and eggs (hard-boiled white, 0.076, and yolk, 0.035) were poor sources. Of the cereals, corn, oats, and rye (0.90–2.60 mg. percent) were quite low, while buckwheat, barley, and whole wheat were slightly richer (4.5–7.0). Most of the vitamin of the wheat was in the bran (25.7–40.0) and middlings (9.2–17.7), while patent flour contained only 0.80 mg. percent. White bread, enriched white bread, and 100-percent whole-wheat bread contained, respectively, 0.66–0.95, 1.51, and 2.88 mg. percent of nicotinic acid on the fresh weight basis.

The presence of free and combined thiamine in milk, N. HALLIDAY and H. J. DEUEL, JR. (*Jour. Biol. Chem.*, 140 (1941), No. 2, pp. 555–561).—Protein-free filtrates obtained by ultrafiltration of milk contained on an average 25.0 $\gamma$  of thiamin per 100 cc., as determined with the Prebluda-McCollum reagent and as corrected on the basis of the percentage of milk lactose in the ultrafiltrate. Treatment of the ultrafiltrate with phosphatase did not give a higher value for thiamin. Apparently, therefore, none of the thiamin in the ultrafiltrate was in the form of cocarboxylase (also dialyzable), since this would have been broken down by the phosphatase. On the basis of the amount of thiamin directly adsorbable on Superfiltrol, by the method of Emmett, Peacock, and Brown (E. S. R., 85, p. 727), an average value of 23.4 $\gamma$  per 100 cc. was obtained. Preliminary treatment of the milk with phosphatase or takadiastase failed to increase the amount of thiamin determined, but preliminary treatment of the milk with either of these enzymes, aided by a proteolytic enzyme such as papain, gave values indicating an average level of 40.5 $\gamma$  per 100 cc. These results indicated that about 60 percent or less of the thiamin in milk is in the free form, the rest being combined in a nondialyzable form, probably combined with phosphoric acid and protein. The averages for free and total thiamin, 23.4 $\gamma$  and 40.5 $\gamma$  per 100 cc., respectively, were obtained with samples of certified Holstein milk. These respective concentrations in the various milk samples were closely similar, with a coefficient of variation of about 10 percent.

Thiamin in sweat, L. L. HARDT and E. U. STILL (*Soc. Expt. Biol. and Med. Proc.*, 48 (1941), No. 3, pp. 704–707).—Four groups of six college football players each underwent regular football practice, with no additional vitamins (two groups) and with supplements of 50 mg. of thiamin chloride and 750 mg. of ascorbic acid immediately before the practice (two groups). For one of each of these groups the exercise lasted 1 hr. and for the other 1½ hr., after which the subjects returned to a room at 80° F., drank 2 cups of warm tea, and stripped to the waist for collection of sweat from the back and front of the chest. A

10-cc. sample of blood and a complete sample of urine were obtained before and immediately after the exercise. These and the sweat samples were tested for ascorbic acid by indophenol titration and for thiamin by the fluorometric thiochrome method.

In the control groups the thiamin content of the sweat was double that of the urine after both periods of practice, but in both urine and sweat the values were somewhat lower after the longer period. In the supplemented groups the thiamin content of the sweat was 71 times that of the urine after the shorter period of exercise and only 8.5 times greater after the longer period. The thiamin in the blood tended to rise with sweating, particularly in the supplemented groups. The ascorbic acid values showed no marked or consistent changes with exercise. The blood values ranged from 0.53 to 0.84 mg. per liter before and from 0.56 to 0.78 mg. after exercise. The sweat values ranged from 1.76 to 4.66 mg. per liter, with a tendency to be somewhat higher in the supplemented groups and somewhat lower in the unsupplemented following the longer period of exercise.

It is estimated that a man at moderate work and in a moderate temperature may lose in sweat from 5 to 15 percent of ingested thiamin, and at harder work in higher temperature the amount lost may be enough to cause serious physiological consequences.

**Further observations on induced thiamine (vitamin B<sub>1</sub>) deficiency and thiamine requirement of man.—Preliminary report, R. D. WILLIAMS and H. L. MASON (*Mayo Found. Med. Ed. and Res., Proc. Staff Mtgs. Mayo Clinic*, 16 (1941), No. 28, pp. 433-438, fig. 1).**—In continuation of the investigation noted previously (*E. S. R.*, 86, p. 278), 11 subjects were maintained on a diet furnishing between 0.40 and 0.45 mg. of thiamin daily, an amount not much if at all below the levels estimated to be provided in the diets classified as poor in the Stiebeling-Phipard survey (*E. S. R.*, 81, p. 142). Disturbing symptoms developed in 1 subject in 93 days, at which time thiamin was administered. Three of the subjects continued on the low-thiamin diet for 132 days, 5 for 169, and 2 for 196 days. Signs and symptoms of deficiency appeared at varied intervals, with the more active subjects the first to show symptoms. These are described in detail, particularly in comparison with those noted in the earlier report of the effects of complete absence of thiamin.

At the end of the period of restricted thiamin intake, 6 of the subjects were selected for study of thiamin requirements, of whom 3 were given 7.5 mg. of thiamin chloride daily for 37 days, after which all 6 were kept on a constant diet, with thiamin added in increasing amounts at 20-day intervals. Within 6 weeks the amounts excreted in the urine were essentially the same for both groups. The effects of the thiamin became evident only after the intake had reached or exceeded 0.5 or 0.6 mg. per 1,000 calories, and no further benefit was secured above 1 mg. per 1,000 calories. These findings are thought to indicate that "the optimal intake of thiamin of man is not less than 0.5 mg. and not more than 1.0 mg. per 1,000 calories obtained from a diet of ordinary composition."

**The urinary excretion of thiamine as an index of the nutritional level: Assessment of the value of a test dose, H. L. MASON and R. D. WILLIAMS (*Jour. Clin. Invest.*, 21 (1942), No. 2, pp. 247-255, fig. 1).**—This discussion of the value of the test dose procedure or of ordinary 24-hr. excretion of thiamin is based upon data secured in the authors' study of thiamin requirements noted above and here reported in detail. They conclude that determination of the 24-hr. urinary excretion of thiamin usually gives as much information as the test dose procedure, and that either determination alone or the two combined is a valuable laboratory aid in the clinical diagnosis of thiamin nutrition if the

intake of thiamin is properly controlled during the test. A balanced diet containing from 800 to 900  $\mu\text{g.}$  of thiamin is considered suitable for the purpose, and a table is given showing the composition of such a diet. Intramuscular injection of 1 mg. of thiamin chloride is recommended as a satisfactory test-dose procedure.

The data on the urinary excretion of five women following the administration of graded doses of thiamin indicated that 0.4 mg. of thiamin per 1,000 calories of diet represented the minimal requirement for these subjects. At this intake the average 24-hr. excretion of thiamin was 119  $\mu\text{g.}$ , and 21 percent of the test dose was recovered. Excretion of  $100 \pm 10$   $\mu\text{g.}$  or more in 24 hr. and recovery of at least  $20 \pm 2$  percent of the test dose are considered evidence of adequate thiamin nutrition.

**B<sub>1</sub> avitaminosis: Roentgenologic studies of gastrointestinal tract in rats on vitamin B<sub>1</sub> deficiency diets,** J. GERSHON-COHEN, H. SHAY, and S. S. FELS (*Amer. Jour. Roentgenol. and Radium Ther.*, 46 (1941), No. 6, pp. 876-881, figs. 4).—In this work, conducted on rats and tested by introducing the water-barium meal directly into the stomach after an 18-hr. fast period, it was demonstrated that deficiency in vitamin B<sub>1</sub> alone is followed by gastrointestinal hypotonicity, dilatation, and stasis in proportion to the degree of deficiency, and that these changes are not accounted for by the mere loss in weight. No other vitamin than B<sub>1</sub> was studied.

**Studies on nutritional achromotrichia in rats,** K. UNNA, G. V. RICHARDS, and W. L. SAMPSON (*Jour. Nutr.*, 22 (1941), No. 6, pp. 553-563, figs. 3).—In studies conducted on approximately 2,000 black and piebald rats, evidence has been obtained that graying of the fur within from 3 to 7 weeks occurs (in the animals which survive) on a vitamin B complex-free diet supplemented with adequate thiamin, riboflavin, nicotinic acid, pyridoxin, and choline, with no pantothenic acid. Simultaneously with the graying there is a retardation of growth, the fur becomes coarse and scant, the whiskers have a blood-stained appearance, the nose becomes inflamed, and adrenal hemorrhages occur. The addition to the ration of 100  $\mu\text{g.}$  of calcium pantothenate prevents or cures the achromotrichia and the other signs and symptoms. The efficacy of whole dried liver and of rice bran in preventing or curing the achromotrichia was found to be proportional to their content of pantothenic acid, but the growth-promoting effect was greater. Black rats on B complex-free rations supplemented with thiamin, riboflavin, nicotinic acid, pyridoxin, choline, and pantothenic acid have been raised through three generations without graying except for some scattered gray hairs in the second and third generations.

**Inefficacy of hormones in nutritional achromotrichia of rats,** C. W. MUSHETT and K. UNNA (*Jour. Nutr.*, 22 (1941), No. 6, pp. 565-571, fig. 1).—The report of Morgan and Simms (*E. S. R.*, 84, p. 419) that extracts of the thyroid and adrenal cortex have been effective in curing achromotrichia in rats produced on a diet free from the filtrate factor, and of these authors and others that pathologic changes occur in the adrenals of rats maintained on diets deficient in pantothenic acid, led to this study of the effect of hormone administration on pantothenic acid-deficient rats, with particular reference to their influence on adrenal hemorrhage and achromotrichia. Daily administration of 0.25 and 0.5 cc. of adrenal cortical extract, 2.5 mg. of desoxycorticosterone acetate, 1, 5, and 10 mg. of thyroid, and 0.25 and 0.5 cc. of anterior pituitary extract was without effect in the prevention or cure of achromotrichia and also in the prevention of adrenal hemorrhages and other lesions occurring in rats on diets deficient in pantothenic acid.

## TEXTILES AND CLOTHING

**Cross-section-area method for determining density of wool fibers, J. I. HARDY and H. W. WOLF** (*U. S. Dept. Agr. Cir. 654 (1942), pp. 10, figs. 5*).—The method developed consists in measuring the cross-section area of wool-fiber bundles under controlled conditions of temperature, humidity, and pressure. In the instrument designed for the purpose, the bundles of fibers are held in a slot 0.045 in. wide and 0.625 in. deep, and the depth of the fibers in the slot is measured with a thickness gage in thousandths of an inch under a dead-weight load of 5 kg. The new method was found rapid and reliable in a comparison with the gravimetric method A, consisting in weighing 100 fibers and relating their weight to the weight of the entire bundle; gravimetric method B, requiring the calculation of the weight of 100 fibers from the diameter, specific gravity, and length of fibers and relating this weight to the weight of the entire bundle; and a third method in which a bundle was cross-sectioned and each fiber was counted. Reliability was indicated by the fact that the correlation and regression coefficients of this method on actual fiber counts approach unity. With the use of the cross-section-area method about 50 samples can be measured in 8 hr., many more than the number weighed and counted by methods used previously.

**A comparison of the aluminum-chloride and the sulfuric-acid methods for quantitative estimation of wool, L. W. DALE and R. EDGAR.** (*Iowa Expt. Sta.*). (*Iowa State Col. Jour. Sci., 16 (1942), No. 3, pp. 391-397*).—The aluminum chloride and the 70-percent sulfuric acid methods for estimation of the wool of cellulose admixtures were compared for their effect on the weight, ash, total sulfur, and sulfate sulfur of plain woven-wool washed and extracted prior to treatment. The results are interpreted as indicating that the 70-percent sulfuric acid method is the better of the two.

**The serviceability of garments as affected by varietal and regional differences in cotton fibers and methods of harvesting** (*Texas Sta. Rpt. 1941, p. 88*).—A comparison of Acala and Rowden cottons, by M. A. Grimes, is briefly noted.

**Synthetic fibers and textiles, H. M. FLETCHER** (*Kansas Sta. Bul. 300 (1942), pp. 40, figs. 18*).—This popular bulletin gives information as to the nature of the raw materials and the methods of manufacture involved in making the various synthetic fibers; comments on the properties that make these fibers suitable for use in place of or along with the natural fibers; and discusses the matter of finishing to deluster, shrinkproof, mildew-proof, fireproof, prevent slippage, and render crease resistant and water repellent. The methods of caring for synthetic textiles, dictated by the physical and chemical properties of the fibers themselves, are discussed from the standpoint of dry cleaning, washing, and ironing. The serviceability of the fabrics under the action of light and heat and the influence of wear and cleaning is discussed. This information is based on laboratory tests which served to predict the relative usefulness of the various textiles, including those from natural fibers, synthetic fibers, and synthetic-natural fiber mixtures.

**Central notations of ISCC-NBS color names, D. NICKERSON and S. M. NEW-HALL.** (*U. S. D. A. et al.*). (*Jour. Opt. Soc. Amer., 31 (1941), No. 9, pp. 587-591, fig. 1; also in Amer. Dyestuff Rptr., 31 (1942), No. 12, pp. P292-P296, fig. 1*).—The central notations for the Inter-Society Color Council-National Bureau of Standards color names were developed to meet the need for color designations "sufficiently standardized to be acceptable and usable by science, sufficiently broad to be used by science, art, and industry, and sufficiently commonplace to be understood, at least in a general way, by the whole public." . . . The terms light, medium, and dark designate decreasing degrees of lightness, the adverb 'very' is added to extend the lightness scale to 'very light' and 'very dark.' The

adjectives weak, medium, strong, vivid, designate increasing degrees of saturation.

"In order that the unwieldy adjective combinations shall not be required, the following terms have been substituted for certain descriptions: Pale as a substitute for light, weak; brilliant as a substitute for light, strong; moderate as a substitute for medium, medium; dusky as a substitute for dark, weak; deep as a substitute for dark, strong. . . . These terms are used to modify the following hue or limited hue range names: Pink, red, orange, brown, yellow, olive, green, blue, purple, and combinations of these terms formed by using two of them, as in blue green, or an -ish suffix with one, as in purplish pink. For the neutral series the terms white, gray, and black are used." The abbreviations to be used for these color designations are given. Munsell notations for the ISCC-NBS central colors are here presented for the first time.

## HOME MANAGEMENT AND EQUIPMENT

**Farm families of two Vermont counties, their incomes and expenditures.** M. MUSE (*Vermont Sta. Bul.* 490 (1942), pp. 48, figs. 4).—"This bulletin deals with the composition, income, and living expenditures of rural-farm families of Chittenden and Franklin Counties in Vermont's Champlain Valley. There was an average of four persons in the 1,012 families studied in this area who were headed by native-born husbands and wives. In 41 percent there were either three or four members, in 24 percent two, in 22 percent five or six, and in 13 percent seven or more. For the 960 families who received no 'relief,' the total family incomes averaged \$1,217 (\$700 cash, \$517 nonmoney income). There were less than \$250 in 3 percent, less than \$500 in 9, less than \$750 in 25, and less than \$1,000 in 46 percent of the cases; \$2,000 or more in 11 and \$2,500 or more in 5 percent of the cases. The cash living expenditures for 538 families averaged \$707; one-half of them were less than \$632, one-third less than \$500, and almost two-thirds less than \$750. The lowest tenth of the living expenses ranged from \$149 to \$335 and averaged \$266, while the highest tenth ranged from \$1,171 to \$2,200 and averaged \$1,482. Childless couples spent \$621, parents and one child \$659, and those with two children \$696. Slightly more than half of the families increased their proprietorship during the year, the increase amounting for the average family to \$25. . . . Food expenditures averaged \$252 per family, or 36 percent of the total cash spent for family living. Family use of the automobile and clothing each accounted for 11 percent and household operation for 10 percent of the total, while 12 other classes of items did for less than 1 to 6 percent. As the income rose, the amounts spent for food increased, regardless of family composition, and the percentages of total expenditures claimed by it tended to decrease."

**Family spending and saving as related to age of wife and age and number of children.** D. MONROE, M. Y. PENNELL, M. R. PRATT, and G. S. DEPUY (*U. S. Dept. Agr., Misc. Pub.* 489 (1942), pp. [4]+126, figs. 3).—"This investigation of family spending and saving concerns families in small cities and villages and on farms in the Middle Atlantic and North Central region. The facts about income and consumption were obtained from schedules collected for the consumer purchases study in 1935-36 (*E. S. R.*, 84, pp. 717, 856). Summary tables showing ways of spending for each income class (\$500-\$999, \$1,000-\$1,499, \$1,500-\$1,999, \$2,000-\$2,999, \$3,000-\$4,999, and \$5,000 or over) for each of the 16 family-composition groups in each of the three types of communities are presented, together with tables giving greater detail concerning the distribution of certain expenditures. The data are discussed only with reference to village families. It is pointed out, however, that the intergroup differences found in

villages tend to be repeated in the farm and urban samples. Analysis of the data showed that the ways of using family funds differed with age. Families in which the wife was under 30 spent more of their income and saved less and had a greater tendency to spend more than they made than families in which the wife was 60 or more years. Clothing and personal services, the automobile, furnishings and equipment, recreation, and tobacco took a larger share of the funds of the younger families than of the older group, but the latter just about balanced the difference by the greater money value of the year's housing, household operation, food, gifts, and welfare. "Since patterns of consumption do not change rapidly in normal years, the ways of income use shown by this report provide a reasonably accurate picture of financial management practices of families throughout the latter half of the thirties up to the period immediately preceding the war, when changes in the price level and anticipated shortages affected family spending."

**Studies in family life**, L. S. STOTT (*Nebraska Sta. Rpt.* [1941], p. 78).—A progress report.

**"Ready for school,"** D. DICKINS (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, pp. 1, 6).—It is emphasized that getting ready for school means more than attending to the clothing supply, and involves correcting physical defects and eating more adequately. The relation of these factors to scholarship and deportment was shown by a survey in five elementary schools in one county in Mississippi. Scholarship and deportment records of the pupils were studied in relationship to the physical examination records. It was found that only about 15 percent of the children rated as poor students were in excellent physical condition, and that nearly twice as many children were rated as having fair or poor deportment in the group having poor physical condition as in the group having good physical condition. The most common defect was in the gums and teeth, and next most common were poor condition of throat and glands.

## MISCELLANEOUS

**Serving Arkansas agriculture: Fifty-third Annual Report [of Arkansas Station, 1941]**, [W. R. HOBLACHER] (*Arkansas Sta. Bul.* 417 (1941), pp. 47, figs. 6).<sup>2</sup>

**Agricultural investigations: Work of the [Missouri] Agricultural Experiment Station during the year ending June 30, 1939**, M. F. MILLER, S. B. SHIRKY, H. J. L'HOTE, ET AL. (*Missouri Sta. Bul.* 444 (1942), pp. 106, figs. 6).<sup>2</sup>

**Mississippi Farm Research, [August 1942]** (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 8, pp. 8, figs. 5).—In addition to articles noted elsewhere in this issue, this number contains *Our Stake in Program of Price Control*, by R. J. Welch (pp. 1, 2); and *Forecasts of Good Harvest for This Year's Farm Crops* (p. 8).

**List of available publications of the United States Department of Agriculture**, F. L. ZIMMERMAN and P. R. READ (*U. S. Dept. Agr., Misc. Pub.* 60, rev. (1942), pp. [1]+I+227).—This is a revision (*E. S. R.*, 62, p. 497) to January 2, 1942.

<sup>2</sup> The experimental work not previously referred to is for the most part noted elsewhere in this issue.

## NOTES

---

**Georgia Station.**—A total of 17 employees are now in the armed service. Thomas S. Boggess, Jr., assistant chemist, has accepted a position with the U. S. Department of Agriculture at the Georgia Coastal Plain Station. Dorothy Mad-dox has been succeeded as nutritional laboratory assistant by Mary Renfroe.

**Mississippi College and Station.**—Dr. James E. Adams has been appointed superintendent of the Delta Substation vice H. C. McNamara, who died last April. T. E. Ashley, associate professor of horticulture and associate horticulturist, has been appointed superintendent of the South Mississippi Substation vice Dr. J. C. Robert, retired, and has been succeeded by Troy H. Jones.

**New Mexico College and Station.**—Drs. G. N. Stroman, associate agronomist, and E. Cooper Smith, assistant chemist, have been granted leave of absence for military service. R. P. Callaway, associate agricultural economist, has resigned to accept a position with the U. S. D. A. Agricultural Marketing Service and has been succeeded by Morris Evans. K. A. Valentine has been appointed assistant animal husbandman.

**Cornell University and Station.**—The retirements are noted of R. S. Hosmer, head of the department of forestry, and George N. Lauman, professor of rural economics.

**Pennsylvania College and Station.**—Dr. F. F. Lininger has been appointed director of the station as of October 1. Dr. S. W. Fletcher, dean of the School of Agriculture, will continue as its chief executive officer in charge of instruction, research, and extension.

Members of the station staff in military service include Drs. Alex Black and A. L. Voris, assistant professors of animal nutrition; C. E. French, instructor in animal nutrition; M. K. Goddard, assistant professor of forestry; H. B. Musser, professor of experimental agronomy; and Dr. H. N. Worthley, professor of economic entomology. Drs. G. E. Brandow and H. R. Cottam, assistant professors of agricultural economics and rural sociology, respectively, are serving with the U. S. Office of Price Administration. Carl Wild, assistant professor of landscape architecture, is engaged in work in connection with defense housing.

**Vermont University and Station.**—Dr. H. R. Varney, extension agricultural economist, has been appointed assistant dean of the College of Agriculture and assistant director of the station and extension service. Dr. W. R. Adams, associate professor of botany and associate botanist, has been granted leave for military service. Dr. N. N. Allen has been appointed associate professor of dairy production and associate animal and dairy husbandman. Margaret M. Cowles, assistant in home economics research, has resigned to accept a position as dietitian in Houston, Tex.

**Association of Land-Grant Colleges and Universities.**—In addition to the general officers noted on page 4, the following section officers were elected at the Chicago meeting of October 28-30, 1942: Agriculture, L. E. Call of Kansas, chairman, W. W. Clark of Wisconsin, vice chairman, and W. G. Taggart of Louisiana, secretary; engineering, H. A. Curtis of Missouri, chairman, and S. S. Steinberg of Maryland, secretary; home economics, Nora A. Talbot of Oklahoma, chairman, Laura W. Drummond of Pennsylvania, vice chairman, and Florence Harrison of Missouri, secretary; and graduate work, W. C. Russell of

New Jersey, chairman, and J. C. Jordan of Arkansas, secretary. Within the section of agriculture, the subsection of experiment station work elected L. D. Bayer of North Carolina as chairman, and C. R. Orton of West Virginia, secretary; the subsection of resident teaching, J. G. Lee, Jr., of Louisiana, chairman, and A. M. Eberle of South Dakota, secretary; and the subsection of extension work, P. O. Davis of Alabama, chairman, and B. H. Crocheron of California, secretary.

In general, expiring assignments to the standing committees were filled by new appointments, but no changes were made in the joint committee on publication of research or in the special committees on relationships, accrediting, and preservation of phosphates and their national use. On the committee of college organization and policy J. L. Morrill of Wyoming and John S. Millis of Vermont succeeded A. C. Willard of Illinois and C. E. Friley of Iowa; on instruction in agriculture Edwin G. Woodward of Connecticut replaced Cornelius Betten of New York; on instruction in engineering N. A. Christensen of Colorado and Joseph Weil of Florida succeeded H. A. Curtis of Missouri and L. J. Lassalle of Louisiana; and on instruction in home economics Marie Dye of Michigan and Wylle B. McNeal of Minnesota succeeded Frances Zull of Wisconsin and Lita Bane of Illinois.

The committee on experiment station organization and policy was enlarged by the appointment of four additional members. In addition to the secretary of the experiment station subsection and the Chief of the Office of Experiment Stations, *ex officio*, it now consists of the following: W. H. Martin of New Jersey, R. E. Buchanan of Iowa, P. S. Burgess of Arizona, and Agnes Fay Morgan of California for 4 years; C. E. F. Guterman of New York, Noble Clark of Wisconsin, Jessie W. Harris of Tennessee, and Clarence Dorman of Mississippi for 3 years; Edmund Secrest of Ohio, J. A. Hill of Wyoming, Mary M. Clayton of Maine, and C. H. McDowell of Texas for 2 years; and M. J. Funchess of Alabama, E. C. Johnson of Washington, R. B. Corbett of Maryland, and Margaret S. Fedde of Nebraska for 1 year. Its subcommittee on home economics was unchanged except that Mary W. Clayton of Maine replaced Esther L. Batchelder of Rhode Island.

On extension organization and policy H. C. Saunders of Louisiana succeeded E. E. Scholl of Oklahoma for 1 year, and P. O. Davis of Alabama and Claribel Nye of California were named for 4 years vice D. W. Watkins of South Carolina and Azalea L. Sager of Oregon. On military organization and policy E. O. Holland of Washington was reappointed for 1 year, and J. W. Harrelson of North Carolina and Alfred Atkinson of Arizona were named for 3 years, the former vice H. C. Byrd of Maryland. N. W. Dougherty of Tennessee succeeded M. L. Enger of Illinois on the committee on engineering experiment stations.

The special committee on radio received two new members, H. J. C. Umberger of Kansas and R. M. Green of Colorado, vice J. W. Harrelson of North Carolina and W. W. Clark of Wisconsin. H. H. Hume of Florida replaced G. D. Humphrey of Mississippi on the committee of land-grant institutions for Negroes, and C. B. Hutchison of California became a delegate to the American Council on Education vice F. M. Hunter of Oregon.

As to the special committees for 1943, F. E. Balmer of Washington retired from that on rural youth. Additional committees were set up as follows: Soil survey, Richard Bradfield of New York, chairman, W. H. Pierre of Iowa, and L. D. Bayer of North Carolina; post-war problems, E. J. Kyle of Texas, chairman, T. W. Schultz of Iowa, and W. I. Myers of New York; and training for Government service, C. E. Friley of Iowa, chairman, F. C. Smith of Tennessee, and C. L. Christensen of Wisconsin.

# EXPERIMENT STATION RECORD

VOL. 88

February 1943

No. 2

---

## RESEARCH AT THE 1942 CONVENTION OF THE ASSOCIATION OF LAND-GRANT COLLEGES AND UNIVERSITIES

The research program of the 1942 convention, held in Chicago last October (E. S. R., 86, p. 1), inevitably reflected the impacts of the war. Although research agencies are likely to be associated in the public mind primarily with the problems of peace, when hostilities threaten they are immediately confronted with new responsibilities and opportunities. Particularly is this true of public service institutions such as the State experiment stations. Under these circumstances the annual conventions of a body such as the Association of Land-Grant Colleges and Universities are first of all occasions for group consideration of the new situations and adjustments which they entail.

Expressed in general terms, the immediate problem becomes one of effective mobilization for the emergency. This situation was well depicted by Director C. B. Hutchison of California in a paper presented before a joint session of the sections of resident teaching experiment stations, and graduate work. Speaking on the topic *How May Research, the Undergraduate, and the Graduate Programs Be More Effectively Coordinated for the War Effort*, he pointed out that these agencies "know as well as anyone, and perhaps better than most, that in the present situation we cannot possibly have 'education and research as usual.' They have pledged their resources, their man and woman power and facilities, totally to the Nation in this crisis. They want these resources used. They are ready to set aside until this war shall have been brought to a successful conclusion any of the things they have been doing and undertake others if only they can be assured that this is their best contribution to the general cause."

Each institution, in his opinion, must determine its own means of effecting the necessary coordination with the war effort. In the case of the stations he maintained that in times of peace their programs "are designed to afford the factual basis for the advancement of agriculture and the enrichment of rural life. To accomplish these ends we direct our efforts to the discovery of facts which when assembled,

synthesized, and translated into practice will advance the efficient and economical production, protection, processing, distribution, and utilization of foods and fibers and promote the protection and conservation of the Nation's resources, human as well as natural, which are used in doing these things. These are appropriate agricultural research war aims, too, in a total war, although emphasis may need to be shifted from certain lines of work to others in the immediate future if we are to aid agriculture most in the gigantic tasks it is being called upon to perform. In general, we shall need to give more attention to immediate needs and less to those of long-term significance, for unless we win this war long-term research will be of little consequence. It is not likely that anything which may be done this year or next on some of our so-called long-time basic projects will have much, if any, effect upon the outcome of the war. On the other hand, it is quite possible that important contributions to the food production programs and the promotion of better nutrition among the people may result from efforts directed toward the diagnosis, assembling of information already extant, synthesis, filling in gaps here and there through short-time approach, and translation of it all, as rapidly as may be possible, into practice."

In a further discussion of the same topic, Dean I. O. Schaub of North Carolina drew attention to some of the complications confronting an apportionment between teaching, research, and extension of available manpower within an institution. "Practically all of our graduate students, some of whom helped in the instructional field as well as in research, are gone. A number of the members of our staff have gone into the Army, either through the Reserve Officers Corps or through selective service, while others have gone into industrial work. Full replacement with qualified men is impossible. Adding to this situation is the enormous demand for assistance of practically all members of our staff in governmental programs and from commercial people who need technical advice in adjusting their business in a topsy-turvy world. These demands cannot and should not be ignored. The combined effect of this pressure from all sides creates an almost impossible situation, and yet a solution must be found. . . . Sooner or later it is coming to the point where a decision must be made as to what is of the least importance and which can be discontinued with the least damage."

In the section of home economics much attention was given to the national cooperative project on the conservation of the nutritive values of foods in the process of marketing, storage, and home preparation. This project had been sponsored by the section at the 1941 convention, and developments had proceeded with Dr. J. T. Jardine, Chief of the Office of Experiment Stations, as coordinator and with

four regional coordinators. Progress reports were submitted by Sybil L. Smith of the Office of Experiment Stations and for the several regions by Director C. McKee of Montana and Dr. Agnes F. Morgan of California, Margaret Fedde of Nebraska, Dr. Statie E. Erickson of Kentucky, and Dr. B. E. Gilbert of Rhode Island. These reports brought out the fact that at least 38 States were participating in the project and that federally supported work of similar scope was under way in at least 5 others. Over 50 commodities were under investigation, with special emphasis on the 10 or 12 foods or food groups deemed of particular significance under present conditions. One of the features of special interest has been the usually broad cooperation between and within the institutions concerned.

Each of the two sessions of the experiment station subsection was devoted to a problem of immediate concern to the directors. One of these dealt with Federal grants, and was discussed in a closed session at which the principal speakers were Director C. E. F. Guterman of Cornell on the topic of Grants to States and Director R. E. Buchanan of Iowa on Grants to Bureaus and Federal Agencies for Cooperation With the States.

The other session dealt with the problem of acquainting the public with experiment station work. Four methods were discussed, those of personal interviews by Director Edmund Secrest of Ohio, publications by Director E. C. Johnson of Washington, organizations by Director W. G. Taggart of Louisiana, and demonstrations by Director L. D. Baver of North Carolina. While the general topic is not a new one, its timeliness needs little justification in a period when full understanding of the significance and value of all publicly supported agencies is unusually important. The papers as a whole indicated, in the words of one of them, that "experiment stations can in numerous ways place before the public the results of meritorious but perhaps in the main unspectacular work. It is up to the stations to find means of doing this job."

An effective presentation of some of the more recent research accomplishments was made by a nonmember of the association, Dr. W. H. Tisdale, manager of the pest control research section of E. I. du Pont de Nemours and Company, Incorporated. Dr. Tisdale, who was the research spokesman in the joint session of the three subsections of agriculture, commended the rapid progress in recent years in the organization and administration of agricultural research institutions. "Agricultural problems," he said, "are being viewed in their broader aspects. Better balanced programs of research are being organized, which include all phases of the agricultural sciences from soil care and improvement to the marketing of the well-graded and packaged products, both plant and animal production included.

Not only have professional bounds been made more flexible, resulting in closer cooperation of individuals and divisions within institutions, but the trend is toward the much needed regional, national, and international cooperation. Only through such cooperation and coordination of effort can these problems be viewed in their broad, as well as in their more local, aspects and larger numbers of trained minds, representing the different sciences and professions involved, employed in their solution. This is the way it should be." Nevertheless he contended that "many of these tasks are of proportions that will require greater painstaking efforts and more extensive cooperation than anything we have yet experienced."

As to the future, he pointed out that "since our declaration of war there has been and there will continue to be curtailment of many meritorious investigations, and special consideration will be given to those problems which are of urgent necessity in the war effort. No one will take exception to this. After we have won the war we will be able to reconsider our agricultural research programs. Many of our trained young research men will return from the front, and those who have remained at home on vital war production research will be available to take their places in a more permanent order. If the ideals set forth in the Atlantic Charter are to prevail, research in all its phases, and especially its international phases, must and will surpass anything yet known, and agricultural research will take its place near the top in the new scheme of things."

A similar appreciation of the post-war opportunities open to the stations was expressed in a paper by Director R. B. Corbett of Maryland entitled *The Experiment Stations' Job in Post-War Planning*. Looking ahead, Director Corbett predicted a severe economic crisis, with price disorganizations, much unemployment, a depressed state of buildings and equipment, and many other conditions needing immediate remedies for which the basis must be laid in research programs with the State experiment stations as essential agencies. He concluded that "the vision and intelligence of experiment station directors is needed now and will be needed in the post-war period as it has never been needed in the past."

Taken as a whole, the convention revealed the research representatives as alert, responsive, and cooperative. Long since have their programs been geared to the war emergency. Despite depleted staffs and many other handicaps, they can be depended upon to render to the extent of their resources the maximum service possible along their appointed lines.

## RECENT WORK IN AGRICULTURAL SCIENCE

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY

**Advances in colloid science**, edited by E. O. KRAEMER, in collab. with F. E. BARTELL and S. S. KISTLER (*New York: Interscience Pubs., Inc., 1942, vol. 1, pp. XII+434, figs. [160]*).—This volume, the first of a projected series, consists of a preface by Kraemer, Bartell, and Kistler and discussions of 12 topics by the authorities in their respective fields noted below: The Measurement of the Surface Areas of Finely Divided or Porous Solids by Low Temperature Adsorption Isotherms, by P. H. Emmett (pp. 1-36); The Permeability Method for Determining Specific Surface of Fibers and Powders, by R. R. Sullivan and K. L. Hertel (pp. 37-80) (Tenn. Expt. Sta.); A New Method of Adsorption Analysis and Some of Its Applications, by A. Tiselius (pp. 81-98); Solubilization and Other Factors in Detergent Action, by J. W. McBain (pp. 99-142); Recent Developments in Starch Chemistry, by K. H. Meyer (pp. 143-182); Frictional and Thermodynamic Properties of Large Molecules, by R. E. Powell and H. Eyring (pp. 183-226); The Constitution of Inorganic Gels, by H. B. Weiser and W. O. Milligan (pp. 227-246); The Creaming of Rubber Latex, by G. E. Van Gils and G. M. Kraay (pp. 247-268); Streaming Birefringence and Its Relation to Particle Size and Shape, by J. T. Edsall (pp. 269-316); Synthetic-Resin Ion Exchangers, by R. J. Myers (pp. 317-351); The Study of Colloids With the Electron Microscope, by T. F. Anderson (pp. 353-390); and Anomalies in Surface Tensions of Solutions, by E. A. Hauser (pp. 391-415).

[**Chemical investigations by the New York State Station**] (*New York State Sta. Rpt. 1942, pp. 19-23, 27-29, 32-34*).—These comprised work on food processing, paper investigations, cleaning and sterilizing studies, food poisoning organisms, biological stains, nonpoisonous insecticides, preparation and preservation of fruit juices and beverages and of vegetable juices, maple products investigation, physical and chemical properties of insecticides and fungicides—their analysis and evaluation, adhesion of fungicides to plant surfaces, and protein investigations with casein-aldehyde plastics and the effect of light on amino acids, proteins, and allied substances.

✓ **A chemical study of quick-test technics for potassium and calcium**, S. W. MELSTED. (Ill. Expt. Sta.). (*Jour. Amer. Soc. Agron., 34 (1942), No. 6, pp. 533-543, figs. 2*).—This article covers a chemical evaluation of various technics involved in quick tests for potassium and calcium. The author points out that the principal factor which determines the accuracy of a quick test for replaceable bases is the quantitateness with which the extracting solution removes the bases from the soil. With this in mind, it is suggested that the first consideration must be the extracting solution. Results obtained indicate that there is no one extracting solution in use for rapid tests that is quantitative for all the replaceable bases, and in the opinion of the investigator, a single extracting solution now in general use for all nutrients should be discouraged. The limitations of quick-test methods that measure the aliquot of extract in drops, as well as

turbidimetric or colorimetric methods that do not give accurate results with standard solutions, are discussed.

**Comparison of dry combustion and Walkley-Black methods for the determination of organic carbon distribution in soil profiles.** C. E. HUTTON and R. W. SIMONSON. (Iowa Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 6, pp. 586-592, fig. 1).—Recoveries of carbon by the Walkley-Black method (E. S. R., 70, p. 742) are compared with data obtained by a dry combustion method for the principal horizons of 12 soils representing 6 great soil groups. While approximate values for organic carbon can be obtained by means of the Walkley-Black method, the variations in recovery are often large enough to obscure important differences between the various horizons in the same profile or similar horizons in different profiles. The deviations were considered too large to permit the general use of the more rapid procedure for the study of carbon distribution in soils.

**Determination of silica and phosphoric acid in soil extracts.** A. SREENIVASAN (*Soil Sci.*, 54 (1942), No. 1, pp. 27-33).—A rapid method for separating silica from soil extracts quantitatively consists in evaporation to small volume and digestion with sulfuric acid and alcohol. Following this the silica, after precipitation, is filtered off, and the phosphate in the filtrate is determined titrimetrically in the phosphomolybdate precipitate.

**A new method for determining the concentration of chlorophyll.** D. I. SAPOZHNIKOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 32 (1941), No. 5, pp. 369-371, fig. 1).—The method described is based on measurement of the absorption band I in the spectrum of chlorophyll by means of a drum spectrometer.

**Application of volatile fatty acidity determination to a study of canned Maine sardines.** J. A. CLAGUE (*Food Res.*, 7 (1942), No. 1, pp. 56-67, figs. 3).—The author concurs with Hillig (E. S. R., 82, p. 441) in finding that volatile fatty acidity may be used as an index of the quality of canned sardines from the standpoint of measuring deteriorative changes which have taken place in the sardines up to the time of canning. The test shows up differences in quality which are not obvious to the average person by organoleptic examination.

Strong brines inhibit the development of volatile fatty acidity. Sardines held in a 60°-65° salometer brine after equilibrium between the brine and sardines had become established showed practically no increase in volatile fatty acidity even after a holding period of 50 hr. The lowest concentration brine to have any practical inhibiting effect would be a 30° brine (after equilibrium). High holding temperatures accelerate the development of volatile fatty acidity in sardines. There was no definite correlation between bacterial count and volatile acid number in the one series of tests made on raw sardines. Under cannery conditions the factor most likely to cause an appreciable increase in volatile fatty acidity is the holding of sardines in the open can after packing.

**Determining the maturity of frozen vegetables: A rapid objective method for whole-kernel corn.** F. A. LEE, D. DEFELICE, and R. R. JENKINS. (N. Y. State Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, pp. 240-241).—The method developed, described as to procedure, equipment, and calculation, involved determination of specific gravity by difference in weight in air and in a mixture of xylene and carbon tetrachloride adjusted to sp. gr. 1.000; or by difference in weight in air and in a weak brine solution of sp. gr. 1.000. The brine method was somewhat the better of the two because of the low cost, ease of preparation, and relative stability of the brine solution in use. The specific gravity results by either method correlated well with organoleptic tests, as indicated by the calculated coefficients of correlation. Tentative standards

are suggested, therefore, based upon results using the brine solution for the determination of specific gravity. According to these standards corn is graded fancy if the specific gravity in brine is 1.080-1.118; reject, immature if 1.079 and lower; and reject, overmature if the specific gravity is 1.119 and higher.

**Objective methods for determining the maturity of frozen whole kernel corn,** F. A. LEE and D. DEFELICE. (N. Y. State Expt. Sta. et al.). (*Canner*, 94 (1942), No. 26, pp. 11-13, 24).—The method described is the same as that noted above. In addition, slight alterations for alcohol-insoluble solids are noted, thus making the method applicable to frozen whole-kernel corn as well as to the corresponding canned product. Consideration is also given to total solids as a method for determining the maturity of frozen whole-kernel corn.

**Determination of the maturity of frozen peas,** F. A. LEE. (N. Y. State Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 3, p. 241).—A revision of the method for determining the maturity of frozen peas (E. S. R., 85, p. 153) involved replacing the xylene-carbon tetrachloride mixture with a sodium chloride solution of sp. gr. 1.000. This solution possesses the advantage of being less expensive, easier to prepare, and subject to less change in specific gravity in use.

**Genetic control of biochemical reactions in *Neurospora*,** G. W. BEADLE and E. L. TATUM (*Natl. Acad. Sci. Proc.*, 27 (1941), No. 11, pp. 499-506, figs. 2).—On the assumption that X-ray treatment would induce mutations in genes concerned with the control of known specific chemical reactions, a procedure was devised using the ascomycete *Neurospora* for discovering and maintaining such mutant strains. Out of about 2,000 X-ray induced mutant strains, 3 were found that grew essentially normally on the complete medium (agar, inorganic salts, malt extract, yeast extract, and glucose) and scarcely at all on a minimal medium (agar, inorganic salts, biotin, sucrose, and fat), requiring the organism to carry on all the essential syntheses of which it is capable. In one of the mutant strains established, the ability to synthesize pyridoxin was wholly or largely lost; in a second, the ability to synthesize the thiazole half of the thiamin molecule was absent; and in a third, *p*-aminobenzoic acid was not synthesized. All of these substances appeared, therefore, to be essential growth factors for *Neurospora*. The growth of the pyridoxinless mutant was shown to be a function of the pyridoxin content of the medium on which it was grown. Growth was measured by the dry weight of the mycelia or by a method, described, involving the progression of the frontier of the mycelia along a horizontal glass culture tube half filled with an agar medium. The results of crosses between normal and mutant strains indicated that the inability to synthesize the pyridoxin was apparently differentiated by a single gene from the ability of the organism to elaborate this essential growth substance. The possibility of using the growth of *Neurospora* strains in the described tubes as a basis of vitamin assay is suggested, but it is also emphasized that additional investigation is essential in order to determine the reproducibility and reliability of the method.

**Study of problems in enrichment of flour,** C. G. HARREL ET AL. (*Southwest. Miller*, 21 (1942), No. 25, pp. 19, 39).—This report, by a subcommittee of the technical committee of the Millers' National Federation, is concerned with additional work (E. S. R., 86, p. 564) on various phases of the enrichment program and includes brief reports on the following studies: I—Fate of riboflavin on baking, by J. S. Andrews; II—loss of vitamin B<sub>1</sub> on baking, by E. Hove; III—color and other changes in bread score caused by the use of riboflavin at the proposed enrichment levels, by W. L. Rainey; and IV—the effect of iron salts when used at the enrichment level, with special reference to stability both in

flour and in the concentrate, by B. Sullivan. These studies, outlined briefly, are summarized as follows:

I. Breads, produced on the commercial scale as well as in laboratory tests, showed no measurable changes in the amount of riboflavin either during fermentation or baking regardless of whether the riboflavin was added to the dough as the pure product or was derived from the flour, whole wheat, yeast, or milk. The riboflavin content of the flour was not affected by bleaching.

II. The higher the baking temperature and the longer the baking time the greater the loss of thiamin regardless of its source (whole wheat, or added synthetic vitamin or vitamin-rich yeast). At normal temperatures and times, practically all of the loss, which averaged about 16 percent in the well-baked loaf, occurred in the crust rather than in the crumb.

III. Color scores, by 10 separate laboratories, of breads made from bleached and unbleached flour, the former with and without the addition of dried skim milk (6 percent) or pure riboflavin (1.2 mg. per pound of flour), indicated that the pure riboflavin imparted a clear creamy color to the crumb of the bread. The amount of riboflavin used contributed more color than did the 6 percent of dried skim milk, but not as much creamy color as did the unbleached flour.

IV. "Experiments on keeping qualities, supplemented by over a year's experience, indicate that if any enriched flour goes out of condition it is not necessarily the presence of the iron added which caused this deterioration, since the unenriched flour, under the same conditions, might have developed rancidity. As the amount of iron is increased, the tendency toward rancidity becomes more marked. Traces of copper have also been found to promote the development of rancidity. It is generally felt, however, that at the present or proposed levels for iron in enriched flour more depends on the nature of the flour itself and its storage conditions than on the exact amount of iron added."

Some problems in enrichment of flour, C. G. HARREL ET AL. (*Bakers Digest*, 16 (1942), No. 11, pp. 249-251, figs. 2).—Essentially noted above.

Die Bestimmung von Carotin in Pflanzen [The determination of carotene in plants], K. SVANHOF and H. DAM (*Ztschr. Vitaminforsch.*, 11 (1941), No. 4, pp. 361-372; *Eng., Fr. abs.*, p. 372).—The present study involved a comparison of the method of Glavind and Heegaard (*E. S. R.*, 85, p. 441) with the official (Danish) method. This latter involved digestion of the plant material with alcoholic KOH, extraction of the pigments with petroleum ether, and treatment of this extract with a methyl alcohol-petroleum ether mixture, by which treatment the pigments were partitioned between the methyl alcohol and the petroleum ether. After proper washing of the layers, the pigment in the petroleum ether phase was determined by means of the photoelectric colorimeter. In the application of these methods to dried spinach, alfalfa, and carrots, it was found desirable to complement the methods by chromatographic separation of the physiologically active carotene. This was accomplished by absorption on a column of  $Al_2O_3$ , the chromatograph being developed with a petroleum ether-benzene mixture, and the carotene being eluted from the upper layer with a solution of alcohol in petroleum ether. For the examination of dried plants, a simplified Willstätter-Stoll method (*E. S. R.*, 30, p. 311) was preferred along with chromatographic separation. By the simplified method, the separation of the carotenoids into two phases was eliminated. In the chromatographic procedure a portion of the carotenoids was lost, this loss averaging about 8.2 percent in the official method, 8.7 percent in the method of Glavind and Heegaard, and about 7.6 percent in the simplified method. A correction factor for these losses was applied, therefore, in results obtained by these several procedures.

**Remarks on the determination of vitamin A and carotenoids in feces,** T. K. WITB (*Ztschr. Vitaminforsch.*, 11 (1941), No. 4, pp. 298-310; *Ger., Fr. abs.*, pp. 309-310).—"The chemical aspect of the determination of carotenoids and vitamin A in feces is discussed. Owing to the heterogeneous nature of feces, the analysis is difficult to carry out exactly for carotenoids, and in the case of vitamin A it is only possible to arrive at a rather rough estimation. Analytical methods used by previous investigators are described and criticized, and some methods in keeping with modern knowledge of the chemistry of vitamin A and carotenoids described in detail."

**The effect of enzymatic digestion on the pantothenic acid content of meats determined by the microbiological method,** H. A. WAISMAN, L. M. HENDERSON, J. M. MCINTIRE, and C. A. ELVEHJEM. (*Wis. Expt. Sta.*). (*Jour. Nutr.*, 23 (1942), No. 3, pp. 239-248).—The pantothenic acid content is reported for more than 80 samples of animal tissues, many of which were samples analyzed earlier by the chick-assay method (*E. S. R.*, 82, p. 231). The pantothenic acid was extracted from dried pulverized or fresh homogenized samples subjected to pancreatic digestion for from 24 to 72 hr. at 38° C. in a phosphate buffered solution at pH 7.0-7.5. The medium, culture, inoculation, and titration procedures used were essentially those reported by Strong et al. (*E. S. R.*, 86, p. 588). Preliminary tests showed that the water-extraction procedure of this method failed to give complete extraction of many animal tissues; autolysis, enzymic digestion with pepsin, with clarse, and with pancreatin produced, in this order, increasing pantothenic acid values for most of the tissues, particularly muscle tissues and more especially cooked meats. Tests indicated that the higher results obtained after pancreatic digestion were due, not to significant amounts of the vitamin in the enzyme preparation or to the liberation of bacterial growth-stimulating substances, but to increased liberation of the vitamin from the tissues. The small value obtained for pantothenic acid in the pancreatin was subtracted as a correction from all values obtained.

Liver (39-88  $\mu$ g. pantothenic acid per gram, fresh basis) and kidney (27-49  $\mu$ g.) of the various species were the richest of any of the tissues, while striated muscle (4-21  $\mu$ g.), heart (12-25  $\mu$ g.), lung, pancreas, brain, and spleen contained appreciable quantities. The pantothenic acid in the animal tissues occurred chiefly in combined form, since it was liberated most completely by digestion with pancreatin. There was a decrease of approximately 30-40 percent of the vitamin in the cooked or commercially processed samples tested.

**A clinical method for the determination of ascorbic acid in blood plasma and urine,** E. STORZ (*Jour. Lab. and Clin. Med.*, 26 (1941), No. 9, pp. 1542-1545).—The method, described in detail as to apparatus, reagents, and procedure and developed with a view to increasing the ease and speed of plasma ascorbic acid determinations in serial analysis, is based upon the fact that oxidized 2, 6-dichlorophenolindophenol can be quantitatively extracted from acid solution with xylene. The metaphosphoric acid filtrate of the plasma, adjusted to proper pH, is allowed contact with the dye solution for the short time necessary for the reaction. The oxidized dye is then extracted into xylene and the layers separated by centrifuging. In xylene the dye, no longer subjected to an acid medium or to slowly reducing substances, is stable for hours. Because of this stability feature, as many of the samples as desired are treated with the dye and extracted, and when all are completed the color of the xylene layers is measured photoelectrically or by use of the visual colorimeter. The extraction of the oxidized dye from acid solution by xylene was shown to be quantitative, and Beer's law was found to be applicable to the xylene solution of the dye in the concentration range of dye

utilized in this test. The method is readily applied to urine, which is first treated with metaphosphoric acid and then filtered.

**Hemoglobin estimation with undiluted reduced blood**, G. BARKAN (*Jour. Lab. and Clin. Med.*, 26 (1941), No. 11, pp. 1823-1828, figs. 2).—The Sicca hemometer, described as to construction and standardization, was developed for application of a new method involving the use of blood without its being measured or diluted but reduced, hemolyzed, and stabilized by the addition of a trace of a reagent powder containing sodium hydrosulfite, saponin, oxalate, and sodium chloride. Some advantages of the new type of hemoglobinometer are noted as follows: "(1) The use of undiluted blood eliminates the sources of error involved in diluting. The handling of the Sicca hemometer is very simple and needs no particular training. (2) The use for colorimetry of acid hematin, repeatedly criticized in earlier work, is abandoned in favor of the color of reduced blood. The latter is stable and independent of time, the errors due to inadequate time for reading being eliminated. (3) The use of constant glass standard and constant electric light in connection with correct filters allows observations with great optical contrast, eliminates the effects of voltage variations and plasma color (icteric blood), and decreases the personal equation to a minimum. (4) The dispersion of repeated readings with the same or with different Sicca hemometers is small, i. e., the reproducibility is particularly good. (5) Spare parts can be used without new standardization."

**Determination of nickel and copper chromates and nickel, copper, and magnesium arsenates in treated wood**, R. H. BAECHELER and P. SERVAIS. (U. S. D. A. coop. Univ. Wis.). (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 19-23).—Oxidation of the organic components of the sample was found best accomplished by means of a sulfuric-nitric-perchloric acid mixture. Dry ashing, though requiring less attention, was slower and could not be used when arsenic was to be determined. Adaptations of customary methods suitable for the separation and determination in the wood sample digests of copper and chromium, copper and arsenic, nickel and chromium, nickel and arsenic, and magnesium and arsenic are described in working detail.

**Relative toxicity of materials recommended for slime control**, J. W. APPLING and B. W. SHEMA (*Paper Mill News*, 65 (1942), No. 35, pp. 14, 16).—A number of chemicals on the market have been recommended for slime control, and the results of tests by the flask method with eight materials are here reported. *Aerobacter aerogenes*, frequently associated with slime development in paper mills, was the test organism, and the petri dish and flask methods for assaying the disinfectants were employed. The latter method proved most promising, and it is believed that a much better correlation between laboratory tests and mill runs will follow from the application of the relative toxicity values presented.

**Cottonseed protein for adhesives, chemical studies**, C. DORMAN (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, p. 3).—Attention has been given to improving the methods of extraction and purification, obtaining manufacturing cost, and improving methods for using the protein as an adhesive for plywood. Some preliminary tests made on plywood glued with cottonseed protein are promising. Work on the determination of calcium and phosphorus in turnip greens is noted under the same title.

**Effect of time and temperature on sulfuring on absorption and retention of sulfur dioxide by fruits**, C. D. FISHER, E. M. MEAK, and J. D. LONG. (Calif. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), Nos. 6, pp. 175-176, fig. 1; 7, pp. 199-200, 217, 219, figs. 3; 8, pp. 237-238, fig. 1).—A survey of sulfuring houses in operation in California showed that temperatures

adjacent to fruit during sulfuring for drying varied considerably with the conditions of sulfuring, locality, and season. Since there was some indication, but not full agreement among investigators, that the high temperatures favored  $\text{SO}_2$  retention, this problem was investigated because there appeared also to be a relation between  $\text{SO}_2$  retention and color retention in the dried fruit upon storage. The present paper describes the sulfuring experiments in which temperature and  $\text{SO}_2$  concentration were controlled in the tests with various fruits, pretreated and dried according to standard commercial practices, and stored after drying. The results, discussed for the individual fruits, showed that cut fruit (apricots, peaches, and pears) as a rule absorbed less  $\text{SO}_2$  during sulfuring, but retained more during storage when sulfured at a relatively high temperature, such as  $120^\circ \text{F}$ . The extent of the temperature effect varied with time,  $\text{SO}_2$  concentration, nature of the fruit, and locality. When whole fruits (grapes and figs) were sulfured at  $120^\circ$ , they absorbed, and retained as well, more  $\text{SO}_2$  than when sulfured at  $70^\circ$ . Prolonged, high-temperature sulfuring treatments tended to cause the cut fruit to bleed, become mushy, and stick to the drying trays. Frequently, the cut fruits sulfured at  $120^\circ$  yielded more slabs but retained a better color and more  $\text{SO}_2$  for a longer period of time than when sulfured at  $70^\circ$ . The retention of color, however, also varied with other conditions, such as variety or drying climate.

**Pasteurization of pickle products, J. L. ETHELLE and I. D. JONES.** (U. S. D. A. and N. C. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 11, pp. 330-332).—This paper presents a discussion dealing with the various aspects of pasteurization for the preservation of pickle products. Attention is called to the fact that pasteurization is valuable not only in the processing of unfermented and partially fermented products, but also in the preservation of genuine dills. "It has been demonstrated that a uniform pasteurization procedure, such as  $165^\circ \text{F}$ . for 15 min. followed by prompt cooling, can be adopted by packers for the manufacture of high-quality pasteurized pickle products of all types."

**Vegetable juices, 1942 model, G. L. MARSH.** (Univ. Calif.). (*Canner*, 95 (1942), Nos. 9, pp. 7-8, 12-13; 10, pp. 15-16).—This discussion indicates, first, how the present practices of preparing most vegetable juices result in loss of flavor and of food value. Specific reference is made to (1) the removal of vitamin A as the juice obtained by pressing passes through a column of vegetable pulp, (2) partial loss of the water-soluble vitamins in the blanching process, (3) further destruction of these by heat in the autoclaving process, and (4) loss of ascorbic acid through oxidation due to the presence of air and failure to destroy the ascorbic acid oxidase by flash heating. Methods recommended for decreasing these losses involve redesign of equipment and introduction of new devices, including (1) extractors, permitting continuous and rapid handling of the vegetable with incorporation of the minimum of air in the juice, (2) deaerators, for removal of dissolved or incorporated air, and (3) flash pasteurizers for high-temperature, short-time heating to effect pasteurization and enzyme destruction, followed by rapid cooling. For the latter process, the utilization of devices to speed the rate of heat exchange is recommended in order to reduce the holding time; since the high temperatures ( $240^\circ \text{F}$ . or higher) required are detrimental to flavor and color, it is further recommended that the vegetable juice be acidified to a point which would allow the use of lower temperatures ( $195^\circ$ - $212^\circ$ ). Acidification problems are discussed with regard to choice of acid, amounts needed as influenced by the initial pH and the buffering capacity of the juice, and consumer acceptability of a sour product.

**The preparation and processing of peach, pear, and plum juices.** E. A. BEAVENS and H. G. BEATTIE. (N. Y. State Expt. Sta. coop. U. S. D. A.). (*Canner*, 94 (1942), No. 21, pp. 15-20).—Cooperative studies led to the development of methods, which are here described, for the preparation and processing of peach, pear, and plum juices of the pulpy type. Careful selection of fruits with regard to variety and proper stage of maturity were the most important factors in obtaining satisfactory juices. Of the peach varieties tested, J. H. Hale and Elberta were the most satisfactory; of the pears, Vermont Beauty and Anjou; and of the plums, the Hungarian, German, and Italian prunes were most satisfactory for the production of red-colored juices, while the Yellow Egg and Reine Claude plums gave the best yellow-colored juices. Pulpy juices were made more palatable by blending with pressed juices from the same fruit or with juices from other fruits, such as the apple, or by diluting with thin sugar sirups. The use of sugar sirup was particularly desirable in the case of certain plum juices, which were sour or astringent, and in the case of peach juices, which were markedly improved in flavor by the addition of the sugar. Peach juices were handled as rapidly as possible in order to prevent browning and oxidation. Red plum juices in which the color darkened through the browning of the suspended pulp were improved by clarification, which removed the muddy appearance. The best pulpy juices were prepared by hot pressing, deaeration (peaches and pears), and flash pasteurization at temperatures of 170°-185° F., followed by packing in cans or bottles and cooling rapidly.

**An improved orange marmalade of high vitamin C content.** A. SEDKY, C. R. FELLERS, and W. B. ESSELEN, JR. (Mass. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 6, pp. 170-172, 185, 189).—The method described for making an orange marmalade high in vitamin C content and excellent in flavor involved the use of orange peel cooked separately in 0.1-0.2 percent citric acid solution. The use of this peel protected the juice from the detrimental effect of prolonged cooking and thus permitted the retention of color, flavor, and vitamin C content. By using a sufficient amount of such peel, the addition of pectin could be eliminated. A 1½:1 ratio of sugar to juice was the most satisfactory, and in this case 1.3 gm. of pectin for each 100 gm. of sugar seemed to be satisfactory. The use of dextrose up to 25 percent as part of the added sugar lessened the sweetness of the product and contributed to the flavor, but resulted in a marmalade of firmer texture. About 80 percent of the ascorbic acid of the juice was retained in the marmalade, and analyses of the product described showed it to contain from 17.5 to 29.2 mg. of ascorbic acid per 100 gm. as compared with commercial marmalades, which were found to contain from 2.1 to 6.3 mg. per 100 gm. A formula which proved very satisfactory is presented for the use of an orange concentrate in making the marmalade. With the use of this concentrate the time of preparation was reduced, thus allowing a greater protection of the vitamin C content and color.

**Fruit concentrates and their use.** W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 6, pp. 165-169, 187, 190, fig. 1).—Fruit concentrates are usually prepared industrially from fruit juices by boiling off and condensing the excess water under vacuum, but by this process flavor and aroma are lost in the vapors and although there are various ways of recovering the volatile flavor constituents, they are not in general use. A continuous vacuum concentrator, consisting of an inclined pyrex tube jacketed with a larger glass tube through which hot water or steam was circulated under low pressure, gave satisfactory results in laboratory trials and

offered possibilities for adaptation on a commercial scale. A vacuum of 29 in. or higher was essential for good results with fresh fruit juices. Concentrating by freezing the juice to a slush of ice and juice, followed by separating the ice and concentrate by centrifuging or draining, gave concentrates of rich flavor and aroma. Laboratory experiments indicated that the procedure would be practicable. Concentration of the juice to only 50°–55° Brix (instead of the usual 70°–72°), flash pasteurization in bottles or cans sealed and stored at 32° F., or better still, freezing storage at temperatures below 15° are recommended procedures for retaining flavor, aroma, and color of stored concentrates.

**Packaging dehydrated fruits and vegetables**, G. J. HUCKER and J. R. SANBORN (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, pp. 1, 7).—The authors report briefly upon the progress made and the difficulties yet to be met in the protection of dehydrated foods against bacterial contamination and penetration of moisture from either temperate or tropical atmospheres, as well as against loss of an inert atmosphere when the last-named protection is needed, without the use either of tins, for which sufficient material is not likely to be available for the present, or of glass containers, which are objectionably heavy and probably cannot be produced in adequate volume. Lamination of sheets of variously treated papers, cellophane, sheet plastics, vegetable parchments, etc., may give better protection by combining the qualities of each of the different types of materials used in the lamination. Most of the closures at present in use are not sufficiently moisture proof. The most severe tests require the packages to withstand 100° F. in a relative humidity of more than 80 percent for a period of 6 mo. Dehydrated foods stored under these conditions are being examined at regular intervals for their microbiological content, moisture and vitamin content, and palatability.

**What's known today about dehydrating vegetables**, W. V. CRUESS and E. M. BRAK. (Calif. Expt. Sta.). (*Food Indus.*, 14 (1942), Nos. 1, pp. 57–60, figs. 2; 2, pp. 41–43, 96–97, figs. 3; 3, pp. 48–49, 96, figs. 2; 4, pp. 57–59, 98, figs. 2; 5, pp. 43–45, 98–99, fig. 1).—This series of articles on the dehydration of vegetables is largely a compilation of present information. General consideration is given to properties of satisfactorily dehydrated vegetables, adaptability of various vegetables to dehydration, and sun-drying v. dehydration. Coverage, in some detail, is given to the following topics: Preparation for drying, including washing, peeling, subdividing, trays and traying, blanching, and waste disposal; dehydrators of natural draft, forced-draft tunnel, air-blast compartment, air-blast combination compartment and tunnel, air blast continuous, and vacuum-drier types; principles of dehydration with reference to functions of air, role of heat, heat and air requirements, air velocity, air recirculation, the parallel-current system, effect of temperature on drying rate, critical temperature, relative humidity, case hardening, moisture content of dehydrated vegetables, and judging of finishing point; specific directions for the preparation and dehydration of 35 vegetable products; yields; storage from the standpoint of insect infestation, fumigation, cold storage, molding, and vitamin losses; packing with reference to cartons, cans, glass containers, and "bricks" and "sausages"; use of dehydrated vegetables, with notes on refreshing and cooking; and laboratory examination involving moisture determination, refreshing and cooking tests, scoring, and vitamin assay. A selected list of references is given.

**The dehydration of vegetables**, W. V. CRUESS and E. M. BRAK. (Calif. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), Nos. 7, pp. 201–204; 8, pp. 241–242; 9, pp. 269–272; 10, pp. 302–307; 11, pp. 337–340).—Essentially noted above.

**The dehydration of vegetables**, E. M. MRAK and W. V. CREUSS. (Calif. Expt. Sta.). ([*War Dept. U. S.*], *Q. M. Corps, Spec. Subsist. Bul.*, 1941, pp. [2] + V+67, figs. 10).—This bulletin contains essentially the same material as that noted in the series of articles above, but includes additional illustrations and a tabular summarization of the procedures for preparing and dehydrating the various vegetables.

**Factors affecting the quality of frozen foods**, H. CARLTON. (Univ. Tenn.). (*Refrig. Engin.*, 43 (1942), No. 4, pp. 205-208, 245, figs. 2).—This survey points out that the rules for production of high-quality frozen foods apply equally to the commercial quick-frozen food industry and to freezer locker operations. High-quality fresh vegetables are necessary for high quality in the frozen pack, and this necessitates that the packing plant be located in a region where such fresh products may be raised. The varieties selected should be those that produce, in the given region, good yield with high quality, that suit the taste of the particular market, and, in the case of commercial plants, are suitable for specific uses and for machine harvesting and mass handling. Other points stressed are the importance of harvesting at proper and uniform maturity, of handling promptly, of maintaining excellent sanitation, and of proper packaging and close wrapping to prevent loss of moisture and flavor.

## AGRICULTURAL METEOROLOGY

**Average precipitation contrasts in the United States**, S. S. VISHER (*Sci. Mo.*, 55 (1942), No. 5, pp. 446-452, figs. 8).—The range in average annual precipitation among the long-established Weather Bureau stations is found to be from 1.5 in. for one in Death Valley, Calif., to 128.6 in. for one near Gray's Harbor, Wash. A score of other stations with records of more than 20 yr. have annual averages of less than 4 in. or over 100 in. The dry ones are in the Southwest and the wet ones in western Washington and western Oregon. The greatest average east of the coast ranges is recorded at two stations in the mountains of western North Carolina, which have long-time averages of about 83 in. The accompanying maps and discussion show the average precipitation annually, during the warm season (April-September), spring, summer, fall, and winter, and the average annual snowfall and number of days with thunderstorms. These pronounced regional contrasts naturally have profound influences on plants, animals, and mankind.

**Hydrologic studies at the West Tarkio Creek Demonstration Project SOS-Ia-1, Shenandoah, Iowa: Compilation of rainfall, run-off, and soil loss from the Tarkio River and West Tarkio Creek watersheds, 1934-40**, W. D. POTTER and S. K. LOVE (*U. S. Dept. Agr., Soil Conserv. Serv.*, 1941, SOS-TP-42, pp. [413], pls. 44).—The hydrologic and land use data here presented are those collected at the West Tarkio Creek and Tarkio River watersheds during the period 1934-40.

**Some notes on the effects of the incidence of rain on the distribution of rainfall over the surface of unlevel ground**, H. G. FOURCADE (*Roy. Soc. So. Africa, Trans.*, 29 (1942), pt. 3, pp. 235-254, figs. 6).—Factors governing the catch of rain over a given area are shown to be the vertical rainfall, inclination of the rain, its direction, and the slope and aspect of the ground. The mathematical relations among these factors are deduced. Methods of measuring the inclination and direction of rain are discussed, suitable gages proposed, and application is made to the determination of the true equivalent rainfall over a catchment area. Neglect of the influence of inclination of rain on the equivalent rainfall is shown to have been a fruitful source of error in interpreting some recorded

catches. An addendum discusses studies along these lines being undertaken by C. L. Wicht.

**On synchronous variations of pressure in tropical regions**, S. FROLOW (*Amer. Met. Soc. Bul.*, 23 (1942), No. 6, pp. 239-254, figs. 5).—Study of the transitory components of the pressure-variation field is especially promising for weather services charged with forecasting in tropical regions. The conclusions from the present study, based on about 30 tropical barometer records, are as follows: For the whole network, in 70 to 80 percent of the cases the 72-hr. pressure difference variations represent very marked similarities with the variation at Fort-de-France, Martinique. Conversely, the variation at Fort-de-France denotes a periodicity, the similarity of which extends to the other stations. Within the limits of the time-scale used, the centers of the variations of 72-hr. pressure differences do not move geographically. These variations are, therefore, synchronous. Over such a large tropical region these variations constitute a common factor in the field of pressure-variation. The theoretical and practical consequences of these conclusions should be investigated, especially as to the origin of the synchronous variations and the usefulness of the isallobaric method for weather forecasting in the Tropics.

**Agricultural meteorology**, J. W. HOPKINS (*Canada Natl. Res. Council Rev. Activ.*, 1941, pp. 25-26).—Based on accumulated records, a study was made to determine the climatological characteristics (April-September, 1890-1937) at Winnipeg, Man.; Swift Current, Sask.; and Edmonton, Alta. The seasonal incidence of rainy and rainless periods was also included, lengthy rainless periods being an important factor in initiating soil erosion by wind action.

**Studies in Guatemalan meteorology.—I, The climates of southwest Guatemala**, F. W. MCBRYDE. (Ohio State Univ.). (*Amer. Met. Soc. Bul.*, 23 (1942), No. 6, pp. 254-263).

## SOILS—FERTILIZERS

**Introduccion al estudio de los suelos [Introduction to the study of soils]**, A. GONZALEZ GALLARDO (*Mexico: Banco Nac. Credito Agr., S. A.*, 1941, pp. [1] + VII + 484, [pls. 43, figs. 31, maps 2]).—This is a textbook of edaphology, having special reference to the soils of Mexico. It is noted that no modern treatise on this subject has previously existed in the Spanish language, still less a work concerned especially with Mexican soils. The book contains previously unpublished information concerning Mexican soils derived in large measure from the completed portion of a general investigation of the agricultural resources of Mexico undertaken by the Mexican National Agricultural Loan Bank. The chapters deal with the formation of the soil, physical characteristics, water content, chemical characteristics, climatic bases of soil distribution, the great soil groups of the world, the Mexican soil map, and agrologic studies.

**[Soil and fertilizer investigations by the Mississippi Station]** (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, pp. 1, 3).—Recommendations concerning the use of available substitute fertilizer mixtures in replacement of the formulas withdrawn by war restrictions are made by C. Dorman under the heading 4-8-4 and 4-8-8 Only Grades Complete Fertilizer for 1943, Nitrogen Limited by War. Boron and phosphate experiments and a vetch fertilizer test are noted by the same author under the heading Fertilizers and Soils for Crop Production.

**[Soil investigations by the New York State Station]** (*New York State Sta. Rpt.* 1942, pp. 23-24, 63-64).—Progress is reported on legume inoculant inspection work, investigations of synthetic soil as a bacteriological culture medium, the pigments produced by certain soil bacteria, and fundamental studies on methods of identifying the various types of micro-organisms that occur in soil,

air, dairy, and other food products. Soil conservation investigations concerned included meteorological data, soil and water losses under different conditions, the effect of texture of erosion material on organic matter content, and the effect of depth of topsoil and percentage of organic matter and nitrogen of soil in four Corn Belt States.

[Soil Survey Reports, 1936 and 1938 Series] (*U. S. Dept. Agr., Plant Indus. [Soil Survey Rpts.], Ser. 1936, No. 18, pp. 65, pls. 2, fig. 1, map 1; 1938, No. 2, pp. 37, fig. 1, map 1*).—These surveys were made in cooperation with the Rhode Island and the North Carolina Experiment Stations et al., respectively: 1936, No. 18, Newport and Bristol Counties, R. I., A. E. Shearin et al.; and 1938, No. 2, Warren County, N. C., W. A. Davis et al.

The comparative physical constitution of water-stable granules and of the originating soil, R. B. ALDERFER and F. G. MERKLE (Pa. Expt. Sta. and U. S. D. A.). (*Soil Sci.*, 53 (1942), No. 2, pp. 105-113).—Noting that Sideri (E. S. R., 80, p. 304) and others sought, by the use of selected organic and inorganic constituents, to explain the chemical and physical mechanisms of structure formation, the authors state as their own purpose to determine the differences in mechanical analyses between water-stable aggregates and the soil from which they are formed. Organic matter both in the whole soil and in the aggregates was determined by Tiurin's modification of Schollenberger's method (E. S. R., 65, p. 504). Water-stable granules were separated from the A<sub>1</sub> horizon of 11 Pennsylvania soil types represented by 15 forested and cultivated areas. A complete mechanical and organic matter analysis was made of the "hand-picked" granules and of the whole soil.

Most of the large stable granules contained a greater percentage of organic matter and clay than did the whole soil from which they were derived. The increase in clay content of the granules was not offset by an equivalent decrease in any other single particle size fraction. The percentage of silt, sand, or gravel in the granules may be thus decreased. The stability index, a measure of granule stability, was found closely correlated with the organic content and the clay content of the soil. The probable permeability was closely correlated with organic content but bore no significant relationship to the clay content. Cultivation generally dispersed existing granules, and the dispersed clay reaggregated to form granules higher in clay and organic content than the whole soil from which they were formed. The granules in young soil profiles seemed to be formed and stabilized largely through the action of organic and biological influences. Those in poorly drained profiles were formed chiefly by disintegration of more massive structural units and stabilized by the action of organic matter, whereas those in well-drained mature profiles, provided the latter contained easily dispersible clay, had granules formed by dispersion and reaggregation of the clay and the organic matter. The granule genesis in the Hagerstown, Montalto, and Chester series may have been effected by the cementing action of hydrated iron oxides when the soil was developing. These granules were found in the forest soil but are gradually dispersed when the soils are brought under cultivation.

Stability of clay soils, E. C. CHILDS (*Soil Sci.*, 53 (1942), No. 2, pp. 79-92, figs. 6).—The method of assessing soil stability by means of moisture characteristics taken before and after artificial weathering was applied to Upper, Middle, and Lower Lias clays. The results are discussed, with particular reference to mole drainage, and it is shown that the Upper and Lower Lias are almost as stable as a Gault soil known to be suitable mole-draining land. Some known drain failures are discussed. The evidence thus far collected is considered, however, to be "insufficient to allow us safely to interpret stability curves in borderline cases." A deep sample of London clay is shown to behave peculiarly in that it withstands

the stresses of rapid wetting from the air-dry state and then disintegrates progressively over a period of days while undisturbed in the saturated state. The subsoiling of unstable clay soils was found to require as careful consideration as does mole draining.

**Structure of a Dunkirk silty clay loam in relation to pF moisture measurements, V. C. JAMISON** (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 4, pp. 307-321, figs. 8).—The relation of soil structure to successful crop production is discussed. Mention is made of the different units for expressing structural conditions of the soil. Using Dunkirk silty clay loam soil, measurements were made of pore size distribution in an attempt to determine the application of the pore size distribution method to the study of structural conditions in field soils. Pore size distribution measurements were found to be helpful in picturing the soil as it is at the time of examination for the particular spot being studied. The method may be used to follow structural changes if sufficient samples are taken and the results analyzed statistically. With the Dunkirk silty clay loam a general increase in pore space was associated with structural improvement.

**Structure of some organic soils and soil mixtures as shown by means of pF moisture studies, V. C. JAMISON** (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 5, pp. 393-404, figs. 7).—Some of the effects on physical and chemical properties of the soil brought about through the addition of organic amendments are discussed briefly. The condition of structure was measured for several organic soils and mixtures of organic and mineral soils by means of pore size distribution studies according to a method described in the article noted above. Pore size distribution was found to be more useful and gave a better picture of soil structure than the commonly used dry weight basis. All organic soils studied, though greatly different in several properties, showed the greatest frequency of pores between pF 1.0 and 3.0, with a smaller second maximum between pF 4 and 5. Adding peats to mineral soils caused the greatest change in pF moisture relations at the lower of the two above ranges.

**Laboratory study of the response of 2- and 4-electrode plaster of paris blocks as soil-moisture content indicators, A. B. C. ANDERSON and N. E. EDLEFSEN.** (Calif. Expt. Sta.). (*Soil Sci.*, 53 (1942), No. 6, pp. 413-428, figs. 7).—A laboratory investigation showed that the two- (E. S. R., 83, p. 307) and four-electrode (E. S. R., 86, p. 594) plaster of paris blocks can be calibrated at all moisture contents by placing them in a soil surrounded by the roots of actively transpiring plants and then observing the relation between soil moisture content and block resistance. Because of the very great lag in response to the value of the moisture content of soil in which no plants are growing, the blocks cannot be calibrated satisfactorily in the absence of roots of actively transpiring plants at the lower ranges of soil moisture content. Both the two- and four-electrode blocks, the preparation of which is described, under like soil moisture contents in the soil tested always had a like resistance at all soil moisture contents extending from the permanent wilting percentage to almost three times the moisture equivalent. Over the entire range of moisture readily available to plants, both the two- and four-electrode blocks served as dependable and practical indicators of the soil moisture content of any locality in a body of soil in which the blocks could be buried and in which the changes in soil moisture content were caused by the removal of the moisture by the roots of actively transpiring plants. As a soil moisture content indicator, the two-electrode is better than the four-electrode block because of the simplicity in the manufacture and in the measurement of the resistance. The two-electrode

resistance of a plaster of paris block was found not very sensitive to variations in the separation of the two electrodes in the midplane of the block.

The electrical capacity of the 2-electrode plaster of paris block as an indicator of soil-moisture content, A. B. C. ANDERSON and N. E. EDLERSSEN. (Calif. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 1, pp. 35-46, figs. 5).—Laboratory and field investigations on the use of electrical capacity of the two-electrode plaster of paris block as an indicator of soil moisture content are reported. The procedure in determining the electrical capacity was similar to that of determining the electrical resistance of the plaster of paris blocks, as described above and by Bouyoucos and Mick (E. S. R., 83, p. 307).

The electrical capacity of a plaster of paris block with its electrodes 2 cm. apart was found not to be changed appreciably by variation of as much as 3 mm. in the separation of the two electrodes in the midplane of the block. In comparison to the electrical resistance, the electrical capacity of the blocks appeared relatively unaffected by changes in the concentration of the soil solution. With decrease of soil moisture content, the electrical capacity of the blocks began to drop from a rather high value (approximately 0.070  $\mu\text{f.}$ ) at about the moisture equivalent, approaching a relatively constant value (around 0.0003  $\mu\text{f.}$ , a little above the permanent wilting percentage of the soil. The dependence of the electrical capacity of the blocks on the soil moisture content showed good reproducibility and an absence of lag in response of the blocks to changes of soil moisture content. The results recorded indicate that the electrical capacity of the plaster of paris block will serve, over the entire range of moisture content readily available to plants, as a practical indicator of the soil moisture content in a body of soil where the blocks can be buried and where the changes in soil moisture content are caused by the removal of the moisture by the roots of actively transpiring plants.

Chemical and physical properties of some of the important alluvial soils of the Mississippi drainage basin, R. S. HOLMES and W. E. HEARN (*U. S. Dept. Agr., Tech. Bul. 833* (1942), pp. 82, figs. 6).—The alluvial soils investigated in the Mississippi drainage area include 11 profiles from the lowlands, 12 from the western tributaries, 6 from the eastern tributaries, soil material from a 100-ft. bored well in the Mississippi alluvium, material from the channel of the river at its mouth, and sedimentary material from the Gulf of Mexico. Descriptions are given of the soil profiles and of other samples, including location, drainage, texture, consistency, and color. Laboratory determinations include mechanical and chemical analyses of the soils, pH values, chemical analyses of the colloids, mineralogical determinations on certain colloidal material, and determinations of certain minor elements on a few of the soils. The chemical composition of the nonclay material is estimated.

The mechanical analyses indicate that the greater part of the coarser material is not carried long distances from its source. The alluvial soils of the lower Mississippi River are composed almost wholly of varying quantities of silt and clay. The chemical analyses, as well as the mechanical analyses of the soils, show little evidence of profile development in place. Variations in drainage, however, have produced differences in contents of calcium and magnesium. The chemical composition of alluvial soils derived from various geological areas reflects, in general, the differences in their geological material as well as the difference in the altered composition of the soils as they developed in the areas made up of these materials. The chemical composition of the colloids of the soils of the lower Mississippi Delta are essentially similar. There are essential differences in the chemical composition of the soils of the eastern and western tributaries which drain the Great Plains. The differences are most pronounced

in the major constituents of the chemical composition of the colloids. The soils and geological material of the Interior Highlands are more of the nature of the eastern tributaries.

The composition of the soils and the river water of the eastern and western drainage areas of the Mississippi show the influence of unequal distribution of rainfall over the two areas. The chemical composition of the soils and colloids of the Mississippi lowlands shows definitely that the major portion of this material is derived from the eastern slopes of the Rocky Mountains and the Great Plains area to the east of them. This is evidenced by the similarity of the composition of the colloids of the Mississippi alluvium and by the data reviewed pertaining to the silt content of the Missouri and the Ohio Rivers.

The productivity of most of these alluvial soils is in harmony with various features of their chemical composition. The chemical features include the relatively high content of bases, phosphorus, and organic matter. These soils are derived from widely separate and diversified geological sources. They apparently contain all the elements essential to plant growth. Of the minor elements, zinc, boron, arsenic, and selenium were found in representative soils of the Mississippi River.

**Morphology and composition of some soils of the Miami family and the Miami catena**, I. C. BROWN and J. THORP (*U. S. Dept. Agr., Tech. Bul. 834* (1942), pp. 55, fig. 1).—The morphological, chemical, and physical characteristics of representative soils of the Miami family and of the Miami catena have been studied. The parent material, climate, and vegetation of the soils are essentially the same. The soils of the Miami family have similar local drainage conditions, but those of the Miami catena have not. A short discussion of the general system of soil classification is accompanied by tables and a figure showing the relationships of the members of the Miami family and the Miami catena. The description of each soil profile examined is preceded by a description of the landscape, the parent rock, and the drainage. The laboratory determinations include pH values, the mechanical and chemical analyses of the soils, and the chemical analyses of their colloids. The data are arranged in tables and discussed with reference to their morphology and the influence of local conditions on the formation of the soils. This is followed by a general discussion of the consequences of local drainage on soil development. It has been shown that iron has been appreciably fractionated and illuviated in the upper horizons of the soil. Lateral subsurface drainage has increased the iron content of the dark-colored soils. Small quantities of carbon dioxide in the leached acid parts of the soils is largely confined to unaltered particles of dolomitic limestone. It is apparent that the organic matter of the soils and colloids has been fractionated more than the inorganic portion. It has been shown that the compositions of this group of soils are essentially alike, largely because of the similarity of climate, vegetation, and parent material. The causes of certain morphological features of the soils are clearly indicated by the analytical data; the general classification of the soils is not. It is suggested that the determination of the soil minerals and certain exchange data may assist materially in explaining the causes of marked differences in the morphology of the soils of the Miami catena.

**Analyses and profile notes of some Laterite soils and soils with iron concretions of Thailand**, R. L. PENDLETON and S. SHARASUVANA (*Soil Sci.*, 54 (1942), No. 1, pp. 1-26, figs. 8).—Profile descriptions and chemical analyses of samples of Laterite soils and some related soils collected from many widely separated localities in Thailand are presented. "Laterite" is used in the strict original sense of an iron-oxide-rich, indurated, quarryable slaglike or pisolitic illuvial horizon developed in the soil profile. Laterite or other lateritic horizons

are easily distinguished in the field, and since Laterite soils are infertile the presence or absence of Laterite in a soil is an important criterion of soil character. Special emphasis is given to a prevailing confusion and to certain misconceptions regarding equatorial soils, especially with regard to the nature and manner of formation of Laterite and Laterite soils. Numerous and detailed observations and analytical data are recorded.

**A biological reduction method for removing free iron oxides from soils and colloidal clays**, L. E. ALLISON and G. D. SCARSETH. (Ind. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 7, pp. 616-623, fig. 1).—Difficulties caused by the presence of free iron oxides in making soil studies involving mechanical analysis, mineralogical analysis, specific gravity separations, and phosphate fixation have long been recognized. In view of the known action of micro-organisms in dissolving iron compounds in nature, the investigations reported were undertaken to determine the solvent and reducing action on iron-bearing compounds in the soil and in colloidal suspensions which have a large surface area. The method is described in detail and was found to be of particular value as a teaching device for demonstrating the relationship between energy materials and important soil transformations.

**Crop rotation as a factor in soil erosion control**, J. R. CARREKER. (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 6, pp. 190-192, figs. 2).—Work from 1930 to 1935 on several soil and water conservation experiment stations has shown that soil loss from corn in a rotation with close-growing crops was less than from corn after corn, and similar results were obtained with cotton. Recent work at the Southern Piedmont Experiment Station at Watkinsville, Ga., indicated that considerable reduction in soil loss and improvement in crop yields may be obtained by rotating cotton with other crops. Of special merit are (1) the 3-yr. rotation of cotton, oats-lespedeza, and lespedeza, and (2) the contour-balk system of cotton culture.

**Effect of erosion on fertility changes in the Shelby loam profile**, D. M. WHITT and C. L. W. SWANSON. (U. S. D. A. and Mo. Expt. Sta.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 6, pp. 283-298, figs. 4).—Shelby loam soil planted to different crops and under different systems of management is compared on the basis of 1-in. horizons with the same soil under continuous bluegrass for total exchange capacity, exchangeable calcium and magnesium, nitrogen and organic matter content, and pH. Exchange capacity, exchangeable bases, and base saturation were found to increase with depth, while organic matter and nitrogen content decreased with increase in depth. Fertility of the soil was maintained by a 3-yr. rotation of corn, wheat, clover-timothy with fertilizer and lime treatments. Rate of soil loss was small enough so that the harmful effects were counteracted by the incorporation of small increments of the subsoil. The clay added from the subsoil was removed in the surface runoff in such amounts as not to alter materially the texture of the soil. Additions of subsoil increased the amounts of exchangeable calcium and magnesium.

**Farms the rains can't take**, K. DAVIS and O. E. HAYS (*U. S. Dept. Agr., Misc. Pub.* 394, rev. (1942), pp. 11-14, figs. 8).—This is a revision of the edition of August 1940 (E. S. R., 84, p. 300), including results from new work on the La Crosse, Wis., erosion and runoff control plats.

**Tests on vegetated waterways**, M. B. COX. (Coop. U. S. D. A.). (*Oklahoma Sta. Tech. Bul.* 15 (1942), pp. 23, figs. 10).—The rate of loss of soil from the test channels was dependent both upon the degree of looseness or openness of the soil at the time of the flow through the channel and upon the duration of flow and time between flows. Under like conditions of flow, ranging from 0.05- to 1.3-in. depth and for durations of from 30 to 60 min., blue grama was superior

to other grasses tested in preventing erosion in the channels. Bermuda and buffalo were approximately the same in erosion resistance, and weeping lovegrass (*Eragrostis curvula*) was the least effective. Bermuda appeared to withstand more soil loss from around the roots than any of the other grasses studied without being removed completely from the channels by the water. Under sustained high velocities (11 ft. per second) Bermuda was superior to the other grasses in protecting the channels from erosion.

The data indicate that Manning's "*n*" varies with several factors, including type and condition of the grass, slope of the channel, and the depth of the flow. Manning's "*n*" for long green Bermuda was found to approximate 0.06 at 0.9 ft. depth of flow and 4 percent slope, buffalo grass 0.04 at 0.5 ft. and 2 percent, blue grama 0.05 at 0.7 ft. and 4 percent, and weeping lovegrass 0.05 at 0.7 ft. and 4 percent. Smooth side walls appeared to have no appreciable effect when the bottom roughness is great as it is in grass channels. This appeared to be true for channels up to 1 ft. in depth and as narrow as 1 ft. Depth of flow (*D*) was substituted for hydraulic radius (in effect omitting the side walls from the wetted perimeter), and in this bulletin the discussion and computations have been confined to the Manning formula written as

$$V = \frac{1.486}{n} D^{2/3} S^{1/2}.$$

An inexpensive soil sterilizer, M. L. PETERSON. (U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 7, pp. 674-676, fig. 1).—The equipment described in detail was developed to meet the needs of the Southern Great Plains Field Station at Woodward, Okla., for soil sterilization necessary in starting grass plants from seed in the greenhouse. The heating chamber is similar in principle to the waterless cooker and was constructed in the station shop at a cost of \$24.93 for materials. The unit has a capacity of 10 flats 15.5 in. wide by 23.5 in. long and 4 in. deep.

Preparation and use of artificial manures, K. J. KUCINSKI (*Massachusetts Sta. Bul.* 395 (1942), pp. 12, figs. 2).—Corn stover, mixed deciduous leaves, oat straw, and mixed leaves and garbage were used in making artificial manure. The author discusses methods of preparation for small- and large-scale amounts. Data are presented on the rate of decomposition, heat and moisture relationships, chemical analyses of the products, and volume and appearance of the finished product, as well as results from pot and field experiments. Both chemical and vegetation tests showed that when Cyanamid or ammonium sulfate was used in the preparation of manure from corn stover, oat straw, or leaves and garbage, a finished product resembling well-rotted farmyard manure was obtained. Leaves used alone decomposed to form artificial manure very slowly, while corn stover decomposed most rapidly.

Forest soil studies.—II, Changes in microflora and chemical composition of decomposing tree leaves, E. A. MARTEN and G. G. POHLMAN. (W. Va. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 1, pp. 67-77, figs. 4).—Ground leaf samples from table mountain pine, beech, red maple, red oak, yellow poplar, and black walnut trees were inoculated, in the second of these studies (E. S. R., 83, p. 25), with a soil suspension from a mixed forest stand and incubated for 32 weeks. Changes in flora and in chemical composition were noted.

The pH of all leaves increased during the incubation period. At the end of the incubation period the black walnut had the highest pH, followed in order by yellow poplar, beech, red oak, pine, and red maple. Rapidity of increases in bacterial numbers was associated with pH, the black walnut showing the most bacteria and red maple the least in the early stages of decomposition. Follow-

ing the initial increase in bacterial numbers and the decomposition of water-soluble material, there was little evidence of relationship between bacteria and reaction. Numbers of fungi increased rapidly in all samples regardless of pH. The types of micro-organisms were found to be the same regardless of the kind of leaf sample used. The early decomposition affected principally the water-soluble materials, whereas some decomposition of cellulose and lignin occurred in the later stages. The extent of lignin and cellulose decomposition appeared to be associated with pH, the higher rate of decomposition occurring at higher pH values. An increase in lignin content of red oak, yellow poplar, and red maple occurred during the first 8 weeks of the experiment. There appeared to be some relationship between lignin and excess base content.

**Nitrogen losses from Alabama soils in lysimeters as influenced by various systems of green manure crop management, R. J. JONES.** (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 6, pp. 574-585, figs. 2).—Nitrate nitrogen leached from Decatur clay loam, Norfolk sandy loam, and Hartsells fine sandy loam was determined over a 4-yr. period with lysimeters under different systems of crop and soil management. Winter and summer legumes and sodium nitrate were used as sources of nitrogen. The influence of the soil treatment on crop yields and nitrogen recovery was determined by growing Sudan grass during the summer. Nitrogen loss from leaching was closely related to the texture of the soil, i. e., the nitrogen lost decreased as the clay content increased. Cropping reduced the amount of nitrogen that was leached. With sandy soils the amount of nitrogen leached increased as the percentage of nitrogen contained in the different materials increased. The growing of a winter cover crop following fall-turned legumes resulted in only a small nitrogen loss from leaching. The author concludes from the results that summer legumes should be turned in the spring on sandy soils, unless a winter cover crop is to be grown, that winter cover crops greatly reduce the loss of nitrogen by leaching, that the loss of nitrates is related to the texture of the soil, and that soils should not be left fallow during seasons of heavy rainfall.

**Persistence of *Rhizobium japonicum* in soil, A. G. NORMAN.** (Iowa Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 5, p. 499).—From a field experiment with soybeans under two levels of fertility to determine the effect of inoculation on yield, the author failed to find any significant difference in number of nodules between inoculated and uninoculated plats, although there was a difference in nodules present under the different levels of fertility, the greatest number being under the lower fertility level. Yields also failed to reveal any significant difference as a result of the inoculation. A further search of the land history revealed that in the season of 1917, immediately before this portion of the farm was taken over for experimental purposes, a crop of beans had been planted on the two ranges concerned. A sufficient number of organisms to produce satisfactory nodulation had thus been maintained in these soils for a period of 24 yr.

**The influence of fertilizers and season on nonsymbiotic nitrogen fixation in Brookston and Bedford silt loams, J. L. ROBERTS and F. R. OLSON.** (Ind. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 7, pp. 624-627).—A higher content of soil nitrogen in fertilized Bedford silt loam in comparison with unfertilized was not found to be due to stimulated nonsymbiotic nitrogen fixation. Also the rate of nitrogen fixation in Bedford or Brookston silt loams was not affected by phosphatic or potassic fertilizers. Relatively few *Azotobacter* were found in the samples studied, and these could not be considered responsible for a significant part of the observed nitrogen fixation.

**The *Azotobacter* plaque test as applied to the determination of phosphate deficiency in Idaho soils, W. V. HALVERSEN and W. G. HOGE.** (Idaho Expt.

Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 6, pp. 503-512).—The authors describe a modified *Azotobacter* plaque test which they state has several advantages over methods used by other investigators. The test was applied to 425 representative Idaho soils of which 17 percent were classified as not deficient, 83 percent ranged from slightly deficient to very deficient, and 66 percent ranked from moderately deficient to very deficient. Since most of these soils are representative productive soils of Idaho, it seems unlikely that 66 percent should logically be classified as moderately to very deficient in phosphorus. Yield data indicate that although the modified procedure overcomes certain difficulties, it is not a reliable indicator of phosphate deficiency in the Idaho soils studied, because *Azotobacter* growth indicated much greater response to phosphate when added to the plaque test than did field crops to normal fertilization with phosphate under field conditions.

**Phosphate fixation in soil and its practical control**, F. E. BEAR and S. J. TOOTH. (N. J. Expt. Stas.). (*Indus. and Engin. Chem.*, 34 (1942), No. 1, pp. 49-52, figs. 2).—Observations of agronomists on crop recovery of applied phosphate, location of applied phosphate within the soil profile, increased response to phosphate fertilization placed in bands, and small loss of phosphate in the drainage water are explained on the basis of phosphate fixation. The factors discussed in connection with phosphate fixation include microbiological consumption, chemical precipitation, and physicochemical adsorption. Fertilizer placement both in bands and below the zone affected by cultivation and summer drought are suggested for increasing the effectiveness of applied phosphate.

**Field experiments with phosphate fertilizers**, T. E. ODLAND and T. R. COX (*Rhode Island Sta. Bul.* 281 (1942), pp. 27, figs. 4).—Superphosphate, concentrated superphosphate, ground bone, basic slag, dicalcium phosphate, and rock phosphate are compared for the period 1926-39 in an experiment involving different phosphate carriers which was begun in 1894. Comparisons were made between rock phosphate and superphosphate on an equal phosphoric acid and an equal cost basis. The crops used consisted of potatoes, field corn, mixed hay, oats, barley, rape, and five vegetable crops.

Superphosphate, either as the ordinary grade or as concentrated, was the most efficient source, in general. Rock phosphate became too slowly available for most crops and cannot be considered a satisfactory source. Ground bone was found satisfactory for some crops, but was too slowly available for most crops, and the cost per unit is too high for general usage. Basic slag was a very satisfactory source, but the unit cost is considerably more than in superphosphate. Dicalcium phosphate was also satisfactory, but the cost per unit was somewhat higher than in superphosphate. If it can be obtained at the same cost per unit as superphosphate it should prove an economical source. The largest response to additional applications of phosphorus was obtained with cabbage, potatoes showed less response, and corn, oats, and mixed hay were intermediate. The authors conclude that considering the availability, cost per unit of effective phosphoric acid, and yields obtained, superphosphate, either as the ordinary grade or in concentrated form, is the most efficient source of phosphorus for fertilizer use in this region.

**Plant culture and nitrification studies with sludge-acid superphosphate**, B. E. BROWN, K. D. JACOB, and F. R. REID. (U. S. D. A.). (*Amer. Fert.*, 96 (1942), No. 7, pp. 5-6, 24, 26).—Acid-sludge from the refining of petroleum products is sometimes used in the manufacture of superphosphate, but in some cases there has developed a prejudice against the use of superphosphate made from the sulfuric acid sludge over that made from clear sulfuric acid. Greenhouse and laboratory tests were undertaken to determine whether there was any

basis for this prejudice. Sludge-acid superphosphate from four different sources was usually found to give results that were not inferior to those obtained from clear-acid superphosphate.

The authors also compared the different phosphates by means of nitrification studies on ammonium sulfate in soil cultures: Conversion of ammonium nitrogen to nitrate was practically the same over a 6-week period for both types of superphosphate.

**Liming the land**, F. E. BEAR (*New Jersey Stat. Cir.* 451 (1942), pp. [4]).—A popular discussion on the importance of using lime for obtaining maximum returns from soils. The question of how much and what type of lime to use is also discussed. In connection with the type of lime to use, the author points out that the purpose of this publication is not so much to deal with the form of lime as to encourage its greater use.

**Manganese for oats and white beans in Michigan**, R. L. COOK and C. E. MILLAR. (Mich. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 6 (1941), pp. 224-227, figs. 6).—A manganese deficiency disease, grey speck of oats, has been found on alkaline mineral soils. Oats growing on alkaline sandy loam soils in Ingham, St. Clair, and Tuscola Counties were found to be seriously affected by the disorder. Applications of manganese sulfate greatly reduced the difficulty. Magnesium sulfate proved to be a partial corrective. During a survey of bean fields in 1940 for symptoms of potash deficiency, a discoloration of the bean leaves similar to that produced by a manganese deficiency was noted. Studies during 1941 showed the difficulty to be present in a number of fields and parts of fields. Soil tests showed the soils to be neutral or slightly alkaline where the deficiency symptoms were observed. Deficiency symptoms were found where an unusually vigorous growth of the bean vines occurred, which led to the conclusion that the luxuriant growth resulted in an exhaustion of the available supply of manganese. Manganese sulfate treatments resulted in a disappearance of the deficiency symptoms.

**Wartime fertilizers for New Jersey** (*New Jersey Stat. Cir.* 452 (1942), pp. [8]).—A condensed summary of recommendations concerning practices to increase the effectiveness of fertilizers and the kind of fertilizer to use for different crops. The problem of meeting the inorganic nitrogen shortage resulting from the use of nitrogen for war purposes is discussed under seven points indicating how nitrogen fertilizers can be used more effectively. Points to consider in getting the most from fertilizers in general are also presented. Recommendations of amounts and methods of application of fertilizers are given for various crops under different soil conditions.

**Water solutions of ordinary mixed fertilizers for use in starting and side-dressing plants**, A. L. PRINCE and V. A. TIEDJENS (*New Jersey Stat. Cir.* 449 (1942), pp. [4]).—Because of the difficulty of obtaining the high-analysis fertilizers originally proposed for use in water solutions for transplanting or side dressing, the suitability of ordinary mixed fertilizers was determined. The percentage of nitrogen, phosphorus, and potash soluble in water is given for 10 grades of mixed fertilizers. Most of the nitrogen and potash was soluble in water, while only from one-half to two-thirds of the phosphate was water-soluble. The authors conclude that ordinary commercial grades of mixed fertilizer can be used for making liquid fertilizers for transplanting and side dressing purposes.

**Cottonseed meal ash as a fertilizer**, P. CORREA DE MELLO (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 7, pp. 677-679).—Due to the loss of northern European markets for cottonseed meal, the price has declined to the point where the producers of the meal are beginning to use it as a fuel, which results in a fertilizer

material known as cottonseed meal ash. Cottonseed meal ash is made up in its entirety of phosphates, potash, magnesium, and calcium, with the amount of carbonate practically insignificant. Its value as a fertilizer has been confirmed by some of the producers in various ways, and, for this reason, the author decided to prepare this brief article in order to dispel whatever doubt exists as to its true value as a fertilizer. The author presents the following analysis as representing typical cottonseed meal ash:  $\text{SiO}_2$  0.92 percent,  $\text{P}_2\text{O}_5$  43.60,  $\text{K}_2\text{O}$  32.70,  $\text{MgO}$  17.80. and  $\text{CaO}$  5.70 percent.

## AGRICULTURAL BOTANY

**Geographical guide to floras of the world: An annotated list with special reference to useful plants and common plant names.**—Pt. 1, Africa, Australia, North America, South America, and Islands of the Atlantic, Pacific, and Indian Oceans, S. F. BLAKE and A. C. ATWOOD (*U. S. Dept. Agr., Misc. Pub. 401* (1942), pp. [1]+336).—The primary purpose of this book is usefulness rather than bibliographical completeness, since it aims to furnish an annotated catalog through 1939 of all the now useful floras and floristic works, including those in periodical literature that list or describe the complete vascular flora (or phanerogams only) of any region or locality, as well as all publications dealing on the same scale with useful and medicinal plants, vernacular names, and botanical bibliography. In general, only the later works referring to a given region or subject are included, and publications dealing with only a part of a flora are covered only when dealing with edible, medicinal, or woody plants. Occasional titles relating to weeds and poisonous species, chiefly from the botanical standpoint, are also included. Papers that are primarily ecological have been omitted unless they contain fairly complete lists of the plants of the areas discussed. It is believed that no list of the scope of this one has ever been published before, and this part covers all the world except Europe and Asia and the islands closely associated with them, comprising about 2,597 primary and 428 subsidiary titles. Author and geographical indexes are provided.

**Vegetacion y riqueza forestal de la Provincia de Esmeraldas (Ecuador): Principales especies medicinales y forestales** [Vegetation and forest wealth of the Province of Esmeraldas (Ecuador): Principal medicinal and forest species], M. ACOSTA SOLIS (*Maderil*, 14 (1942), No. 165, pp. 13-16, fig. 1).

**The vegetation and natural resources of British Honduras**, C. L. LUNDELL (*Chron. Bot.*, 7 (1942), No. 4, pp. 169-171, fig. 1).

**The vegetation of Jamaica**, F. SHREEVE (*Chron. Bot.*, 7 (1942), No. 4, pp. 164-166).

**Two new dwarf species of Rubus from western China and Tibet and their Asiatic relatives**, E. H. WALKER (*Jour. Wash. Acad. Sci.*, 32 (1942), No. 9, pp. 260-262).

**The ecology of turf grasses**, J. C. CARROLL (*Ohio State Univ., Abs. Doctoral Diss.*, No. 36 (1941), pp. 29-33).—The author investigated the relative survival of a number of turf grasses when subjected to different degrees of drought and temperature, and the effect of nitrogenous fertilizers in conjunction with these other factors. Analyses were also made of the tissue for moisture, bound water, total nitrogen, and total sugars.

**Researches on drought resistance in spring wheat.**—II, **The effect of time of day on survival of plants during exposure to artificial drought**, C. B. KENWAY, H. B. PETO, and K. W. NEATBY (*Canad. Jour. Res.*, 20 (1942), No. 8, Sect. C, pp. 397-402).—Continuing these studies,<sup>1</sup> the time of day during which

tests were conducted was found to have a pronounced effect on the injury sustained by wheat plants subjected to artificial drought. When the day was divided into four 6-hr. periods, beginning at 6 a. m., the period from then to noon provided the most severe test. In 12-hr. and 18-hr. exposures, relatively severe damage to the plants was associated with the inclusion of the 6 a. m.-to-noon period.

**Preliminary investigation of the rhythmic fluctuations in transpiration under constant environmental conditions**, J. C. MONTERMOSE and A. R. DAVIS. (Univ. Calif.). (*Plant Physiol.*, 17 (1942), No. 3, pp. 473-480, figs. 2).—Leaves and cuttings of *Coleus blumei* rooted in the usual manner under normal greenhouse conditions exhibited rhythmic transpiration fluctuation when placed under constant environmental conditions of darkness, temperature, and humidity. The diurnal maximum and minimum fluctuations could be reversed by subjecting the plants to reversed light-dark periods using artificial light. There was a gradual transition of the maximum and minimum so that within 4 days a complete reversal was accomplished. There are 14 references.

**Root modifications induced in *Zea mays* seedlings by irradiating dry seeds with soft X-rays**, G. F. SMITH and H. KERSTEN (*Plant Physiol.*, 17 (1942), No. 3, pp. 455-464, figs. 19).—External and histological modifications occurring in the primary roots of corn seedlings grown from X-rayed seeds are described and illustrated. See also a previous note (E. S. R., 85, p. 745).

**Tree growth and the environmental complex: A critique of "ring" growth studies with suggestions for future research**, A. W. SAMPSON and W. S. GLOCK. (Univ. Calif. et al.). (*Jour. Forestry*, 40 (1942), No. 8, pp. 614-620).—This conference report (August 1941) presents the views of a group of specialists on the formation and interpretation of "tree rings." Much emphasis is placed on the complexity of the environmental factors influencing tree growth and on the biometric difficulties in attempting to correlate tree growth with rainfall. It was agreed that extensive experimental studies under controlled conditions would be desirable, and that the cooperation of physiologists, ecologists, climatologists, soil scientists, etc., is essential to a determination of the effects of the various environmental factors on growth.

**Looking into a banana "tree": Structure and growth of the world's largest herb revealed**, H. W. RICKETT (*Jour. N. Y. Bot. Gard.*, 43 (1942), No. 510, Sect. 1, pp. 141-148, figs. 5).

**Growth and development of white poppy on varying daylength**, N. A. KHLEBNIKOVA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 32 (1941), No. 7, pp. 503-504).—In experiments reported with two subspecies (not specified) of *Papaver somniferum*, the growth rate and development were deeply influenced by day length. The form from Tarbagatai (Chuguchak) possessed a long-day habit whereas the one from Tien-Shan proved more plastic, easily tolerating a short photoperiod.

**Studies in the effects of prolonged rotation of plants on a horizontal klinostat**.—III, **Physiological reactions in the hypocotyl of *Lupinus albus***, E. D. BRAIN (*New Phytol.*, 41 (1942), No. 2, pp. 81-90, fig. 1).—Geotropic response, pH of the cell sap, suction-pressure value of the cell sap, extensibility of the cell walls, and growth-substance distribution were examined in white lupine hypocotyls grown on a horizontal klinostat, and the results are presented in detail. The evidence indicates that differential growth-substance distribution is a fundamental process in geotropic response and induces greater extensibility of the cell walls receiving the increased growth-substance supply.

<sup>1</sup> *Canad. Jour. Res.*, 17 (1939), No. 8, Sect. C, pp. 294-296, figs. 2.

**On the causes of regeneration after longitudinal splits,** R. SNOW (*New Phytol.*, 41 (1942), No. 2, pp. 101-107, figs. 4).—In young stems split longitudinally the halves of the cambial ring are known to become rounded off into two rings by regeneration of the inner sides, and root tips behave similarly. Evidence is offered, mainly from experiments on sunflower hypocotyls, that the causal factor of this regeneration is neither a wound substance nor the formation of a new surface, but that in split stems it is the interruption of the continuity of the old cambial ring in the transverse directions. It is argued that if the splits cause regeneration by interrupting transverse continuity, then they must interrupt some process which normally occurs in these directions and maintains the unity of the organ. The evidence offered appears to indicate that this transverse process is not the movement of a hormone capable of diffusing out of the cells, and that it needs continuity of protoplasm.

**Physiological studies in plant nutrition.—XII, Carbohydrate changes in the several organs of the barley plant during growth, with especial reference to the development and ripening of the ear,** H. K. ARCHBOLD and B. N. MUKERJEE (*Ann. Bot. [London], n. ser.*, 6 (1942), No. 21, pp. 1-41, figs. 9).—It is shown that there is no material interchange of carbohydrate between roots and aerial parts during ear development, so that the roots do not constitute a reserve for the ear. The amount of soluble glycosides, found highest in the leaves, fell towards harvest, but the loss was quite insignificant in relation to ear growth, so that this possible source of supply to the ear is also excluded. During the period of falling steam sugar (40 percent of the growth cycle) 60 percent of the ear growth was made, but the loss of sugar accounted for only about 10 percent of the final dry weight of the ear. Since there was also a further 10 percent loss from the fraction insoluble in alcohol and cold water, there was no major break-down of cellulose complexes to supply the ear, and it is suggested that this loss of insoluble material was in fact not of carbohydrate but of N compounds. At least 80 percent of the ear dry weight must therefore result from direct assimilation by the leaves, stems, and ears themselves, and stored sugar cannot be regarded as essential to ear development. The sugar in the immature ear amounted to only 5 percent of its final weight, and it is doubtful if even this amount was actually condensed to starch. It is suggested that the demands of the ear exercise no special control over loss of stored sugar.

The rates of sugar loss observed were probably not higher than might be expected if the sugar were lost in respiration, but the rapid loss from the leaf sheaths relative to leaves and from N-deficient plants relative to full-N plants makes it difficult to accept this as a complete explanation of all the loss. It is suggested that each internode acts as a separate unit receiving supplies from the attendant leaf and sheath, and there may be some movement of stabilized sugar from sheath to corresponding internode but it is deemed doubtful if there is a transference between the internodes themselves. There was no evidence of conversion of fructose to glucose or vice versa. Although the precise fate of the stored sugar remains uncertain, it was demonstrated that it plays no important part in ear development, and it is not yet certain that there is any upward translocation of such sugar at all. There are 22 references.

**The culture of albino maize,** H. A. SPOERRE (*Plant Physiol.*, 17 (1942), No. 3, pp. 397-410, figs. 2).—Albino corn plants were kept alive for several months by artificial nutrition with sucrose and showed a definite increase in dry weight above that of the seed from which they sprang. They also produced the same

number of leaves as normal plants and staminate and pistillate inflorescences. The albino leaves formed starch when infiltrated with sucrose and dextrose solutions but, in contrast to green leaves, not with solutions of glycerine or sorbitol. Some theoretical aspects of the use of cultures of albinos for elucidating certain phases of the photosynthesis problem are discussed. There are 18 references.

**Effect of saline substrate on hourly levels of carbohydrates and inorganic constituents of barley plants**, H. G. GAUCH and F. M. EATON. (U. S. D. A. and Tex. Expt. Sta.). (*Plant Physiol.*, 17 (1942), No. 3, pp. 347-365, figs. 6).—To determine the relation between cyclic variations in transpiration rates on the accumulation of inorganic constituents and the effect of saline substrates on the accumulation of carbohydrates, barley plants were grown in sand cultures with base nutrient (control), and with this plus 100 milliequivalents per liter of chloride and 200 m. e./l. of sulfate, respectively, sampled six times over a 24-hr. cycle. The relative weights of the three lots on a fresh weight basis were 100, 43, and 28, and on a dry weight basis 100, 61, and 43, respectively. The average moisture content of the three sets of plants was 90.6, 86.8, and 85.7 percent, respectively. Under all treatments essentially uniform concentrations of Ca, Mg, Na, K, P, N, sulfate, and chloride in the dry matter occurred over the 24-hr. cycle in which temperature rose to 98° F. and the relative humidity dropped to 13 percent at noon.

Addition of both chloride and sulfate salts reduced the Ca concentrations relative to controls, left Mg unchanged, caused a marked increase in Na and a marked decrease in K, and had little effect on total N and P concentrations. Accumulation of chloride in the controls was notably high, and addition of chloride brought about a further uptake. The controls contained 17 and the 200-sulfate plants 27.7 m.e. of S per 100 gm. of dry matter. Associated with this accumulation of S in the sulfate plants there was a depression in chloride content, but there was no change in the S content of chloride plants associated with chloride accumulation. Analyses for starch and sugars (4 p. m.) in the three sets of plants indicated that the accumulation of carbohydrates was associated with salt accumulation, showing that the salts interfered with the utilization of carbohydrates in cellular elaboration rather than with photosynthetic activity. There are 19 references.

**Induced formation of a  $\beta$ -glucoside in the radish**, L. P. MILLER (*Contrib. Boyce Thompson Inst.*, 12 (1942), No. 5, pp. 359-360).—"Through its isolation as the tetraacetate,  $\beta$ -2-trichloroethyl-D-glucoside was shown to be formed in both roots and leaves of the radish from absorbed chloral hydrate."

**The chlorophyll-protein compound of the green leaf**, E. L. SMITH (*Chron. Bot.*, 7 (1942), No. 4, pp. 148-149).—A review and brief general discussion, with bibliography.

**Nitrogenous character of penicillin**, E. P. ABRAHAM, W. BAKER, E. CHAIN, H. W. FLOREY, E. R. HOLIDAY, and R. ROBINSON (*Nature [London]*, 149 (1942), No. 3778, p. 356).—Penicillin was shown to contain N.

**Sulphur content of seeds and seed weight in relation to effects of sulphur deficiency on growth of sunflower plants**, S. V. EATON (*Plant Physiol.*, 17 (1942), No. 3, pp. 422-434, figs. 5).—Seeds from sunflower plants grown in a minus-S nutrient solution were fewer per head and much smaller than the plus-S seeds, but they contained the same percentage of S as the latter though much less on the absolute basis. The plus-S seeds were smaller than the originals, and contained slightly less actual S per seed than the latter though more on a percentage basis. The small minus-S seeds germinated practically as well as the large plus-S and slightly better than the original seeds. Deficiency of S reduced

the size of plants from minus-S seeds more than that of plants from plus-S seeds, though this difference was small. As a means of reducing the error from S impurity in the seeds, the method proved unsatisfactory because of the relatively small plants produced by the small minus-S seeds. The effect of seed weight on the size of the plant was clearly shown, plants developing from the small minus-S seeds being much smaller than those from the larger plus-S seeds. However, considering the three lots of seeds the plus-S intermediate in weight between the minus S and the originals produced the largest plants. Relative to size of seeds, plants from minus-S seeds were larger than those from plus-S seeds, and this advantage was greater in plants grown with than without S in the nutrient solution. As shown by top-root ratios, size of seed affected the root more than the top, but the S-deficiency effect was the reverse. Production of larger plants by heavier seeds was due mainly to the greater amount of storage substances in the seeds. The only compound determined in this study was S, and the greater amount in the larger plus-S seeds was clearly one reason for the larger plants produced by these as compared with the minus-S seeds. It is unknown why the original seeds, which were larger and contained slightly more S than the plus-S seeds, failed to produce as large plants as the latter. It is suggested that competition among plants may account in part for the results obtained in this study.

**Absorption of selenium by corn from *Astragalus* extracts and solutions containing proteins.** S. F. TRELEASE, S. S. GREENFIELD, and A. A. DISOMMA (*Science*, 96 (1942), No. 2488, pp. 234-235, figs. 2).—Corn plants in culture solution absorbed far more Se from a water extract of *Astragalus* than from Na<sub>2</sub>SeO<sub>4</sub>. Furthermore, added bactotryptone, neopeptone, sodium caseinate, and proteose peptone approximately doubled the Se accumulation by corn, and smaller increases were obtained with other organic substances tested. It would seem obvious that various cultivated crops, themselves unable to rival the true indicator plants, might still be capable of significant activity as Se accumulators and converters in a soil rich in organic materials.

**Absorption and accumulation of rubidium bromide by barley plants: Localization in the root of cation accumulation and of transfer to the shoot.** F. C. STEWARD, P. PREVOT, and J. A. HARRISON (*Plant Physiol.*, 17 (1942), No. 3, pp. 411-421, figs. 2).—In barley roots there is a longitudinal gradation in cation accumulation similar to that shown for an anion (E. S. R., 76, p. 457), and such gradation was demonstrated for Rb and K by use of spectrographic methods. Like excised roots, those attached to the plant and in contact with a salt solution showed a gradation in salt concentration along their length—the highest being at the apex. Barley plants grown without access to external salts accumulated in their roots a greater concentration of Rb than of bromide from aerated RbBr solutions. The leafy shoot is the principal region of Rb accumulation, and the average concentration attained may exceed that even in the root tip. Br moves to the shoot more readily than Rb. After contact with RbBr solutions, and when transferred to solutions free of this salt, the shoot depleted the root of the salts it had previously absorbed—especially the bromide.

When the shoot removes Rb and bromide from the root it does so first from the younger segments. Eventually, however, ions (especially bromide) may be withdrawn even from levels at which the endodermis should be impermeable. During this process the normal gradient of salt accumulation may be reversed. It is in the region of the root in which growth and vascular differentiation occur that transfer from the storage cells of the root to the stele for movement to the shoot is localized. Accumulation of Rb did not progress for long in excised roots, which lacked the stimulus of the shoot, but in attached roots, despite some removal to

the shoot, the concentrations continued to increase for at least 130 hr. The shoot, which provides the stimulus for salt removal from the root also, by promoting the continued growth of the root, maintains at its apex the development and activity of the tissue chiefly responsible for absorbing salt from the external solution and transferring it to the stele and thence to the shoot. The uptake and distribution of salt is therefore responsive to the factors which in the whole organism correlate and integrate the growth of its parts. There are 12 references.

**Substituted phenoxy and benzoic acid growth substances and the relation of structure to physiological activity**, P. W. ZIMMERMAN and A. E. HITCHCOCK (*Contrib. Boyce Thompson Inst.*, 12 (1942), No. 5, pp. 321-343, figs. 6).—Several new growth substances are described and their effects on plants compared and contrasted with those reported for other hormonelike compounds. Among them, 2,4-dichlorophenoxyacetic acid and its derivatives proved most active for growth, inducing cell elongation of tomato at concentrations as low as 0.0007 percent in lanolin and comparing favorably with naphthaleneacetic acid. *p*-Chlorophenoxyacetic acid and *o*-chlorophenoxyacetic acid were less active, in the order named. When a Br group was substituted in the para position in the ring, the resulting compound was less active than when Cl occupied the same position. 2-Bromo-3-nitrobenzoic acid showed growth activity down to 0.05 percent in lanolin, and this is the first active compound with the carboxyl group linked directly to the ring. All the chlorophenoxy compounds exhibiting growth activity also induced another response having to do with morphogenesis. 2-Bromo-3-nitrobenzoic acid and 2-chloro-5-nitrobenzoic acid induced formative effects, though the latter was inactive for cell elongation. The new compounds varied in their capacity to induce adventitious root development, the *p*-chloro and 2,4-dichlorophenoxyacetic acids and amides being the most active. The chlorophenoxy compounds induced parthenocarp when applied to flowers of tomato and cucumber. Considering the activity of halogen substituted derivatives, it is believed likely that additional research in this new field will yield many more active compounds. There are 14 references.

**The inhibition of germination**, M. EVENARI, E. KONIS, and S. B. ULLMAN (*Chron. Bot.*, 7 (1942), No. 4, pp. 149-150).—This is a brief account of the authors' work on germination inhibition exerted by seeds and fruits on seeds of their own or of other species.

**Seaweeds at Beaufort, North Carolina, as a source of agar**, H. J. HUMM (*Science*, 96 (1942), No. 2488, pp. 230-231).—In initiating a systematic testing of all the more common larger species of red algae of the Atlantic Coast from Beaufort southward to the Florida Keys, preliminary tests indicated that in the most common species (*Gracilaria confervoides*) 25-35 percent of its air-dry weight is agar. The alga is present in large amounts, is easily collected, and the method of preparation is described. Another common species is *Hypnea musciformis*, from which agar can also be made but which thus far, though usable, has been inferior in quality. Determinations on two species of pelagic *Sargassum* showed their content in alginic acid to be very small. Similar determinations of other red and brown algae are planned.

**Formation of nicotine in plants grafted on tobacco**, A. SHMUCK, A. SMIRNOV, and G. ILYIN (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 32 (1941), No. 5, pp. 365-368).—When scions of *Solanum nigrum*, tomato, and *Datura stramonium*, none of which normally synthesize nicotine, were grafted onto tobacco stocks, all three species were found to elaborate nicotine. Conversely, when tobacco scions were grafted onto stocks of these three species, the tobacco itself lost its power to synthesize the alkaloid. It thus seems obvious that formation of nicotine by tobacco is connected in some obscure way with

the root system and stem of the plant. Tobacco grafted onto *Nicotiana glauca* also lost its ability to elaborate nicotine, forming anabesine instead, but when *N. glauca* was grown on a tomato stock it produced as much anabesine as control plants on their own roots. The significance of these findings are briefly discussed.

**Interaction between *Lycopersicum esculentum* and *Datura stramonium* in the case of grafting**, J. J. KERKIS and N. N. FIGULEVSKAYA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 32 (1941), No. 7, pp. 505-508, figs. 3*).—In the grafting experiments reported, atropine was found in all parts of the tomato scion on *D. stramonium* stock and no correlation was noted between the amount and the relative ages of the graft components involved. However, the concentrations in different parts of the graft differed greatly, the lowest quantities occurring in the fruit. With tomato as stock under *Datura*, its fruit contained only insignificant amounts of atropine, but the amounts in the green parts of the tomato differed but little whether it was used as stock or scion. Atropine was always present in *Datura* grown on tomato stock, but none was contained in the progeny of seed from plants receiving their atropine by way of grafting. Though the biochemical properties of all parts of the tomato plant underwent considerable changes from grafting on *Datura*, the form of its fruit was very little affected.

**Ergot**, J. C. NEILL (*New Zeal. Jour. Sci. and Technol., 23 (1941), No. 3A, pp. 130A-137A, figs. 8*).—The occurrence in New Zealand and life history of ergot (*Claviceps purpurea* and *C. paspali*) are briefly described, and an account is given of preliminary commercial production trials on rye.

**The chemistry, pharmacology, and toxicology of ergot (*Claviceps purpurea*)**, I. J. CUNNINGHAM (*New Zeal. Jour. Sci. and Technol., 23 (1941), No. 3A, pp. 138A-145A*).—Some new toxicological data are included in this study.

**Manual of methods: Supplement to Leaflet I (*Pure Cult. Study Bact., 10 (1942), No. 3, pp. [2]+8*)**.—A review is presented of certain basic considerations underlying the purposes for which the publications of the Committee on Bacteriological Technic of the Society of American Bacteriologists are issued. These include the meaning of pure culture study, relation to taxonomy, publications of the committee, pitfalls to be avoided by the student, and practical hints.

**Routine tests for the descriptive chart: Morphological and biochemical**, H. J. CONN ET AL. (*Pure Cult. Study Bact., 10 (1942), No. 2, Leaflet 5, 8. ed., pp. [2]+23, fig. 1*).

**Growth factors for bacteria.—XIII, Purification and properties of an eluate factor required by certain lactic acid bacteria**, B. L. HUTCHINGS, N. BOHONOS, and W. H. PETERSON. (Wis. Expt. Sta.). (*Jour. Biol. Chem., 141 (1941), No. 2, pp. 521-528*).—"A method for the preparation of concentrates of the nitrit eluate factor is presented. The active principle is an acid and probably contains an amino group. The nutritional importance of the compound is indicated by its indispensable role in the nutrition of certain bacteria and its probable requirement by the chick."

**On the width and origin of bacterial flagella**, G. KNAYS. (Cornell Univ.). (*Science, 95 (1942), No. 2468, pp. 406-407*).—Using methods described and a photograph of *Aerobacter cloacae* taken with the electron microscope, the width of the flagellum was found to be between  $0.02\mu$  and  $0.03\mu$  in thickness, with an average ratio of 1:22 between the width of the dried flagellum and that of the dried cytoplasm. Furthermore, the flagellum apparently arises from the cytoplasm rather than the cell wall.

**Bacteria attacking petroleum and oil fractions**, R. W. STONE, M. R. FENSKE, and A. G. C. WHITE. (Pa. State Col.). (*Jour. Bact., 44 (1942), No. 2, pp. 169-178*).—Cultures capable of attacking crude oil, lubricating oils, vaseline, asphalt, and all other petroleum fractions used were obtained from garden soil

and their reactions studied in detail. All were motile gram-negative rods, including *Pseudomonas* and many white-mucoid types. They were obtained from all soil samples tested and appeared to be of common occurrence. The cultures exhibited no specific ability to attack one type of oil but rather a capacity to adapt themselves, according to conditions, to attack any particular oil present. There are 15 references.

**A bacteriological comparison between synthetic and natural glycerol,** H. J. PEPPLER (Kans. Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 2, pp. 233-236).—Studies of growth on glycerol-salts media and of dehydrogenase activity of suspensions of micro-organisms (*Mycotorula* and bacteria of widely different genera) indicated synthetic glycerol (Shell) to be as good a substrate as glycerol derived from lipids. Culture of *Phytomonas tumefaciens* and *Salmonella pullorum* in the synthetic media had no deleterious effect on their virulence.

**Nitrogen fixation in leguminous plants.—I, General characters of root-nodule bacteria isolated from species of Medicago and Trifolium in Australia,** H. L. JENSEN (*Linn. Soc. N. S. Wales, Proc.*, 67 (1942), pt. 1-2, pp. 98-108, pl. 1, figs. 3).—From host plants grown in Australia, 24 strains each of *Rhizobium meliloti* and *R. trifolii* were isolated, and as a whole they conformed to the general descriptions of the two species. Carbohydrate fermentation revealed no subgroups within the species, but was stronger in *R. meliloti*. The limits for growth were pH 5.1-5.3 for *R. trifolii* and pH 5.3-5.5 for *R. meliloti*. In well-buffered nutrient solutions, particularly in the presence of organic salts, *R. trifolii* failed to grow at pH 7.1-7.5 and had an optimum at pH 5.5-6.5, whereas *R. meliloti* had an optimum at pH 7-8 and grew at values above pH 8.7. All *R. trifolii* strains (except one) produced nodules on sterile seedlings and appeared to be effective on some species of clover; the inefficiency of strains from white clover on subterranean clover and vice versa was an inconstant phenomenon. All strains of *R. meliloti* produced effective nodules on alfalfa, but in burr trefoil this was true only for strains isolated from varieties of *M. hispida*. These strains belonged to a group apparently differing from the rest in being slightly more sensitive to acid reaction and in not readily forming a clear zone in milk. Some *R. meliloti* strains dissociated, giving rise to two types of variants, one producing a mucoid and the other a firm and wrinkled growth. There are 20 references.

**The effectiveness of certain strains of the soya-bean nodule organism when associated with different varieties of the host plant,** J. BOYES and G. BOND (*Ann. Appl. Biol.*, 29 (1942), No. 2, pp. 103-108).—The results of observations on N fixation by four strains of soybean nodule bacteria, when associated with four host varieties (Manchu, Brown C, Black O, and Green Jap) grown in sand culture in the greenhouse, agreed with those of certain previous investigators in showing that the relative effectiveness of some of the strains varied when associated with different host varieties. The reason for this variation is briefly discussed, and consideration is given to the best basis for comparing the effectiveness of bacterial strains associated with host varieties of different growth habit or with the same host variety under different conditions. Those strains effective with the American variety Manchu were also effective with the British varieties. There are 13 references.

**The mycorrhizal relations of larch.—III, Mycorrhiza formation in nature,** J. E. HOW (*Ann. Bot. [London]*, n. ser., 6 (1942), No. 21, pp. 103-129, pl. 1, figs. 6).—In continuation (E. S. R., 85, p. 601), the roots of *Larix decidua* were found capable of being grouped into two classes, lateral and sublateral, corresponding to the long and short roots of pine. The majority of the mycorrhizas were normally formed by infection of the sublaterals. *Boletus elegans* and

*Paxillus involutus* were isolated from larch mycorrhizas, and *Mycellum radialis atrovirens* from pseudomycorrhizas. Evidence is presented that infection of the sublaterals by a mycorrhiza-former such as *B. elegans* results in an increase in the number of cortical cells in the roots as compared with the uninfected or with infection by pseudomycorrhizas. Detailed descriptions are given for the structural features resulting from infection by *B. elegans*, *B. viscidus*, *P. involutus*, a yellow hymenomycete mycellum, *M. radialis atrovirens*, and two unidentified mycellia. The general features of mycorrhiza formation in larch are discussed, and an appendix takes up mycorrhiza formation in experimental culture. There are 30 references.

**Respiratory studies of the micrococci**, T. D. NUNHEIMER and F. W. FABIAN. (Mich. Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 2, pp. 215-232, figs. 2).—The results of a study of the respiratory activities of *Micrococcus luteus*, *M. flavus*, *M. aurantiacus*, *M. cinnebareus*, and *M. freudenreichii* are presented in detail.

**Bactericidal effects of *Aspergillus clavatus***, B. P. WIESNER (*Nature [London]*, 149 (1942), No. 3778, pp. 356-357).—Two strains of *A. clavatus* proved capable of sterilizing fluid media inoculated with *Staphylococcus aureus* and other organisms. The active substance differed from penicillin not only by being bactericidal as well as bacteriostatic but also in several other characters.

**A simple photoelectric relay**, E. B. WORKING. (Kans. State Col.). (*Science*, 96 (1942), No. 2490, p. 281, fig. 1).—The relay described was used in the station milling research laboratory for controlling an adiabatic calorimeter for measurement of the heating of damp wheat.

**An atmospheric halatometer**, C. P. SIDERIS. (Univ. Hawaii). (*Plant Physiol.*, 17 (1942), No. 3, pp. 497-499, fig. 1).—Measurement of salt water carried by strong winds from the ocean and deposited on crop plants grown in fields near the coast becomes at times an important economic problem. For use in this and similar studies, an apparatus for collecting salt particles from the atmosphere was developed and is described and illustrated.

## GENETICS

**Mock-dominance and hybrid vigor**, F. D. RICHEY (*Science*, 96 (1942), No. 2490, pp. 280-281).—Two plant varieties, one with twice as many internodes of half the length as the other, will be equal in height. A hybrid between them will exceed their height by 12.5 percent if internode number and length are exactly intermediate in inheritance, i. e., without dominance. This effect, here termed "mock-dominance," "results from the fact that plant height is determined as the product of number and length of internodes and from the relations that obtain between the means of products and the product of means." The same principle applies to other characters such, e. g., as yields of grain, leaf areas, growth rates, and chlorophyll content v. leaf area. The applications to plant breeding are briefly discussed.

**Western Guatemala a secondary center of origin of cultivated maize varieties**, P. C. MANGELSDORF and J. W. CAMERON (*Harvard Univ., Bot. Mus. Leaflet*, 10 (1942), No. 8, pp. 217-252, pls. 2, fig. 1).—In a previous publication by Mangelsdorf and Reeves (*E. S. R.*, 82, p. 177), the tripartite theory of the origin of corn was presented. This study concerns itself with the concept that new types of corn originating directly or indirectly from the *Zea-Tripsacum* cross and admixture with *Tripsacum* comprise the majority of Central and North American varieties. Chromosome knob counts in 162 varieties from 38 western Guatemala localities showed a range in numbers from 1 to 16, and all of the 18 knob positions known in corn and also 3 previously unreported positions were

encountered. The greatest diversity was found in a small area where low-knob and high-knob varieties occur in close proximity, and this is also the area in which teosinte is found growing in the wild. The corn of western Guatemala exhibits great external morphological diversity, but plants with 6 knobs or less uniformly possess pubescent leaf sheaths, a coarse seminal root system, and susceptibility to lodging and smut. These varieties were found only at altitudes of 6,500 ft. or more. The number of chromosome knobs was associated with various characteristics which may have been derived from *Tripsacum*. The combined evidence suggests that a South American corn variety—characterized by pubescent leaf sheaths, coarse seminal roots, and susceptibility to lodging and smut—hybridized with a species of *Tripsacum* to produce the new genus *Euchlaena* and new corn varieties exhibiting *Tripsacum* admixture. Western Guatemala is thus regarded as a secondary center of origin of cultivated corn varieties. The potential value for purposes of plant breeding of the tripsacoid corn varieties of Guatemala is pointed out. There are 22 references.

**The association of mutants with homozygous deficiencies in *Zea mays*, B. McCLINTOCK.** (Univ. Mo.). (*Genetics*, 26 (1941), No. 5, pp. 542-571, pls. 2, figs. 2).—Corn mutants were found to arise following changes in the chromatin constitution of the ring-shaped chromosomes, such changes being produced after their aberrant behavior in some of the mitotic divisions. The types of mutants produced by these altered chromosomes were simple (composed of a single recognizable character) or compound (composed of two or more of the characters recognizable as simple mutants). In a number of cases the altered ring-shaped chromosomes producing the simple or compound mutants were isolated. By appropriate tests it was proved that the compound mutants were the products of two or more of the simple mutants. One group of mutants was located within the limits of the proximal four chromomeres of the short arm of chromosome 5, and the second group within the limits of the next five chromomeres. Evidence led to the conclusion that each mutant character was produced by a homozygous minute deficiency and associated with loss of a particular minute segment. The simple mutants were associated with loss of one such segment, and the compound with loss of two or more.

**Incomplete seed failure as a result of somatoplastic sterility, R. A. BRINK and D. C. COOPER.** (Univ. Wis.). (*Genetics*, 26 (1941), No. 5, pp. 487-505, figs. 7).—In the cross *Nicotiana rustica* ♀ × *N. tabacum* ♂, most of the hybrid seeds collapse before capsule maturity, but in *N. rustica* selfed seed formation is normal and in *N. rustica* ♀ × *N. glutinosa* ♂ all the seeds abort at an early stage. The course of development of the *N. rustica* × *N. tabacum* seeds was similar to that in the *N. rustica* × *N. glutinosa* in the retardation of endosperm growth, pronounced hyperplasia of the nucellus, and failure of the integumentary cells between the vascular bundle apex and the chalazal pocket to differentiate into conducting elements, but development of the former hybrid was less abnormal than that of the latter. The two kinds of hybrid seeds differed from each other and from normal *N. rustica* seeds even at the 2-cell proembryo stage in relative volumes of endosperm and nucellus. The proportions of seeds of the different hybrids in which the endosperm was occluded by overgrowth of the nucellus at the 8- to 16-cell embryo stages are compared. In all *N. rustica* × *N. tabacum* seeds continuing growth beyond the early stages the endosperm was in direct association with the integument through a narrow gap in the nucellus at the chalazal end, and the endosperm and embryo in persisting seeds grew at the expense of the integument. This hybrid is interpreted as a case of incomplete somatoplastic sterility, the developmental changes associated with this phenomenon usually proceeding to a point resulting

in seed failure. These findings are discussed in relation to seed failures in other plants, particularly cultivated fruits. There are 23 references.

**Genetic nature of self- and cross-incompatibility in potatoes**, B. P. PAL and P. NATH (*Nature* [London], 149 (1942), No. 3774, pp. 246-247, fig. 1).—The results of the four crosses outlined are said to show that self- and cross-incompatibility in *Solanum caldasii* and *S. subtilis* are distinctly inherited characters. Detailed examination of the available data indicated five sterility factors which, operating in various combinations, determine self- and cross-incompatibility. The genetic composition of the eight major groups of plants was established and is diagrammatically shown. It is pointed out that the two species not only resemble each other closely in floral and vegetative characters and in reactions to short-day conditions, but also possess sterility factors in the same allelic series. Thus there appears no valid reason for regarding them as separate species.

**An amphidiploid *Lactuca***, R. C. THOMPSON. (U. S. D. A.). (*Jour. Hered.*, 33 (1942), No. 7, pp. 253-264, figs. 5).—Partially fertile  $F_2$  progenies were obtained in certain crosses of 9- and 17-chromosome *Lactuca* species. Detailed cytological examinations of the  $F_1$  root tips and of microsporogenesis in the  $F_2$  plants revealed that these are amphidiploids with 26 pairs of somatic chromosomes. In an  $F_2$  population of 127 plants there was no evidence of segregation, the plants appearing identical as in a fixed species. The possible origin of the amphidiploids is discussed in detail. Evidently reduction division in the  $F_1$  generation must have failed in the genesis of the female gametophyte, and all of the plants in the  $F_2$  generation must have developed from the union of the unreduced gametes.

**Induction of polyploidy in crop plants**, L. S. S. KUMAR and A. ABRAHAM (*Cur. Sci. [India]*, 11 (1942), No. 3, pp. 112-113, figs. 4).—This note deals with the colchicine technic and detailed results of induced polyploidy in black gram (*Phaseolus radiatus*=*P. mungo*), and with the consequences of autopolyploidy.

**Tetraploidy in tomatoes induced by the use of colchicine**, E. C. STAIR and R. K. SHOWALTER. (Ind. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 383-386, figs. 2). Tetraploid tomato plants were produced by immersing the tips of young vigorous plants in vials of colchicine solution and by soaking seeds in the same material. The tetraploid plants produced seed which resulted in large nonfruitful tetraploids. The production of tetraploids would appear to have no commercial value insofar as increased size of fruit or yields is concerned, but conceivably might be of value in facilitating the crossing of some rather distantly related species needed in breeding programs.

**Apple breeding: Variation within and between progenies of Delicious with respect to freezing injury due to the November freeze of 1940**, H. L. LANTZ and B. S. PICKETT. (Iowa Expt. Sta. Coop. U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 237-240).—Slightly over one-half of 1,603 trees, representing 24 different crosses in which Delicious occurred as one parent, were rated as having none or slight injury following the disastrous November 1940 blizzard. The individual progenies varied widely in their behavior, but in nearly if not all of the lots some trees were found which were free from freezing injury. The hardiness of the second parent was the potent factor with Wealthy, Patten, and Antonovka crosses, all of which contained a high percentage of hardy seedlings. The Jonathan×Delicious combination, despite the fact that both parents suffered great damage in the freeze, contained some seedlings with a high degree of cold resistance. In general, it was evident that hardy parents transmitted hardiness to a relatively high percentage of their seedlings.

**An analysis of the fruit characteristics of seedlings of Rome Beauty, Gallia Beauty, and Golden Delicious parentage**, F. O. HARTMAN and F. S.

HOWLETT. (Ohio State Univ. and Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942) pp. 241-244).—In discussing the results of apple breeding studies, the authors suggest that the varieties Rome Beauty and Gallia Beauty have only very limited use in breeding work where good color and dessert quality are desired. These varieties transmitted predominantly the factors for late blooming, only fair color, poor quality, January season, medium size, and mid-October picking maturity. Apparently both varieties have a heterozygotic genetic constitution, and a number of factors or genes, both cumulative and differential, govern the inheritance of the characters considered in the experiment.

Cytogenetic studies in *Poa pratensis* and its hybrid with *Poa alpina*, E. ÅKERBERG (*Hereditas*, 28 (1942) No. 1-2, pp. 1-126, figs. 61).—This monographic study (with 88 references) includes investigations of 12 specially selected strains of *P. pratensis*, progeny investigations of material collected in nature, and the results of crosses with *P. alpina*.

Genetic control of biochemical reactions in *Neurospora*: An "amino-benzoicless" mutant, E. L. TATUM and G. W. BEADLE. (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 6, pp. 234-243, figs. 4).—An X-ray-induced mutant strain of *N. crassa* was obtained which requires *p*-aminobenzoic acid, its growth being a function of the amount supplied. With adequate amounts available it was indistinguishable from the parent strain, from which it was found to differ by a single gene. Sulfanilamide inhibited the growth of both parent and mutant strains, and in both cases the inhibition was overcome by excess *p*-aminobenzoic acid. A number of substances related to *p*-aminobenzoic acid were able to replace it, but their activities were much less pronounced. It is concluded that none of them is concerned with its normal synthesis, and that this biosynthesis probably does not involve the introduction of an amino group into a preformed benzene ring. There are 13 references.

Tetraploidy in *Antirrhinum majus* induced by sanguinarine hydrochloride, T. M. LITTLE. (U. S. D. A.). (*Science*, 96 (1942) No. 2486, pp. 188-189).—In this preliminary report, tetraploidy is said to have been induced by this alkaloid in at least 5 percent of the treated snapdragon plants, and the effect on mitosis in excised *Lilium* roots was also similar to that of colchicine in producing shortened and split "C-chromosomes."

A centrifugação fonte de variações cromosômicas [Centrifugation as a cause of chromosome variations], A. CÂMARA (*Agron. Lusitana*, 2 (1940), No. 2, pp. 181-202, pls. 3, figs. 14; *Eng. abs.*, p. 200).—Centrifuging the pollen mother cells of *Rhoeo discolor* proved effective in producing chromosome variations, the quantitative variations most frequently observed being those resulting from nondisjunctions. Structural changes consisted chiefly of chromosome fusions, resulting in the formation of bridges and fragments. The method is believed to show promise for inducing the polysomic condition in plant breeding. There are 25 references.

Raças cariológicas na *V. sativa* L. [Karyological races of *Vicia sativa*], L. A. COUTINHO (*Agron. Lusitana*, 2 (1940), No. 4, pp. 379-403, figs. 8; *Eng. abs.*, pp. 402-403).—This study was undertaken as a contribution to the systematics of lines of *V. sativa* subspecies *angustifolia* and *obovata*, *V. amphicarpa*, and *V. macrocarpa*, and to provide data for breeding. The same chromosome constitution ( $2n=12$ ) and the same morphological types were found for the *V. sativa* lines studied, and a partial analogy was also observed between them and *V. macrocarpa* with regard to chromosomes B, C, D, and E. Plants of a hybrid line showed some alterations in chromosome number and also some nonhomologous chromosomes associated with sterility for the great majority of individual plants. This sterility is discussed. It was possible to identify *V. sativa* and *V.*

*macrocarpa* as the parents of this hybrid through the presence of the more complete chromosome sets peculiar to those species. From these studies on *V. sativa* and *V. macrocarpa* and work of others on *V. sativa* and *V. amphicarpa*, it is concluded that the three species are distinct (mainly due to the presence of "unstable" chromosomes A, B, F, G, and H), though closely related as shown chiefly by the characteristic "stable" chromosomes C, D, and E.

**Hereditary transmission of induced tetraploidy and compatibility in fertilization**, A. B. STOUT and C. CHANDLER (*Science*, 96 (1942), No. 2489, pp. 257-258).—The present report confirms previous results (E. S. R., 85, p. 602), the condition of induced tetraploidy eliminating the self-incompatibility of the diploid somatic parent in *Petuna axillaris*. This condition was transmitted to all tetraploid recombinations of genetic factors obtained in each of the seed progenies. Also among the members of each progeny there was complete cross-compatibility for at least some one of the classes of pollen segregating from the tetraploid complex. In backcross relations the only incompatibility that continued was when the haploid pollen of a self-incompatible parent was used to pollinate a pistil of the tetraploid offspring. In the diploid plants of *P. axillaris* there is genetic control (E. S. R., 80, p. 29) in the relations of fertilization which effects self- and cross-incompatibilities, but when these genetic factors were duplicated in tetraploid branches and in their seed progenies there was no longer expression in respect to seed production of either self-incompatibility or intra-sib cross-incompatibility.

**The influence of inbreeding on birth weight, rate of growth, and type of dairy cattle**, J. W. BARTLETT, R. P. REECE, and O. L. LEPARD. (N. J. Expt. Stas.) (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 206-212).—Data are presented showing that inbreeding can be practiced successfully with dairy cattle provided one begins with genetically superior animals and employs rigid selection (E. S. R., 82, p. 239). In the conduct of this study 112 Holstein-Friesian heifers produced by 5 sires were classified for body type, with weights and measurements taken at birth and approximately 5-mo. intervals up to and after calving. Inbreeding directed toward the family of Ormsby Sensation 45th indicated that there were carried factors for heavier weight at birth, but no relation was found between intensity of inbreeding and type.

**Cross-breeding for beef production**, R. W. PHILLIPS, W. H. BLACK, B. KNAPP, JR., and R. T. CLARK. (U. S. D. A. coop. Mont. Expt. Sta.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 213-220).—Data are presented on the weights, feed consumption, and carcass grades of 57 crossbred Shorthorn ♂ × Hereford ♀ steers in comparison with 67 purebred Hereford steers. These data showed the crossbreds to excel in rate of gain, dressing percentage, and fewer digestive disorders than were experienced in purebreds. Differences in the efficiency of gain, slaughter grades, and carcass quality were not statistically significant. In general crossbred steers exhibited less variability than purebreds in the 2 yr. of the study.

**Prenatal development of the bovine**, L. M. WINTERS, W. W. GREEN, and R. E. COMSTOCK (*Minnesota Sta. Tech. Bul.* 151 (1942), pp. 50, figs. 65).—The prenatal development of the bovine, as ascertained from specimens of ova, embryos, and fetuses of known age in their dams, slaughtered at periodic intervals, is described. Measurements are presented as well as indications of the attachments and changes occurring at different stages of development.

**Crossbreeding for lamb and wool production**, J. A. GORMAN, F. S. HULTZ, R. L. HINER, O. G. HANKINS, and D. A. SPENCER. (Coop. U. S. D. A.). (*Wyoming Sta. Bul.* 254 (1942), pp. 48, figs. 12).—Study of the carcass quality and character of wool produced by lambs from Rambouillet grade ewes mated with

Columbia, Corriedale, Lincoln, and Romney rams over a 5-yr. period showed that in the character of the fleece the first-cross Corriedale lambs ranked highest, whereas the Lincoln rams produced the best length of 12-month fleeces, and the Columbia lambs excelled in pounds of grease wool produced in 12 months. The wool produced by the crossbred ewes at different ages did not significantly alter the order of superiority. In average wool weight at 1, 2, 3, or 4 yr. of age second-cross hybrids were not significantly better than the original grade Rambouillet ewes. The staple length was greater but much variation in fleece weight, fleece grade, and staple length existed within the groups sired by rams of the different breeds. In sheared body weight at 12 mo. of age the hybrids from the several sires ranked as Columbia, Lincoln, Romney, and Corriedale. Of the ewes that actually raised lambs those bred to Columbia rams produced an average of 82.52 lb., as contrasted with 77.27, 76.71, and 71.85 lb. by Romney, Corriedale, and Lincoln rams, respectively. The first-cross ewes, Corriedale  $\times$  Rambouillet, produced 121 second-cross lambs, of which 108 were raised per 100 ewes. A brief summary is presented, based on detailed studies and measurements of the carcasses, proportion of the cuts, color, cooking qualities, and palatability. These results showed that the lambs at slaughter generally rated medium, with the Lincoln  $\times$  Rambouillet being slightly inferior. The lambs sired by the Columbia rams produced carcasses which graded medium after both the first and second cross. Carcasses sired by the other rams received less favorable grades.

**Influence of heredity and other factors on 180-day weight in Poland China swine, J. A. WHATLEY, JR. (Iowa Expt. Sta.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 5, pp. 249-264, figs. 5).**—Statistical analyses of variance of 180-day weights of 1,394 Poland China pigs produced in 267 litters in relation to the inbreeding in the continuance of the herd closed to outside blood (E. S. R., 78, p. 469) indicated that at least 30 percent and perhaps more than 40 percent of the individual variance was due to the additive effects of genes. Studies were made of variance within litters and between litters having the same and different sires and dams. The degree of heritability depending on the resemblance between related and unrelated animals was calculated as 20 percent from paternal half sibs, 40 percent from full sibs not litter mates, and 30 percent as a result of the action of genetic factors combining additively. Regression of variance on percentage inbreeding supplemented and confirmed these estimates. The regression coefficient indicated an average decrease of 0.76 lb. in weight for each 1 percent increase in inbreeding. Weaning weight was twice as important as birth weight as an indication of the 180-day weight. Seasonal differences and year-to-year changes in environment were influencing factors, as were differences in the age of dams, but the latter influence was small. Because of the selected nature of the parents it was considered that correlations of 0.051 and 0.132 between paternal and maternal half sibs, respectively, 0.152 between dam and offspring, 0.339 between litter mates and 0.202 between nonlitter mate sibs were underestimates of what should occur in an unselected population.

**Close linkage between mutations with similar effects, L. C. DUNN and E. CASPARI (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 5, pp. 205-210).**—In connection with further studies of the morphological effects of genes, which the authors have found to be located in similar areas of the chromosomes of mice, attention is called to five mutations which are designated as *Fu*, *Ki*, *t*<sup>2</sup>, *t*<sup>3</sup> and *t*<sup>4</sup>. These are shown to be grouped in two classes: One involves *Fu* and *Ki* and the other the *T* series discussed by Gluecksohn-Schoenheimer (E. S. R., 84, p. 313). There is indication in the single tailless animal produced in 785 progeny that *Ki* and *T* may produce a greater interaction when both are present on the same chromosome. The simplest assumption concerning the relationship of *T* *Kink* and *Fused* is

that they represent mutations in duplicate loci lying next to each other in the chromosomes. This of course is an assumption.

**Growth in silver dwarf mice, with and without injections of anterior pituitary extracts,** R. W. BATES, T. LAANES, E. C. MACDOWELL, and O. RIDDLE (*Endocrinology*, 31 (1942), No. 1, pp. 53-58, fig. 1).—Significant weight increases were shown to result in Silver dwarf mice (E. S. R., 86, p. 32) from treatment with 1  $\mu$ g. daily doses of two anterior pituitary fractions—one involving prolactin and the other practically free of prolactin. It was shown that a 30-percent gain in body weight was induced by the treatment.

**Skeletal abnormalities of short spined turkeys,** V. S. ASMUNDSON. (Univ. Calif.). (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 1, pp. 120-123, figs. 2).—In a closely inbred strain of Bourbon Red turkeys there were noted 3 segregating families from which there were produced 69 normal to 14 progeny with shortened necks and bodies which failed to hatch. The lethal mutation was considered due to the action of an autosomal recessive. The heads were abnormal in those not hatching, and such birds showed the necks and bodies to be reduced in length due to a crowding of the vertebrae. Ash analysis showed the wing and leg bones to be approximately normal, but the ash in the scapula and ilium was reduced.

**Pituitary weight in growing New Zealand white rabbits in relation to live weight,** H. H. KIBLER, A. J. BERGMAN, and C. W. TURNER. (Mo. Expt. Sta.). (*Endocrinology*, 31 (1942), No. 1, pp. 59-62, fig. 1).—Based on 328  $\sigma$  and 370  $\phi$  New Zealand white rabbits over 3 kg. in weight, it was shown that the sex relations to body weight were statistically significant. In both sexes the ratio of pituitary to body weight was found to decline during growth. Tables are presented for calculating pituitary weights for both sexes from variable body weights.

**Ovulation and its relation to estrus in cows,** A. NALBANDOV and L. E. CASIDA. (Univ. Wis.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 189-198).—In 72 heat periods of 22 grade dairy cows, ovulation usually occurred at approximately 11 o'clock in the morning with oestrous ending at 8-9 o'clock the evening before. From these data it appeared that mating or insemination during the afternoon of day of heat would probably be better than mating in the morning. Differences in the time of termination of oestrous and the occurrence of ovulation were noted between cows first found on heat in the afternoon and in the morning. A considerable part of the variance in time of ovulation was attributed to differences between individuals. The later the hour that heat ended the later the time of ovulation. These results with dairy cattle showed much similarity to those for beef cattle noted by Brewster and Cole (E. S. R., 85, p. 239).

**Effects of crystalline estrin implants on the tibia of young hypophysectomized female rats,** E. A. KIBBICK, M. E. SIMPSON, H. BECKS, and H. M. EVANS. (Univ. Calif.). (*Endocrinology*, 31 (1942), No. 1, pp. 93-96, figs. 4).—No histological differences were noted between the tibia of hypophysectomized rats treated by subcutaneous implantation of pellets of oestrin and their untreated controls. The typical picture of hyperossification of the subepiphyseal zone of the tibia was not produced in the absence of hypophysis. The study was conducted with 20  $\phi$  rats hypophysectomized at 54-58 days of age, with one-half being treated with the oestrin implants and one-half serving as controls. An additional 10 normal  $\phi$ s were included.

**Reports on biological standards.—V, Variables affecting the estimation of androgenic and oestrogenic activity,** C. W. EMMENS ([*Gt. Brit.*] *Med. Res. Council, Spec. Rpt. Ser. No. 234* (1939), pp. 71, figs. 22).—In continuation of the series previously noted (E. S. R., 77, p. 297), the author found the influence

of various conditions and factors on the oestrogenic activity of extracts showed the need for uniformity of dosage and method and number of injections of ovariectomized mice. Conditions must also be uniform for the determination of the potency of androgens as to their influence on comb growth in capons and day-old chicks.

Observations on the transport of tubal ova, H. O. BURDICK, R. WHITNEY, and B. EMERSON (*Endocrinology*, 31 (1942), No. 1, pp. 100-108, figs. 9).—Ova were seen under proper lighting conditions in the fallopian tube of the albino mouse. Peristaltic movements seemed responsible for transportation of tubal ova, but cilia may play a part in this movement. After fertilization gentle contractions roll the ova about and the cumulus cells drop away in 24 hr. Transportation through the isthmus requires only about 24 hr.

Effects of lactogenic and gonadotropic hormones on hypophysectomized pregnant rats, E. CUTULY (*Endocrinology*, 31 (1942), No. 1, pp. 13-22, pls. 2).—The interruption of pregnancy in 40 rats hypophysectomized from 1 to 9 days after mating was prevented by the administration of hypophyseal gonadotropin and lactogen but not by pregnant mare serum. These results suggested that gonadotropic substances may cause the formation of corpora lutea and stimulate them to secrete progesterone.

Detailed description of technique for androgen assay by the chick comb method, R. T. FRANK, E. KLEMPNER, F. HOLLANDER, and B. KRISS (*Endocrinology*, 31 (1942), No. 1, pp. 63-70, fig. 1).—Details of the technic employed in this method are described.

The effect of the method of making semen smears upon the number of morphologically abnormal spermatozoa, G. W. SALISBURY, E. L. WILLETT, and J. SELIGMAN. (Cornell Univ.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 199-205).—The most satisfactory method for the preparation of semen smears consisted of drawing a drop of diluted semen between two microscopic slides, drying and clearing in chlorazene, and staining in carbol fuchsin and gentian violet. In the conduct of the study comparison was made by variance of samples collected from successive ejaculates of four bulls with variable reproductive records and single samples from three bulls. There were significant differences between individuals with respect to the effect of preparation of the smear and the occurrence of abnormal types. The study emphasized the need for a standard procedure for examining the samples and the examination of more than one sample from each animal.

Artificial insemination of farm animals, W. W. GREEN, L. M. WINTERS, and R. E. COMSTOCK (*Minnesota Sta. Bul.* 336, rev. (1942), pp. 24+[7], figs. 14).—A revision of the bulletin previously noted (*E. S. R.*, 80, p. 330) bringing up to date the more advanced methods of artificial insemination of livestock and poultry, with recommendations for the management of sires and dams.

## FIELD CROPS

[Agronomic research in the Southern States] (*Assoc. South. Agr. Workers Proc.*, 43 (1942), pp. 30-31, 35-37, 41, 42-45, 68-87, 88-89, 181, 182-183, 209-210, 211, 219, 220-221).—Papers of interest to agronomists, presented at the convention of the Association of Southern Agricultural Workers at Memphis, Tenn., February 4-6, 1942, reported largely in abstract form, included Some Indicated Benefits of Rotating Cotton With Close Growing Crops, by J. R. Carreker (p. 30), The Effect of Grazing in Maintaining Open Drainage Ditches, by H. Matson (p. 31), The Use of Kudzu in a Rotation System, by E. C. Richardson (p. 41), *Lespedeza, sericea* in Crop Rotations, by L. D. Eagles (pp. 42-43),

Influence of Organic Mulches and Incorporated Organic Matter on Runoff, Erosion, Soil Structure, and Microbial Activity (pp. 72-73) and Influence of Mulches Versus Incorporated Organic Matter on Soil and Moisture Conservation (p. 219), both by T. C. Peele, The Use of X-Ray in Estimating Strength Differences in Cotton Varieties, by H. W. Barre and E. E. Berkley (pp. 83-84), and Machinery Developments in Relation to Stubble Mulch Culture, by R. M. Merrill (pp. 220-221) (all U. S. D. A.); The Effect of Different Phosphatic Fertilizers on the Chemical Composition of Pasture Herbage, by R. E. O'Brien (pp. 35-36), and The Effect of Organic Matter on the Physical Properties of Berks Silt Loam, by S. S. Obenshain and P. T. Gish (p. 72) (both Va. Expt. Sta.); Breeding Sorghums for Low Cyanide Content, by P. G. Hogg (pp. 36-37), The Present Status of the Program for Determining the Complete Usage of the Sweet Potato Plant for Silage and Other Types of Feed, by H. W. Bennett (pp. 68-70), The F<sub>1</sub> and F<sub>2</sub> Generations of a Sorghum  $\times$  Johnson Grass Hybrid, by H. W. Bennett and P. G. Hogg (pp. 84-85), and Root Pressures and Injury to Cotton Roots by Cultivation, by O. A. Leonard (pp. 209-210) (all Miss. Sta.); The Effect of *Lespedeza sericea* on Soil Fertility, by B. P. Hazlewood (p. 44), *Lespedeza sericea* as a Silage and Hay Crop, by G. A. Shuey (pp. 44-45), and The Divergence in the Behavior of Limestone and Dolomite in Supplying Calcium and Magnesium, by W. H. MacIntire (pp. 76-77) (all Tenn. Sta.); Curing and Storage of Sweet Potatoes, by W. S. Anderson (p. 68) (Miss. State Col.); Some Observations on Soil Organic Matter, by H. R. Smalley (p. 70); Hairy Vetch as a Green Manure Crop for Cotton, by E. B. Reynolds (p. 71) (Tex. Sta.); Relation Between the Carbon Content of Soils Under Burning and Nonburning, by R. L. Donahue (p. 71) (Tex. A. and M. Col.); Soil Fertility Comparisons Between Leguminous Plant Material Incorporated With the Soil and Leguminous Mulches, by F. Moser (pp. 73-74) (S. C. Sta.); Uses of Soil Survey Data in a Regional Development Program, by G. A. Johnsgard (pp. 74-75); Soil Productivity in a Profitable Agriculture, by L. D. Baver (p. 75), and Comparison of Soil Tests, Tissue Analysis, and Seed Analysis as an Index of Soil Fertility With Peanuts, by E. R. Collins (pp. 78-79) (both N. C. Sta.); Soil Testing as a Basis for Making Fertilizer Recommendations, by I. E. Miles (pp. 75-76); Acid-Forming Fertilizer Not Supplemented With Limestone Prevents the Growth of Winter Legumes on Two Coastal Plain Soils, by J. H. Hunter and R. D. Lewis (p. 77); Results of Plant Tissue Tests and Soil Tests for Predicting the Fertilizer Requirements of Cotton and Corn, by L. C. Olson (p. 78), The Effect of Surface-Applied Phosphate and Limestone on Soil Nutrients and pH of Permanent Pastures, by O. E. Sell and L. C. Olson (pp. 80-81), The Relative Production of Roots, Rhizomes, Runners, and Leaf Shoots of Bermuda Grass Under Several Pasture Conditions, by O. E. Sell (pp. 85-86), and The Carotene Content of Sweet Potatoes, by H. L. Cochran (p. 181) (all Ga. Sta.); The Effect of Certain Natural Fertilizer Materials on the Growth of Turnips, by F. L. Wellborn, M. M. Philipps, and S. S. Obenshain (pp. 79-80), and Time and Rate of Nutrient Absorption by Peanuts, by A. L. Grizzard and J. L. Strauss (pp. 81-82) (both Va. A. and M. Col.); Varieties and Methods of Planting Vetch for Seed Production, by H. R. Albrecht (p. 82), The Effect of Lime and Fertilizers on the Composition and Yield of Pasture Herbage From Different Soil Types, by J. W. McClendon and E. L. Duggar (pp. 86-87) (Ala. Polytech. Inst.); Relative Yield and Shelling Properties of 18 Large and Small-Seeded Peanut Varieties and Selections When Grown in Virginia and South Carolina, by C. E. Steinbauer, E. T. Batten, and J. McCown (p. 182) (U. S. D. A. and Va. and S. C. Stas.); The Use of Electricity in Curing and Storing Sweet Potatoes, by J. B. Edmond and G. H. Dunkleberg (p. 182) (Clemson Agr. Col.); and Factors Influencing Flowering in Sweet Potatoes and Kudzu, by J. C. Miller (p. 211) (La. Sta.)

[Farm crops research in Mississippi] (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, pp. 1, 2-3, 4, 6, 7).—Progress in current agronomic work is reported in articles entitled AAA Pasture Allowances Under New Program, by T. M. Patterson (p. 1); Drainage Highly Important Factor in Growing Vetch, by J. L. Anthony (pp. 2, 7); Moderate Use of Phosphate and Lime Recommended as Fertilizer for Vetch, by J. L. Anthony and J. Pitner (p. 2); Basic Slag Leads Super, Colloidal, for Vetch Growth, by C. D. Hoover (p. 2); and Phosphate More Than Doubles Pasture Yields—Sources Compared on Cost Basis, by H. W. Bennett (p. 7). This number also includes brief reports by C. Dorman on field crops work in the State, including breeding work with corn, potatoes, and sweetpotatoes; variety tests with cotton, corn and hybrids, oats, sweetpotatoes, soybeans, clovers, and lespedeza; cultural tests with soybeans, cowpeas, and sweetpotatoes; trials of Alyceclover; effect of soil preparation on distribution of cotton roots; storage, spacing, and slip production experiments with sweetpotatoes; fertilizer trials with sweetpotatoes, lespedezas, pastures, and summer and winter legumes; mowing of pastures and other pasture studies; and control of nutgrass and other weeds.

[Seed stock and cover crop studies] (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, pp. 8, 9, 11, fig. 1).—What the Control Fields Show About 1942 Seed Stocks, by L. E. Everson, reports on the merits of seed stocks of corn and oats offered for sale to New York farmers. Domestic Rye Grass—A New Cover for Vineyards, by T. A. Merrill, mentions the superiority of domestic ryegrass over other cover crops to replenish and maintain organic matter in vineyard soils. Differences in the control field behavior of seed stocks of red clover are noted briefly.

Green manure crops for soil improvement, D. W. THORNE (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, pp. 3, 9-10, figs. 2).—Alfalfa, sweetclover, vetch, small grains, and non-noxious weeds, according to station tests, are of value in supplying humus to Utah soils. Cultural practices are suggested.

Cover crops for soil conservation, W. V. KELL and R. MCKEE (*U. S. Dept. Agr., Farmers' Bul.* 1758, rev. (1942), pp. 11-14, figs. 10).—A revision of the publication noted earlier (E. S. R., 76, p. 179).

Regrassing areas in South Dakota, C. J. FRANZKE and A. N. HUME (*South Dakota Sta. Bul.* 361 (1942), pp. 48, figs. 13).—Measures to promote reestablishment of grass in locations in the three regrassing areas of South Dakota are based on extensive experiments and observations. Important species are described and illustrated, with remarks on distribution and adaptation. Merits of many other species are also noted briefly.

The species adapted to conditions of growth within the specific area are limited largely to the native grasses, western wheatgrass, blue grama, buffalo grass, feather bunchgrass, side-oats grama, big and little bluestem, sand dropseed, Sandberg blue, and junegrass. Introductions found well adapted for many conditions include bluegrasses, smooth brome, crested wheatgrass, intermediate wheatgrass, and Russian wild-rye. Appropriate seeds-mixtures and rates, depths, and dates of seeding are shown for the grasses included in the three areas.

A firm seedbed has been found necessary for seeding grasses and residue covers for protection against wind erosion and soil incrustation. Drilling of grass seed has been better than broadcasting, because it places seed at an even depth with shallow covering. As a general rule, warm-season grasses should be seeded in the spring early to mid-May. Although optimum conditions for germination and growth of cool-season grasses are more difficult to determine, fall or early spring plantings should be made when conditions are favorable.

**Range reseeding gives promise of increased feed supplies**, A. F. BRACKEN (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, pp. 8-9, figs. 2).—Spring-fall range in Utah, situated between winter-grazed deserts and summer-pastured forest lands, was originally largely covered with grass, but as a result of overgrazing and misuse, the grass has been replaced extensively by sagebrush, with great reduction in grazing capacity. On areas receiving 10-11 in. of rainfall, plowing up the sagebrush lands and broadcasting or drilling crested wheatgrass or other suitable grasses has corrected this condition. Other establishment practices are mentioned.

**Better pasture and hay crops**, G. H. AHLGREN and C. EBY (*New Jersey Sta. Cir.* 448 (1942), pp. 7, figs. 6).—The merits and adaptations of timothy, orchard grass, Alta fescue, tall oatgrass, bromegrass, and reed canary grass, and alfalfa, red, alsike, and Ladino clovers, and birdsfoot trefoil for pasture and hay are described, with suggested seeding practices and seeds mixtures for situations differing in soil type, fertility, and drainage.

**Continuous and rotation grazing of alfalfa-brome grass pastured with ewes and lambs**, C. M. HARRISON, C. L. COLE, and H. C. RATHER. (Mich. Expt. Sta.). (*Soil Sci. Soc. Amer. Proc.*, 6 (1941), pp. 303-308).—Alfalfa and smooth bromegrass mixture on 11 1-acre paddocks similarly limed and fertilized was grazed to test differences between a 4-field rotation, 3-field rotation, continuous, and second-crop grazing on weight gains or losses of the animals and pasture condition. At the end of a grazing season, acre gains differed very little with rotation or continuous grazing. Considering gains by plats based on weights when the sheep were moved in the rotation scheme resulted in absurdly crediting the one area in the rotation with gains out of proportion to anything that might be maintained over a grazing season. Season-long results rather than gains or losses on any one plat appeared to be the true test of a management plan. No advantage of pasturing a second crop of the mixture over that of continuous grazing where feed was ample in both cases was apparent. Appearance and quantity of forage on a pasture may result in misleading observations on livestock behavior in terms of weight gains or condition.

**Fertility needs of dairy farm crops in the Connecticut Valley**, F. S. PRINCE, P. T. BLOOD, and G. P. PERCIVAL (*New Hampshire Sta. Cir.* 61 (1942), pp. 12).—An experiment involving a rotation of corn followed by a hay seeding which was harvested 1938-41 was conducted near Claremont. The soil previously (E. S. R., 76, p. 469) had shown strong response to K in increased yield when applied to alfalfa and clovers.

Compared to legumes, corn (silage) responded much more to P than to K and made its largest yields on plats receiving manure with P (superphosphate). In a mixed clover-timothy seeding after corn, K stimulated yields most, due largely to clover which persisted on all K treatments. Timothy on these plats also made a larger growth. P used alone did not increase yields significantly, but with K the yield increase was more than twice as much as the increase due to K alone. Of the treatments, K alone gave the greatest return on the investment, while PK and complete fertilizer gave the highest returns per acre. This and previous tests suggest, on soils of this area, liberal treatment of corn with manure

and P. Hay crops after corn in the rotation should receive annually a PK mixture, with complete fertilizer or with properly supplemented manure, if yields are to continue at a high level. If red clover does not persist in the hay stand the farmer evidently has not kept available K at a high enough level, and commercial K should supplement the manure.

**Plot technic studies with small grains, E. E. DOWN.** (Mich. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 5, pp. 472-481).—Fall-sown wheat and spring-sown barley plats were studied for five seasons to determine the plat width needed to overcome the influence of competition between contiguous nursery plats. Ten replications of competitive plats were alternated for two seeding rates and for two varieties for both grains, using plats 1, 3, 5, or 7 rows wide. The influence of competition did not extend significantly beyond the outside border rows of a plat. A 5-row plat for wheat and a 3-row plat for barley with border rows discarded at harvest appeared satisfactory for nursery investigations. A minimum of three replications for wheat and seven for barley was needed to reduce the standard error of the mean to 5 percent of the mean.

**Fertilizer needs of alfalfa on New Hampshire soils, F. S. PRINCE, P. T. BLOOD, G. P. PERCIVAL, and P. N. SCRIPTURE** (*New Hampshire Sta. Cir. 58* (1942), pp. 12).—Fertilizer tests near Greenland, N. H., supported previous findings (E. S. R., 69, p. 502) indicating that alfalfa responds well to annual fertilizer treatments, and that liberal quantities of plant food used judiciously may give excellent returns. On the Whenal farm plats, elements used singly returned in increased hay produced for K \$3.72, N \$2.29, and P \$1.39 for each dollar invested in fertilizer. Plats receiving applications of all three elements annually outyielded untreated comparable checks 1.41 tons per acre each year, and the returns amounted to \$2.48 for each dollar invested in fertilizer. The increases for N, P, and K applied separately totaled 1.31 tons per acre. Two tons of ground limestone applied in 1926 plus 1 ton in 1933 proved as effective as 4 tons applied in 1926. In a trial with alfalfa on unmanured soil on the Ireland farm, 1936-40, elemental N up to 30 lb. per acre paid good returns, and even 30 lb. more was profitable, although much less effective in stimulating yields. Under test conditions, 750 lb. of a 4-16-16 or even an 8-16-16 fertilizer equivalent could profitably be applied. Applying all the P and K before seeding proved slightly superior to applying the same quantities in equal annual top dressings.

**Growing field beans in humid areas, V. R. BOSWELL** (*U. S. Dept. Agr. Leaflet 223* (1942), pp. 8, fig. 1).—The main factors and operations involved in producing dry beans, i. e., climatic and soil needs, varieties and seeds, growing, harvesting, and handling the crop, and insects and diseases and their control, are outlined for growers in the eastern part of the United States.

**The growing of sea island cotton in the Coastal Plain of Georgia, J. G. JENKINS.** (Coop. U. S. D. A., Ga. Expt. Sta., et al.). (*Georgia Coastal Plain Sta. Bul. 33* (1942), pp. 21, figs. 11).—Cultural and field practices and harvesting, ginning, and boll weevil control methods involved in growing sea-island cotton are described, with comments on marketing the crop. Emphasis is placed on planting pure seed (E. S. R., 77, p. 777), its maintenance and distribution, roguing seed fields, and advantages of one-variety communities in maintaining purity. Dosages for seed treatment are recommended, and a home-made treater is illustrated.

**Peanut production in the Coastal Plain of Georgia, S. A. PARHAM** (*Georgia Coastal Plain Sta. Bul. 34* (1942) pp. 19, figs. 6).—Information given on varieties of peanuts, soils and their preparation, fertilizers, seed and planting, cultivation and harvesting practices, hogging-off, and insects and diseases and their control is based extensively on prolonged experiments at the station and on experience

of growers. Practices indicated from the experiments include 200-400 lb. of fertilizer on thin land or after unfertilized crop, 2-10-4 or 2-10-6 formulas, and planting in hills 6 in. apart in from 24- to 30-in. rows between March 15 and May 1 for Spanish and from 8 to 12 in. apart in from 36- to 42-in. rows and after March 15 to April 15 for North Carolina Runner peanuts.

**Potato production in the Southern States**, E. L. LECLERG (*U. S. Dept. Agr. Farmers' Bul.* 1904 (1942), pp. [2]+44, figs. 32).—The practical information given on cultural and fertility needs of potatoes grown in the South, seed treatments and planting practices, harvesting and storage, potato diseases and insects and their control, and production centers and potato varieties grown in the several Southern States supersedes and enlarges on that in *Farmers' Bulletin* 1205 (E. S. R., 45, p. 234).

**Sweet potato investigations in New Jersey**, V. A. TIEDJENS and L. G. SCHERMERHORN (*New Jersey Stat. Bul.* 697 (1942), pp. 20, figs. 12).—Cultural and fertilizer (E. S. R., 84, p. 182) experiments in field and greenhouse, 1928-41, showed that substantial yield increases may follow certain practices, including use of a starter solution on plant beds after first plants are pulled and good-sized vigorous plants, setting plants with a starter solution, keeping dry fertilizer away from the roots, applying from 300 to 500 lb. of pulverized Mg limestone per acre in the bottom of the plowed furrow on soils with a pH of 5.0 or less, mulching on gravelly or light sandy soils, and harvesting after September 20, if possible.

The method of applying fertilizer in water was found more dependable than any dry methods used, which weather conditions may make hazardous. In dry seasons row applications of dry fertilizer reduce yields by burning the plants, and in wet years such heavy vine growth is produced that the crop fails to mature before frost. The most effective methods of fertilizer placement, in the order of their value, are (1) set plants with starter solution and side dress with 100 lb. of 13-26-26 in 200 gal. of water per acre 2 weeks, and again from 3 to 4 weeks later; (2) set plants with starter solution and side dress with 400 lb. of 3-12-15 dry fertilizer 2 weeks, and again 5 weeks later; and (3) broadcast and plow under 800 lb. of 3-12-15 and set plants with starter solution (this method requires the least labor).

**Cooperative tests of sweetpotato varieties, introductions, and seedlings for starch production and market purposes**, C. E. STEINBAUER, L. L. HARTER, G. P. HOFFMAN, J. M. MCCOWN, R. M. KINGSBURY, W. S. ANDERSON, and H. T. COOK. (Coop. Miss., Va. Truck, and S. C. Expt. Stas.). (*U. S. Dept. Agr. Cir.* 653 (1942), pp. 42, pls. 6).—Results of cooperative studies, 1934-39, in Maryland, Virginia, South Carolina, and Mississippi on the appearance, yields, starch production, wilt resistance, market quality, and other characteristics of numerous varieties, introductions, and seedlings of sweetpotatoes are reported. Important characters of 13 well-known American varieties and 26 other sorts are tabulated.

Big-Stem Jersey, Nancy Hall, Pierson, Porto Rico, Red Bermuda, Southern Queen, Triumph, Vineland Bush, Wennop, Yellow Jersey, 24171, B-33, and B-52 made definitely superior yields at two or more locations, although not always at all places. Certain varieties, as Japanese Yam, Oebi Saboelan, Kloranda Dutch Yellow, Red Brazil, and Vineland Bush, yielding exceptionally well at Beltsville, Md., yielded rather low in certain locations in the lower South. The reverse of this situation was noted with a few other sorts, as Southern Queen and Triumph. This observation indicated a rather definite regional adaptability among certain varieties, although many are consistently high producers within the area in these studies. Kloranda Dutch Yellow, Japanese Yam, Norton, Oebi Saboelan, Pierson, Red Bermuda, Red Brazil, Southern Queen,

Triumph, Wenholz 2, Wennop, Yellow Strasburg, 029878, and B-33 showed high or very good starch percentages and yielding capacity enough to make them appear desirable for commercial starch manufacture. Within this group seedling B-33 has been most promising. Excessive production of latex in Wennop might interfere with its use for commercial starch recovery. Varieties including most of the sweetpotatoes currently used for market (culinary) purposes were not among the sorts appearing most promising for starch manufacture. Determinations of stem rot, or wilt, susceptibility in field and greenhouse indicate that many varieties and seedlings studied have at least moderate resistance to this disease. Although many sorts appeared relatively poor as market or starch-yielding sweetpotatoes, certain ones, because of high starch percentages or of outstanding resistance to stem rot infection, may be valuable as parent stocks for breeding.

**The effects of carbon disulphide upon germination and baking quality of wheat,** H. S. SMITH and H. W. STATEN (*Oklahoma Sta. Tech. Bul. 14 (1942), pp. 13, figs. 6*).—When samples of Turkey wheat were treated with different amounts of CS<sub>2</sub> for different periods, no significant differences in germination were found until concentrations greater than 4 times the rate recommended for insect control, about 4 gal. per 1,000 bu., were applied. Percentage of germination decreased rapidly when amounts equal to 20 times the normal rate were used. Effects due to duration of treatment were not apparent until concentrations heavy enough to affect germination were used, after which a significant difference was found between 1 and 2 days' treatment. Three- or 4-day treatment periods did not result in lower germination. With the higher concentrations greenhouse germination exceeded that in the germinator. Baking quality was reduced at the same concentration which lowered germination. Applications decreasing germination percentage all had adverse effects upon loaf volume, dough character, crust color, grain, and texture.

**[Seed investigations]** (*New York State Sta. Rpt. 1942, pp. 75-76, 78, 79*).—Brief reports are made on the general merits and characteristics of official samples of field crops, vegetable and flower seeds, and special seed mixtures; responses for peas, beans, corn, and oats to treatment with hormones; and germinative characteristics of flower seed.

## HORTICULTURE

**Practical applications of plant growth-substances in horticulture,** F. E. GARDNER. (U. S. D. A.). (*Fla. State Hort. Soc. Proc., 54 (1941), pp. 20-26*).—With a view to assisting Florida growers, the author points out the various plant responses that have been obtained from applications of growth substances and discusses some of the applications which have been developed therefrom. Information is presented on the timing of preharvest sprays for reducing dropping of the Pineapple orange and on the effect of growth substances on the solids and acid contents of Pineapple and Valencia oranges.

**A grating spectrograph for mineral nutrition studies,** R. C. NELSON. (Minn. Expt. Sta.). (*Plant Physiol., 17 (1942), No. 3, pp. 492-496, figs. 2*).—A description is given of an inexpensive spectrograph utilizing a concave diffraction grating replica to disperse light. The apparatus proved satisfactory for the analysis of plant ashes, being both rapid and economical in operation.

**Influence of ice upon temperatures in air-cooled storages,** C. E. BAKER. (Ind. Expt. Sta.). (*Ind. Hort. Soc. Trans., 1942, pp. 81-84*).—Temperature records taken in three locations, (1) outdoors, (2) ventilated storage room, and (3) ice-and-salt-cooled room, showed very definitely the beneficial effect of icing.

In many of the autumn weeks the average temperature was actually higher in the air-ventilated room than outdoors. The iced room was approximately 20° F. cooler than either of the other two locations, and this lower temperature, though not ideal, was reflected in the better condition of the apples. Additional information is contained in the discussion of this paper.

[**Horticultural studies by the Mississippi Station**] (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, p. 4).—Brief information is presented by C. Dorman on the following studies: Spacing and fertilizer trials with cucumbers; variety and cultural tests with tomatoes; variety and strain trials with pole beans; variety tests of sweet corn, peaches, plums, apples, and pears; and the use of low temperature for breaking the rest period of the azalea.

**Small fruits and vegetable varieties for irrigated central Washington**, W. J. CLORE. (Wash. Expt. Sta.). (*Wash. State Hort. Assoc. Proc.*, 37 (1941), pp. 69-78).—Information is presented on fruit characters, growth habits, yielding capacity, season of maturity, etc., of a large number of varieties of fruits and vegetables.

[**Vegetable studies by the New York State Station**] (*New York State Sta. Rpt. 1942*, pp. 68-69, 74, 80-86).—Included are reports upon the use of X-rays in tomato and bean breeding; the development of disease-resistant and improved varieties of squashes; fertilizer placement; soil requirements of canning peas; use of starter solutions; fertilizer requirements of the tomato; comparison of various nitrogen fertilizers and inoculation for peas; plant tissue tests in relation to fertilizer needs; strain tests, culture, and breeding of sweet corn; testing of new varieties of peas for canning and freezing; squash and muskmelon breeding; selection of vegetables for dehydration value; improvement of canning beans; and the testing of tomato varieties.

**Fall and winter gardens needed to supply war foods**, E. A. CURREY (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, p. 7).—Information is presented on desirable vegetables for fall planting, the importance of good culture and fertilization, and the control of insects and plant diseases.

**The vegetable seed plantings**, B. E. CLARK (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, pp. 8, 11).—Brief comments are presented upon the results of field trials of cucumber, eggplant, onion, and pepper seed stocks. The cucumbers and eggplants were generally true to name and of good quality, while the onions and peppers varied greatly and were frequently of very low quality.

**Station explores possibilities of vegetable seed production in Utah** (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, p. 12, fig. 1).—Information is presented on new investigations in cooperation with the U. S. Department of Agriculture by M. Shapovalov and L. H. Pollard, designed to reveal possibilities in vegetable seed production, particularly table beets and carrots.

**The influence of starter solutions on lettuce and celery seedlings on the Everglades muck**, F. S. ANDREWS. (Fla. Expt. Sta.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 127-130).—Without exception the yields of all lettuce plats receiving starter solutions were higher than those transplanted with water alone. The average increase was 71 crates per acre. However, in a later planting on a more fertile soil there was no evidence of a marked increase in yield growth due to starter solutions. In the case of celery, one planting showed little stimulation from starter solutions while a second planting did show some significant benefit.

**Snap beans for marketing, canning, and freezing**, B. L. WADE (*U. S. Dept. Agr., Farmers' Bul. 1915* (1942), pp. [2]+14, figs. 3).—General information is presented on the adaptability of the bean crop, varieties, cultural require-

ments including fertilizers, grading and marketing, control of diseases and insect pests, etc.

**Chemical factors influencing the set of Henderson lima beans, B. WOLF** (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 7, pp. 646-650).—Marked differences were recorded in the chemical content of well- and poorly set plants. The former had substantially higher concentrations of nitrate N, K, available Ca, and Mg but less available P than poorly set plants. The concentrations of nitrate N and of available Ca in the main stems were closely associated with seed set. Results of analyses of the soil beneath the plants indicated that soil pH values, available P, K, and Mg were not limiting in this study. Organic matter had a beneficial effect upon set and yield. There was slightly more Ca in the soil collected beneath the well-set plants.

**The viability of lettuce seed: A physiological and microchemical study, A. E. GRIFFITHS** ([New York] *Cornell Sta. Mem.* 245 (1942), pp. 39, figs. 8).—Work with several varieties of lettuce seed showed an important interrelationship of moisture content and of temperature in maintaining viability. The decline in viability was more rapid at high temperatures when the seed moisture was above the critical moisture content, which was usually slightly below the air-dry moisture content but varied with the sample, the variety, and the region where the seed was produced. The critical moisture content of most of the seeds used in the study ranged from 3 to 5 percent. The air-dry water content of seeds ranged from 6 to 7 percent of the oven-dry weight. Within limits, the moisture content of lettuce seed varied with the relative humidity of the atmosphere.

Seeds of the New York variety were not killed as quickly under conditions of high temperature and high moisture as were those of the Grand Rapids variety. This difference was due to a lower rate of moisture absorption by the seeds of the New York variety, a situation which, in turn, was attributed to the presence of a highly suberized membrane surrounding the embryo. The acidity of the embryos remained the same in dormant seeds as in nondormant seeds during storage. At 60° C., the excised embryos were killed more rapidly than whole seeds when both were moist. When dry however, excised embryos and entire seeds were killed at about the same rate. From the standpoint of accuracy in determination of the moisture content of lettuce seeds, a temperature of 80° in vacuo gave results that appeared least subject to further fluctuations with time. A temperature of 60° in vacuo did not remove a sufficiently large percentage of the free water before the results were affected by oxidation.

**Progress report on investigations in the production of iceberg lettuce, J. R. BROKENBACH.** (Fla. Expt. Sta.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 121-125, figs. 3).—Grown on raised beds with centers about 40 in. apart and two rows per bed, lettuce plants were spaced at different intervals in the rows. With all spacings cutting well over 90 percent, it was found that the wider-spaced plants cut much more heavily in the first two cuttings, and in direct ratio to their spacing within the row. The wider the spacings, the larger were the heads. Nitrogen studies indicated that not less than 60 lb. per acre are needed, and not more than 100 lb. are desirable. Sulfate of ammonia proved to be a satisfactory source of nitrogen.

**A method of statistical analysis of a factorial experiment involving influence of fertilizer analyses and placement of fertilizer on stand and yield of cannery peas, J. F. DAVIS, R. L. COOK, and W. D. BATEN.** (Mich. Expt. Sta. coop. U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 6, pp. 521-532, figs. 2; *abs. in Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, p. 74).—The

results of an experiment to determine the effect on the yield and stand of canary peas of different fertilizer mixtures, placed in various locations with respect to the seed, showed that the placement of fertilizer is exceedingly important. The need was indicated for separating the sum of squares for treatments into their various components in order to arrive at a full and correct interpretation of the data. A complete fertilizer placed in contact with the seed at the rate of 300 lb. per acre on a Brookston loam reduced significantly the stand and yield. When a 0-20-0 or a 0-16-8 material was used, yield alone was reduced. The plats receiving the 0-16-8 material yielded as well as did those receiving the 4-16-8 and produced significantly larger yields than those on which a 0-20-0 material was used. There was no significant difference in yield between plats on which the fertilizer was applied in bands 0.5 in. to the side and 1.5 in. below the seed and in plats in which the fertilizer was placed 2 in. to the side and 1.5 in. below the seed.

Experiments with greenhouse tomatoes: Varieties, cultural methods, and relationship between yield and vegetative vigor, F. A. ROMSHE (*Oklahoma Sta. Bul.* 260 (1942), pp. 30, fig. 1).—Of seven varieties of tomatoes tested in four crops, Michigan State Forcing and Forcing Marglobe were found most desirable for greenhouse production in Oklahoma. Plants spaced 24 by 21 in., 3.5 sq. ft. per plant, yielded more tomatoes per square foot of area than did wider spaced plants. Training plants to a single stem was found more satisfactory than training to two stems. The fresh weight of tomato leaves grown under conditions of the experiment was found to be an accurate measure of leaf area. No consistent relationship was found between leaf area and yield with plants set at the various spacings and arrangements used. Correlations between plant stem diameters and the number of flowers, number of fruits, and weight of fruit per cluster varied considerably for the different crops and varieties. Proper management to maintain fairly vigorous, vegetative growth, as indicated by the diameter of the stem, is needed to maintain good production over an extended period of time.

Effect of potassium iodide on the ascorbic acid content and growth of tomato plants, R. H. HAGERMAN, E. S. HODGE, and J. S. MCHARGUE. (*Ky. Expt. Sta.*). (*Plant Physiol.*, 17 (1942), No. 3, pp. 465-472, figs. 3).—Observations on tomato plants grown in sand cultures containing potassium iodide in concentrations ranging from 4 to 100 p. p. m. of iodine showed no reduction in growth (as measured by dry weight) at the 4 p. p. m. concentration. With 16 p. p. m. or more of iodine, growth was seriously injured and production was curtailed. Injury was evidenced by a loss of green color in the plants, necrotic edges of the lower leaves followed by curling, and death. The injury moved progressively upward from branch to branch. All concentrations of potassium iodide caused a marked decrease in ascorbic acid content of the plants. Manganese and copper uptake by the treated plants was more pronounced than any of the other mineral constituents.

[Pomological and floricultural studies by the New York State Station]. (Partly coop. U. S. D. A. et al.). (*New York State Sta. Rpt.* 1942, pp. 61-63, 64-68, 69-73).—Herein are reported progress reports on fertilizer experiments with apples, peaches, and plums; cultural studies with the Montmorency cherry; culture of blueberries on different soils; fertilizer requirements of the strawberry and raspberry; application of nutrients in the form of sprays; the testing of fruit varieties; the breeding of new and improved fruits; cytological studies with snapdragons, *Tradescantia*, and *Trillium*; testing of chemicals other than colchicine for their effect on cell division and growth; X-ray effects on *Tradescantia* chromosomes; testing of dwarfing and seedling rootstocks for apples; the use of

intermediate body stocks to reduce winter injury in the apple; time interval between full bloom and fruit ripening; histology and development of apple fruits; chemical changes in developing peach fruits; rootstocks for grape varieties; pruning and fertilization of grapes; and the testing of varieties of hops.

**Propagation of trees and shrubs by seed**, M. AFANASIEV (*Oklahoma Sta. Cir. 106* [1942], pp. 43, pls. 8).—Dormancy in seeds is due to various causes, two of the most important of which are impermeability of the seed coat to water and dormancy of the embryo. Methods of breaking dormancy are sulfuric acid, hot water, and scarification treatments, followed by stratification. Specific information is given on the handling of a large number of tree and shrub seeds.

**The home fruit garden in the Northeastern and North Central States** (*U. S. Dept. Agr. Leaflet 227* (1942), pp. 8, figs. 2).—This is one of a series (E. S. R., 87, p. 670), designed to aid in the selection of varieties, planting, and care of fruits.

**Forecasting the time of fruit harvest by blooming dates**, H. B. TUKEY (*Farm Res. [New York State Sta.], 8* (1942), No. 4, pp. 3, 11, fig. 1).—A study of bloom and harvest records accumulated over a period of years showed that the interval between full bloom and fruit maturity is very constant from year to year for a given variety. The apple was more consistent than any of the other fruits studied. Within a given species, there was apparently a greater variation in the bloom-maturity interval in early-maturing than in late-maturing varieties. The author suggests that growers, by keeping records, may obtain information which should be useful in planning their orchard operations.

**1941 experiences with sprays to delay fruit drop**, C. L. BURKHOLDER and M. McCOWN. (*Ind. Expt. Sta.*). (*Ind. Hort. Soc. Trans.*, 1942, pp. 13-19).—In 1941 preharvest sprays were effective in delaying the dropping of Delicious apples, thus affording opportunity for better coloring and lengthening the harvest season. In view of the labor shortage, the extended season for picking was very helpful. Good results were obtained with Rome Beauty and Winesap trees on the Indiana Station farm at Bedford. Here the use of chemicals returned a substantial profit above costs. Fruit drop control sprays gave good results on Delicious, Rome Beauty, and Winesap, but had little beneficial effect on Grimes Golden, McIntosh, and Jonathan. Additional information is continued in the discussion of this paper.

**Further studies with certain chemicals to prevent fruit drop and increase red color**, E. L. OVERHOLSER, F. L. OVERLEY, and D. F. ALLMENBINDER. (*Wash. Expt. Sta.*). (*Wash. State Hort. Assoc. Proc.*, 37 (1941), pp. 79-85, fig. 1).—In this further discussion (E. S. R., 85, p. 481), evidence is presented that varieties differed in their response to preharvest sprays, especially in the effective period following application. The period of effectiveness began usually 2 to 3 days following spraying and lasted for 9 to 10 days with McIntosh but for 2 to 3 weeks or more with the other varieties tested. If low temperature prevailed following spraying a longer period was required for the spray to become effective, but the effective period might be somewhat longer. The use of spreaders or oil appeared to increase slightly the effectiveness of preharvest sprays. A concentration of 10 p. p. m. appeared nearly correct. There was no apparent effect of preharvest sprays on fruit maturity or storage behavior. Although  $\alpha$ -naphthylisothiocyanate sprays improved the color of apples slightly, their use is not yet recommended commercially.

**The Atchison Experiment Orchard**, R. J. BARNETT (*Kansas Sta. Bul. 301* (1942), pp. 31, figs. 8).—A descriptive account is presented of the site, plan, and operation of an experimental orchard located about 10 miles south of Atchison, Kans., and operated under lease by the station from 1932 until

1941. In 1940 a disastrous November freeze ruined many of the trees and forced the termination of the investigations. Of the four varieties of apple—Winesap, Jonathan, Richared Delicious, and Grimes Golden—planted in the orchard, Winesap was first to come into bearing and was the heaviest producer in each of the three cropping seasons. In training experiments there was some evidence that four framework branches are too many to leave on apple trees which have been grown the second year in the nursery. An interplanting of corn decreased the wind effect and permitted easier training to the desired form. Of five systems of soil management tested, namely, red clover sod, winter vetch, cowpeas, corn intercrop, and straw mulch, the last was most effective as measured in gain in trunk diameter and annual growth. In the straw mulch area more trees survived, were larger in size, and bore more fruit. The value of straw mulch was probably increased by the fact that some of the hottest and driest weather ever recorded in Kansas occurred during the lifetime of the experiment.

**Effect of orchard fertilizer applications on the composition of apples,** J. L. ST. JOHN, E. L. OVERHOLSER, and F. L. OVERLEY. (Wash. Expt. Sta.). (*Plant Physiol.*, 17 (1942), No. 3, pp. 435-446).—Studies upon the mineral and carbohydrate composition of Jonathan and Winesap apples harvested from plats receiving beneficial fertilizer treatments showed, in general, that the effects of different fertilizers on fruit composition were relatively small. Increases in terminal growth and fruit production opposed increases in percentages of N, P, and K in apples as a result of fertilizer applications. Since increases in growth and production resulted primarily from added N, applications of N, alone or in combination, resulted usually in reduced percentages of N, P, and K in the fruits. Variations in the sugar content of the fruit were somewhat larger in relation to the total amount of sugar present than was the case with the minerals. These variations were not consistent when considered in the light of variations from year to year and of natural sample variations. Since there was no evidence of a deficiency of either P or K in the soils involved, the authors conclude that the effects might have been more marked if the trees had been growing in the presence of a deficiency of one or both of these elements.

**Russetting of Golden Delicious apples,** F. B. CHANDLER and I. C. MASON. (Maine Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 120-122).—Observations on fruits of 25 Golden Delicious trees which had been sprayed with lime-sulfur, mild lime-sulfur, and calcium arsenate with lime, but never with copper materials, showed a range in percentage of russetting from 30.6 to 100 percent, according to individual trees. Scions taken from high- and low-russet trees and grafted into other trees tended to perform as did the original parents, thus indicating that the scions carried an inherent factor, possibly a bud mutation, that influenced russetting behavior. However, there was evidence that environmental factors, such as soil, rootstock, and understock, were also involved. The application of boron to certain of the high-russet trees failed to affect the amount of russetting. A climatic influence was noted which in some years caused apparently a higher than usual percentage on all the trees.

**Methods of handling Elberta peach pits in relation to nursery germination,** W. H. UPSHALL (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 279-282).—In 9 of 12 yr., nonshelled Elberta peach pits bedded in soil for 1 yr. and then thinned in the nursery row gave fair to good stands of seedlings the following spring. In the other 3 yr. practically all of the viable pits germinated in the bed the first spring, leaving wholly or largely worthless pits. In such in-

stances a satisfactory stand of seedlings was obtained the following spring by cracking, in mid-April, of pits of the preceding year's crop which had been put in the soil bed as soon as the flesh was removed.

**New peach varieties, M. J. DORSEY.** (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 343-352).—Among new varieties of peaches Redhaven, developed by the Michigan Experiment Station, was found outstanding. Several promising peaches developed by the Illinois Station, but still carried under breeding numbers, are described, and some of these are expected to become important factors in peach production in the State. Some information is presented on carlot shipments of peaches in 1941.

**Observations on the inheritance of horticulturally important characteristics in the highbush blueberry, S. JOHNSTON.** (Mich. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 352-356).—The author points out desirable bush and fruit characters in the blueberry and from observations on seedling progenies of various crosses evaluates the potentialities of certain named varieties in breeding for these desirable characteristics. For example, Rubel transmitted upright growth, large size of bush, light blue color, firmness, and late ripening of fruit. For large size of berry, Pioneer was the best parent. Adams yielded early-maturing seedlings. Pioneer and Harding gave sweet flavor to their seedlings. All varieties transmitted easiness of picking.

**The effect of mulch on soil moisture, soil temperature, and growth of blueberry plants, F. B. CHANDLER and I. C. MASON.** (Maine Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 335-337, figs. 2).—Based on investigations in Maine conducted on sandy loam at Monmouth, clay loam at Cherryfield, and a highly sandy soil at Deblois, the authors conclude that mulch retains soil moisture, maintaining the average above that resulting from clean culture. Mulches decreased the average soil temperature during warm weather, increased the growth of blueberry plants in clay loam soil, and reduced their growth in sandy soil.

**Lower temperature cranberry storage tests to reduce loss, C. I. GUNNESS.** (Mass. Expt. Sta.). (*Cranberries*, 7 (1942), No. 5, pp. 7, 10).—Of various temperatures employed in the storage of cranberries, 35° F. was found most satisfactory from the standpoint of reducing losses. However, in the case of poorly colored berries 45° was more satisfactory because the berries developed better color at that temperature. Above 50° there was little change in color, and the losses were markedly increased. The economic aspects of cranberry storage are considered.

**"Milton"—a new red raspberry, G. L. SLATE** (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, pp. 7, 9).—Milton, obtained from a cross between Lloyd George and Newburgh, is described as to plant and fruit. The variety is being introduced as a probably mosaic-free late variety for commercial and home use.

**Studies on some raspberry soils of British Columbia, H. J. ATKINSON and L. E. WRIGHT** (*Sci. Agr.*, 22 (1942), No. 5, pp. 287-297).—A study of soil samples collected from areas which showed varying levels of growth of raspberries failed to show any correlation between the organic matter content and water-holding capacity and growth. Boron content was apparently important since samples from all areas showing good growth had higher boron contents, with the highest boron from the field where excellent raspberry growth occurred. A part of each soil sample was sterilized and analyzed. As a result of sterilization the solubility of organic matter was noticeably increased, as were also the contents of water-soluble sulfates and exchangeable manganese.

**The use of seed characters in the identification of grape varieties, H. P. OLMO.** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 305-309).—

Studies with three varieties of grapes—Carignane, Alicante Bouschet, and Burger—grown at Glen Ellen, Calif., without irrigation and at Davis with irrigation showed that the seeds are useful in variety identification and have the added advantage over fruit in that they may be stored in a permanent collection for study at any convenient time. The mature seed, as judged by weight, length, and width measurements, is far more constant than any of the other fruit characters commonly used in variety descriptions. Although length of seed may increase appreciably with increased size of berry, the width remained fairly constant under the two environments. The use of a ratio of length to width is not warranted because the two factors do not respond in the same manner to changes in environment.

The performance of Champlel grapes under different pruning treatments, N. H. LOOMIS. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 310-312).—The yields of own-rooted Champlel grapes grown at Meridian, Miss., were significantly increased by spur pruning as compared with cane pruning. Pinching the new crop just beyond the last blossom cluster at the time of bloom increased significantly the weight of the clusters. There was no significant difference in yield between pinching and no pinching with respect to vine yields, nor any significant difference between spur and cane pruning as measured by fruit cluster weights.

Plant breeding possibilities for southern Florida, H. S. WOLFE. (Univ. Fla.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 144-146).—Possibilities in the improvement of the avocado, peach, persimmon, jujube, papaya, annona, sapodilla, and other fruits by breeding and selection are discussed.

New avocado varieties, S. J. LYNCH. (Fla. Expt. Sta.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 142-144, pls. 4).—Descriptions and comments are given on certain new varieties, such as Hickson, Herman, Bonita, Lindgren, Blair, and Harris.

Juice color and quality in certain varieties of Florida citrus fruits, E. V. MILLER and J. R. WINSTON. (U. S. D. A.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 64-67).—The total carotenoid pigments in the juice of Florida oranges were observed to increase with their maturity. Since certain of these pigments are converted to vitamin A in the animal, it is concluded that vitamin A potency also increases with ripening. Mandarin oranges, which are notably low in ascorbic acid, are relatively high in carotenoid pigments. A greater use of highly pigmented oranges for human and animal consumption is recommended with respect to vitamin A supply.

Early diagnosis of magnesium deficiency in Florida citrus, B. R. FUDGE. (Fla. Expt. Sta.). (*Citrus Indus.*, 23 (1942), No. 9, pp. 1, 4-5, 14, figs. 4).—The possibility of determining, by analysis of the early spring foliage, the probability of Mg deficiency 4 or 5 mo. later was indicated. If the Mg content of the moisture-free spring flush foliage was greater than 0.35 percent in April and soluble Mg to the extent of 2-4 units of MgO is contained in the summer fertilizer along with 3-4 units of N, the experiment indicated that no deficiency of Mg would occur that autumn. When the first visual symptoms of Mg deficiency appear, it is too late to apply Mg fertilizer with the hope of preventing further development of leaf injury.

The mineral composition of citrus juice as influenced by soil treatment, B. R. FUDGE. (Fla. Expt. Sta.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 4-12).—Analyses of foliage and fruit from some 50 groves located on soils differing widely in chemical composition indicated that differences in the composition of the juice are much smaller than the differences found in the soil or in foliage composition. The Ca content of the juice of fruits grown on hammock

soils was significantly higher than that of juice of fruits grown on sandy soils, but the difference was not so marked as in the foliage. K was slightly higher in the juice of fruit grown on sandy soils, whereas the P and Mg contents were about equal. Essentially, fruit from hammock groves could not be considered as having any great advantage for animal nutrition. The large supply of exchangeable Ca found in the soil as a result of applying  $\text{CaCO}_3$  or dolomite was not reflected in the Ca content of the juice. The amount of Mg found in the juice of both oranges and grapefruit was apparently increased to a considerable degree where there was a large supply of exchangeable Mg in the soil. The large amounts of materials that must be applied to the soil to produce relatively small increases in mineral composition of the juice are not considered warranted in practical culture. Essentially, cultural practices that produce and maintain vigorous trees should give the best quality fruits.

The effect of certain fertilizer practices on the time of maturity and composition of grapefruit and oranges, F. F. COWART and C. R. STEARNS, JR. (Fla. Expt. Sta.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 12-19).—The application of Mg, Cu, Zn, and Mn to trees on a great many of the Florida soils devoted to citrus resulted in marked improvement in fruit quality, along with a general betterment in tree vigor and production. The time of maturity of grapefruit was not materially affected by these elements. A probable slight delay in maturity of the Pineapple orange was indicated. The application of the four above-named elements, particularly Mg, improved the quality of Pineapple oranges as measured by increased acidity, total solids, sugars, and vitamin C contents. In the absence of Mg, the other three elements, Cu, Mn, and Zn, improved quality, but their effects were apparently masked by the beneficial effect of Mg on tree growth and production.

Weekly absorption of nitrate by young, bearing orange trees growing out of doors in solution cultures, H. D. CHAPMAN and E. R. PARKER. (Calif. Citrus Expt. Sta.). (*Plant Physiol.*, 17 (1942), No. 3, pp. 366-376, figs. 3).—Records taken over a 3-yr. period on the weekly nitrate absorption by two young bearing Valencia orange trees growing outdoors in complete nutrient solutions showed the period of maximum absorption to be that of late spring, summer, and early fall. The least absorption occurred during January and February. The periods of varying absorption were related to solution and air temperatures, but varied widely at times even when temperature was rather constant. The relation between the quantities of nitrate and of water absorption was rather variable from week to week, with indications that nitrate absorption was more closely related to periods of active root growth and water absorption to cycles of active top growth.

"Puffy" tangerines in the packing house process, C. K. CLARK and C. R. STEARNS, JR. (Fla. Expt. Sta.). (*Fla. State Hort. Soc. Proc.*, 54 (1941), pp. 45-52).—Studies of the nature, cause, and prevention of damage of puffy tangerines, brought about in various packing house operations, showed that curing by heating had no merit, in fact even 80° F. caused a material increase in damage. The number of treatments to which such fruit are subjected should be reduced to a minimum, leading to the practical suggestion that simply washing with soap, rinsing, and drying on a roller conveyor would appear to be the best method of handling puffy fruits.

Studies of the root system of *Coffea arabica* L.—III, Growth and distribution of roots of 21-year-old trees in Catalina clay soil, J. GUISCARFÉ-ARBELLAGA and L. A. GÓMEZ (*Jour. Agr. Univ. Puerto Rico [Univ. Sta.]*, 26 (1942), No. 2, pp. 34-39, figs. 2; *Span. abs.*, p. 38).—Continuing this investigation (E. S. R., 84, p. 764), data presented on the distribution of roots of six 21-year-old coffee

trees growing in Catalina clay soil showed 94 percent of the roots to occur in the uppermost foot. Primary, secondary, and tertiary roots comprised 57.22, 25.72, and 17.06 percent of the whole root system, respectively. The top: root ratio was 4:1.

**The Croisic (Cordelia) fig, I. V. CONDET.** (Calif. Citrus Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 255-258).—The author discusses the history, nomenclature, distribution on the Pacific coast, fruiting behavior, and flower structure of the Croisic fig, so named in France in 1882 but called Cordelia in California. It is said to be essentially a caprifig, producing ordinarily a heavy proficli crop, a light mammoni crop, and very few or no mammee figs. Blastophagous insects oviposit in the short-styled pistillate flowers, and all stages of the insect may be found in the syconia at various times.

**Effect of stratification and time of planting on germination of tung seed, R. H. SHARPE and S. MERRILL, JR.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 286-291, fig. 1).—Stratification of hulled tung seeds was of definite aid in hastening and improving germination, especially so with seed from parent trees whose seeds germinate slowly. Stratification of whole fruits resulted in much poorer and slower germination than when the seeds were hulled. January planting proved better than March planting of dry-stored seeds, but did not particularly benefit stratified seeds. Stratification thus permitted later planting, with better weed control. Moderately cold temperatures gave better results in stratification than did cold storage temperatures.

**Preliminary storage experiments with pollen of tung (Aleurites fordii Hemsl.), D. L. FERNHOLZ and L. HINES.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 251-254, figs. 2).—Pollen of tung (*A. fordii*) germinated readily on 1 percent agar with 10 percent sucrose when incubated 24 hr. at room temperature in a practically saturated atmosphere. Pollen taken from buds collected just before anthesis gave the best viability and longevity. Storing whole flowers in paper bags at about 5° C. (41° F.) in an ordinary household refrigerator was found a practical method for keeping pollen for breeding operations.

**Michigan State: A new hybrid Kalanchoe, C. E. WILDON** (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 29-32, pl. 1).—A description is presented and the cultural requirements outlined of a new hybrid obtained from a cross of *K. blossfeldiana* × *K. kirki* (= *velutina*).

**Adaptability studies with bearded iris in Texas, S. H. YARNELL** (*Texas Sta. Bul.* 615 (1942), pp. 33, figs. 5).—A total of 582-odd varieties of bearded iris was tested for adaptation when grown on a Lufkin fine sandy loam. Of the total, 149 received a rating of 7 or better, which represented good adaptation. Of the 149, 1 was rated excellent in adaptability, 15 rated very good, 44 good, and 89 moderately good. Recent introductions were found to be about as well adapted to the conditions of the test as were the older varieties and provided a wider range of color. Varieties which had proved to be generally good elsewhere had a better-than-average chance of being well adapted to the Texas conditions. Under the existing conditions at College Station, November through December, when there was ample moisture, was found the best time to transplant iris. April, May, and June proved to be the most unfavorable time. When moisture conditions 1 week before and 5 weeks after setting were good, the plants thrived much better than when the soil was dry. In 14 crosses where adaptability ratings were available for both parents, the offspring averaged higher in rating than the parents. Varieties with somatic chromosome numbers of 24, 36, 40, and 44 averaged better in adaptability than those with 47 to 50 chromosomes. The result was attributed to a lack of factors favoring adaptability rather than to the high chromosome numbers.

## FORESTRY

[Forestry studies by the New York State Station] (*New York State Sta. Rpt. 1942*, pp. 78-79).—Brief reports are presented upon germination studies with coniferous seed, sulfuric acid treatment of the hard seeds of certain forest species, and the testing of planting stocks of Scotch pine and Norway spruce.

Trees of the eastern United States and Canada: Their woodcraft and wildlife uses, W. M. HARLOW (*New York and London: McGraw-Hill Book Co., [1942], pp. XIII+288, pls. [5], figs. [163]*).—This descriptive manual (with keys to tree groups and species), prepared especially for hobbyists, hikers, campers, and woodcrafters, approaches the subject with a minimum of technical terms and with particular emphasis on the pioneer uses of trees and their peculiar value to the woodcrafter.

Forest tree seed of the North Temperate regions, with special reference to North America, H. I. BALDWIN (*Waltham, Mass.: Chron. Bot. Co., 1942, pp. XVI+240, figs. 28*).—This text, which is essentially a progress report on the status of investigative work with seeds, deals with the structure and development of seeds, their production by trees, the effect of seed origin on growth, seed collection and extraction, storage, control of biotic enemies, factors affecting germination, the chemistry of seeds, etc.

Douglas fir seed from young trees, G. S. ALLEN (*Jour. Forestry, 40 (1942), No. 9, pp. 722-723*).—Evidence was obtained that young trees are capable of producing normal, viable seeds and factors other than age are important. One requirement would appear to be adequate cross-pollination, which is often lacking in young stands which produce little pollen. A cutting test of seed from sample cones is essential to determine the percentage of filled seeds. At least 60 percent of the seeds should be filled before a stand of trees may be considered a suitable source of seed.

Stratification as a means of improving results of direct seeding of pines, T. F. McLINTOCK. (U. S. D. A.). (*Jour. Forestry, 40 (1942), No. 9, pp. 724-728*).—Stratification improved both the germination and catch of directly seeded Virginia, shortleaf, and pitch pines but reduced the catch of loblolly pine. The best results were obtained with Virginia pine. The effects of stratification were much more pronounced on north than on south slopes. The results indicated that, for Virginia, shortleaf, and pitch pines grown in the Central States, stratification removes much of the hazard from direct seeding as a method of reforestation and makes such seeding feasible and practical on favorable sites.

Yield of even-aged stands of loblolly pine in northern Louisiana, W. H. MEYER (*Yale Univ. School Forestry Bul. 51 (1942), pp. [4]+39, figs. 13*).—Measurements taken over a period of years on 273 sample plats in comparatively fully stocked even-aged loblolly pine forests in northern Louisiana and southern Arkansas are utilized as a basis for various tables and charts, such as yield tables, stand and stock tables, etc.

Height of red pine saplings as associated with density, H. L. SHIRLEY and P. ZEHNGRAFF (U. S. D. A.). (*Ecology, 23 (1942), No. 3, p. 370*).—Trees growing in relatively dense stands made greater height growth than did scattered trees of the same age. Whether the increase in height resulted from the greater density of the stand or from some more favorable soil factors in the thicket is unanswered.

Effects of the 1940 Armistice Day freeze on Siberian elm in the Plains country, H. E. ENGSTROM and L. S. MATTHEW. (U. S. D. A.). (*Jour. Forestry, 40 (1942), No. 9, pp. 704-708*).—This article, with supplemental comments by C. G. Bates, points out that native species survived the freeze without serious

damage, while many introduced species suffered severely. Exotics, such as Siberian elm, should be included in the plantings only to the extent necessitated by temporary benefits. There was evidence of strain differences in the Siberian elm and that this species is best adapted to dry-land and protected sites.

**The Central American species of Quercus**, C. H. MULLER (U. S. Dept. Agr., Misc. Pub. 477 (1942), pp. III+216, pls. 124).—Botanical descriptions are presented for a large number of species, supported by information on subgeneric and species concepts, morphological basis of classification, etc.

**Forest site determination by soil and erosion classification**, W. E. COOPER (U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 709-712).—Apparently various factors, such as topographic features, profile characteristics, soil acidity, chemical relationships, and forest litter, have an important bearing on forest growth. No one but rather all of these factors should be taken into consideration, and any method which centers on any one factor to the exclusion of the others would not be entirely accurate. Classification of sites by soil series and by the intensity of erosion appears to be broad enough to include most of the factors mentioned and is simple enough to provide the necessary means for recording differences in fertility.

**Natural restocking of redwood cutover lands**, H. L. PERSON and W. HALLIN (U. S. D. A. coop. Univ. Calif.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 688-688, figs. 2).—Much of the redwood land cut-over in Mendocino and Humboldt Counties, Calif., between 1920 and 1935 was found to be seriously understocked. Sprouts provided less than 10 percent of full stocking, leaving the main reliance upon seedlings. Satisfactory regeneration did not occur on severely burned high-lead and slack-line settings, where an average of only one good seed tree to each 5 acres was found over large areas. The minimum trees needed to provide fairly good stocking ranged from 4 per acre on favorable north slopes to 8 or more for south exposures. The importance of full removal of litter and slash in providing adequate regeneration was indicated. Redwood being more shade-tolerant than its principal associates, white fir and Douglas fir, was better able to reestablish itself in selectively logged areas. Partial shade, exposed mineral soil, and a good seed supply assured adequate natural regeneration on good redwood sites.

**Dendrochronology in pines of Arkansas**, E. SCHULMAN. (Univ. Ariz.). (*Ecology*, 23 (1942), No. 3, pp. 309-318, figs. 7).—Late wood, early wood, and total ring chronologies 160 yr. in length are presented for shortleaf pine growing on a well-drained site in the Ouachita Mountains, Ark. Crossdating between trees was found strongest in the late wood and to hold for the maxima nearly as well as the minima. The relationship of late wood growth to precipitation of July-September for 83 yr. of record was found to be moderately close; little relation existed between early wood and precipitation, except for the extreme years; and there was little evidence for any carry-over effect from year to year of precipitation, although some small influence of spring precipitation on late wood growth was occasionally evident. Late wood growth was shown to be to some extent inversely proportional to the mean temperatures of July through September.

**Collect the bounty on your wolf-trees**, G. R. CONDIT, M. A. HUBERMAN, and J. R. MCGUIRE. (U. S. D. A. et al.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 680-682, fig. 1).—White pine wolf trees, those with huge side branches and very little potentially valuable lumber, are undesirable because of the space they occupy and their harmful effect on underlying reproduction. With a strong demand for boxboards and for fuelwood, it is conceded a good time to cut such trees and, if the work is done by the owner, a fair profit may be realized. With

care, sufficient reproduction may be conserved beneath the trees to regenerate the stand.

**Variations in fire-danger factors on a ranger district in the longleaf pine region, P. KNOX.** (U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 689-692).—A comparison of variations in danger factors on several sites located in an area of some 384,000 acres in Alabama showed no significant difference among stations with respect to the moisture percentage of basswood indicators. Very significant differences were recorded among the stations as to wind velocity and rate-of-spread index. The desirability of running a series of checks of anemometer readings on tentative sites before establishing a permanent fire-danger rating station, even on relatively level longleaf pine lands, is suggested.

**Measuring the efficiency of fire control in California chaparral, D. H. ROGERS.** (U. S. D. A. coop. Univ. Calif.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 697-703).—The following correlations were established between age of chaparral cover and size of fire under a given standard of fire protection: Fires of 0 to 0.24 acre will occur in covers of any age; fires of 0.25 to 9.99 acres require at least a 3-year-old cover; fires of 10 to 39.99 acres require at least a 7-year-old cover; and fires of 40 acres or more require at least a 13-year-old cover. As the age of the cover increases above the minimum ages required for each size class, individual fires tend to become larger.

**Transect method of estimating forest area from aerial photograph index sheets, P. R. KRAMER and E. E. STURGEON.** (U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 693-696).—A method of transecting is described which may be used for estimating the extent of various land-use areas from aerial photograph index sheets. Linear measurements are made along uniformly spaced transect lines, superimposed on the photographs by use of a celluloid guide. The measurements are then totaled and converted to figures for ground area.

## DISEASES OF PLANTS

**The nature and prevention of plant diseases, K. S. CHESTER** (Philadelphia: Blakiston Co., [1942], pp. XII+584, [pl. 1], figs. 207).—"The subject matter of this book and the manner of treatment have been largely dictated by the needs of students to whom an elementary course in plant pathology is a part of the background fitting them for useful work in agriculture. . . . The book has the dual purpose of introducing the student to the essential features of the science, as exemplified in important diseases of our leading crops, and of providing him with a work to which he may refer for detailed and specific directions on plant disease control."

Diseases of major importance to agriculture in the southern United States are given special attention.

**The Plant Disease Reporter, [October 1 and 15, 1942]** (U. S. Dept. Agr., Bur. Plant Indus., *Plant Disease Rptr.*, 26 (1942), Nos. 18, pp. 389-405, figs. 4; 19, pp. 407-420, figs. 2).—In addition to the host-parasite check-list revision, by F. Weiss (Nos. 18, *Spartium* to *Syringa*, and 19, *Tabebuia* to *Thespesia*), the following are included:

No. 18.—*Heterodera rostochiensis*, the golden nematode of potatoes, in New York State, by B. G. Chitwood, R. L. Clement, R. Morgan, and R. Tank; recently active leaf diseases of woody plants in Idaho, by J. Ehrlich; barley scab and blight present in local areas in the 1942 crop, by J. G. Dickson; and brief notes on potato late blight—first report for Nebraska, a new introduction of tobacco black shank into Kentucky, small grain diseases in South Dakota, and spotting of cherry fruits caused by the leaf spot fungus.

**No. 19.**—Ergot epiphytotic in southwestern pastures, by K. S. Chester and C. L. Lefebvre; the meadow nematode (*Pratylenchus pratensis*) on tobacco in South Carolina, by T. W. Graham; current notes on plant diseases in Massachusetts, by O. C. Boyd; reports on *Helminthosporium* leaf blight of corn in New York, corn diseases in Maryland, and *Helminthosporium* leaf spot and bacterial wilt on field corn in Indiana; and brief notes on *Peronospora* on soybean in Virginia, and carnation bacterial wilt in Indiana.

**Plant diseases: Their nature, cause, and control.** (Coop. U. S. D. A. et al.). (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, pp. 4, 5).—Brief summaries and progress reports are presented by C. Dorman relative to control work by the station on wilts, nematodes, and seedling diseases of cotton; disinfection of sweetpotato roots; wilt-resistant strains of watermelons; early blight prevention and wilt resistance in tomatoes; and control of cabbage downy mildew and wire stem.

[Work on plant diseases by the New York State Station] (*New York State Sta. Rpt.* 1942, pp. 52-58, 59-60, 76-78).—Reports of progress are included on averting spray injury in the apple scab control program in western New York; apple scab and its control in the Hudson Valley; epidemiology and control of rust diseases of the apple in the Hudson Valley, and of cherry leaf spot; cause and control of peach cankers; summer spray program for peaches; diseases of grapes, raspberries, currants, and gooseberries and their control; a survey of canning crop diseases; effect of seed treatment on the growth of pea plants, and of pea seed protectants on nodule bacteria; effect of environal conditions on seed decay, damping-off, and root rot of canning crops; lima bean seed treatment; diseases of canning tomatoes and their control; production of disease-free bean seed with special reference to mosaic; yellows-resistant cabbages; spraying for control of downy and powdery mildews, leafhoppers, and sooty mold on hops; seed treatment and spraying and dusting of lima beans; breeding cauliflower for resistance to black rot; seed-borne micro-organisms of spinach, peas, and corn; and seed treatment tests in the laboratory and field, including several of the newer fungicides such as Spergon, 1205FF, U.S.R. No. 604, 154-6B, and DuBay 1228E.

**Recent phytopathological events in South Dakota**, W. F. BUCHHOLTZ. (*S. Dak. Expt. Sta.*). (*S. Dak. State Hort. Soc., Ann. Rpt.*, 39 (1942), pp. 43-46).—The author refers to the increased emphasis on phytopathological research in the State and to recent outstanding cases of plant diseases and their control, including an extreme epidemic of fire blight on apple in a northern Black Hills area, serious damage by *Fusarium* wilt in a watermelon-growing district, and stand failures in grass reseeding due to soil-borne seedling and root parasites.

**Organization for plant pathology in England and Wales—retrospect and prospect**, W. C. MOORE (*Brit. Mycol. Soc. Trans.*, 25 (1942), pt. 3, pp. 229-245).—This address refers particularly to the applied aspects of plant pathology, including diseases due to fungi, bacteria, viruses, and nonparasitic causes, as well as to insects and other plant pests.

**List of diseases of economic plants recorded in Scotland**, R. W. G. DENNIS and C. E. FOISTER (*Brit. Mycol. Soc. Trans.*, 25 (1942), pt. 3, pp. 266-306, fig. 1).—An annotated list, with introductory discussion.

**Elimination of contaminants with ultra-violet radiation**, A. M. KLIGMAN (*Science*, 96 (1942), No. 2481, pp. 69-70).—Irradiation of a small inoculating room, containing several tables, for 4 hr. with a Westinghouse Sterilamp rendered the originally contaminated atmosphere practically sterile.

**Breeding disease-resistant crops**, F. N. BRIGGS. (Univ. Calif.). (*Science*, 96 (1942), No. 2481, p. 60).—Referring to a recent paper by Stevens (E. S. R.,

87, p. 527), attention is called to the method of backcrossing for avoidance of the danger of introducing genes for susceptibility to one or more diseases when breeding for resistance to another.

On the generic name of the gram-positive bacterial plant pathogens, W. J. DOWSON (*Brit. Mycol. Soc. Trans.*, 25 (1942), pt. 3, pp. 311-314).—It is recommended that these six bacterial species, listed in the Bergey Manual of Determinative Bacteriology (E. S. R., 81, p. 489) under *Phytomonas*, be referred to the genus *Corynebacterium*. There are 20 references.

The genus *Peronospora* in the Punjab, KARTAR SINGH THIND (*Jour. Indian Bot. Soc.*, 21 (1942), No. 3-4, pp. 197-215, pl. 1, figs. 16).—The author describes 16 species of *Peronospora* on 20 hosts, 6 of the fungi being new records for India and 7 of the plants new host records.

*Puccinia phyllocladiae* Cooke, a new record for India, KARTAR SINGH THIND (*Jour. Indian Bot. Soc.*, 21 (1942), No. 3-4, pp. 195-196, fig. 1).—This rust is reported on *Asparagus gracilis*.

A technique for the anatomical study of root parasitism, L. S. S. KUMAR, A. ABRAHAM, and S. SOLOMON (*Ann. Bot. [London]*, n. ser., 6 (1942), No. 21, pp. 177-182, pl. 1).—The new technic described involves fixation in Nawaschin's fluid, clearing in 1 percent KOH solution, and staining by a modified Feulgen technic. The advantages of the method are indicated.

El agotamiento del humus en el terreno y su influencia sobre ciertas clases de podredumbres de la raíz, que aparentemente son de origen patógeno y que realmente no son más que casos de inanición y muerte por hambre debido a una alimentación deficiente de la planta [Exhaustion of humus in the soil and its influence on certain classes of root rots which appear to be of pathogenic origin but which actually are cases of starvation and death due to nutritional deficiencies], J. A. ALVARADO (*Café El Salvador*, 12 (1942), Nos. 135, pp. 170-192, figs. 11; 136, pp. 242-252, figs. 5; 137, pp. 282-301, figs. 8; 138, pp. 346-362, figs. 8; 139, pp. 396-409, figs. 5; 141, pp. 523-534, figs. 2).

A cancerous neoplasm of plants: Autonomous bacteria-free crown-gall tissue, P. R. WHITE and A. C. BRAUN (*Cancer Res.*, 2 (1942), No. 9, pp. 597-617, figs. 13).—"Secondary or metastatic tumors frequently arise on sunflower plants inoculated with *Phytomonas tumefaciens* at considerable distances from the primary tumefactions. These have been shown by cultural and serological methods to be characteristically bacteria-free. Tissue cultures isolated from these tumors show a rapid disorganized type of growth contrasting sharply with the slow, moderately organized growth of those isolated from healthy tissues. Upon implantation into uninfected plants of the same or related species, these tissues produce typical crown-gall tumors. This capacity for unrestrained, invasive, potentially malignant growth both in vivo and in vitro in the absence of the original excitant differentiates these tissues from any other plant materials reported to date and places them in a category comparable to cancerous growths in animals." It is believed that these findings may well render great service in the study of the origin and character of those changes in cell behavior which are considered to be the basis of "the cancer problem."

Crystallography and plant viruses, F. C. BAWDEN (*Nature [London]*, 149 (1942), No. 3777, pp. 321-322).—This is a brief review of recent techniques and results in virus studies which have opened up a field of research that promises to be extremely fertile. It is seen that it is their internal regularity, lack of water, and chemical simplicity which separate the viruses most sharply from the simplest recognized organisms. With extension of X-ray analysis to spacings as great as 1,000 a. u. and improvements in the electron microscope, particles

of all sizes from bacteria to atoms become capable of direct examination, and a serious gap in the technics for studying colloidal particles has been filled.

**Virus nomenclature and classification**, W. D. VALLEAU. (Ky. Expt. Sta.). (*Chron. Bot.*, 7 (1942), No. 4, pp. 152-154).—This is a general review and discussion of recent contributions to the subject, with the author's suggestion that as rapidly as viruses affecting certain plant groups have been sufficiently studied to demonstrate their relationships to one another and to some of the well-known viruses, they be assigned binomials which would either place them with recognized genera, or, if evidence warranted, in newly established genera.

**Presence of virus in the primordial meristem**, F. M. L. SHEFFIELD (*Ann. Appl. Biol.*, 29 (1942), No. 1, pp. 16-17).—It was at first thought that the absence of intracellular inclusions from the apical meristem of infected plants might be due to failure of the virus to penetrate there. However, when this tissue was dissected out from shoots or roots of plants with tobacco or aucuba mosaics, infections were obtained from it.

**Results of experiments with chlorotic streak in 1941**, E. V. ABBOTT. (U. S. D. A.). (*Sugar Bul.*, 20 (1942), No. 18, pp. 161-165).—This is a progress report on continued field experiments (E. S. R., 86, p. 795), with this sugarcane virus, summarizing data on the effects of the disease on yields, varietal resistance tests, and control by roguing and hot water treatment.

**Studies on the mechanism of fungicidal action**, II, III, A. F. PARKER-RHODES (*Ann. Appl. Biol.*, 29 (1942), No. 2, pp. 126-143, figs. 2).—Continuing this series (E. S. R., 87, p. 380), two papers are presented:

II. *Elements of the theory of variability* (pp. 126-135).—Variability is defined and methods of estimation are outlined. It is shown that variability of a given population of spores to a compound which can penetrate their walls is less than to any other compound of the same element which cannot do so unless it undergoes one or more reactions on the spore surface with substances secreted by it, and the greater the number of such successive reactions required to bring it to a permeable form, the greater will the variability be. Instability in a compound increases the apparent value of the variability of the spores to it. Their variability to any compound is proportional to the square of the number of atoms of the effective element in a molecule of that compound; and the index of variation is inversely proportional to that number, provided only one compound is permeative. If a molecule undergoes a very small dissociation into parts, some of which contain none of the active element but which are permeative whereas the undissociated molecule is not, then the variability to such a compound is proportional to the square of the number of parts into which it dissociates, and the index of variation inversely proportional to that number. Most kinds of synergism occurring between constituents of a mixture used in a test or between a compound under test and any product formed therefrom in the course of its toxic action will interfere with the results by increasing the apparent value of the variability. The application of these laws to analysis of experimental results is discussed.

III. *Sulphur* (pp. 136-143).—The reactions of spores of *Macrosporium sarcinaeforme* to a selection of S compounds (including elementary S) were studied, and details are given of the methods used with  $H_2S$ , involving examination of the behavior of the spores in a static atmosphere containing the gas. It is inferred from the results that S can be absorbed by the spores only in the form of the ions hydrosulfide, dithionite, or pyrosulfite, or else only as thiosulfite, and of the yellow and white isomers of the ions it is thought possible that only the latter can be absorbed. It is believed probable that in the given case S exerts

its effect indirectly through the pyrosulfoxyolate ion in the hydrolysate. Agreement of the results with the theory of variability is noted.

There are 18 references to the two parts.

**Substitutes for copper and zinc in fungicidal sprays**, J. W. ROBERTS. (U. S. D. A.). (*Indus. and Engin. Chem.*, 34 (1942), No. 4, pp. 497-498, fig. 1).—A preliminary report.

**"Fermate"**—new Du Pont fungicide, D. H. PALMITER and J. M. HAMILTON (N. Y. State Expt. Sta. et al.). (*Agr. News Letter*, 10 (1942), No. 3, pp. 57-58).—A note on the new fungicide Fermate (ferric dimethyl dithiocarbamate). Good control with this material is reported for apple scab, cedar-apple rust, and brown rot on sweet cherries.

**Derivatives of dithiocarbamic acid as pesticides**, W. H. TISDALE and A. L. FLENNER (*Indus. and Engin. Chem.*, 34 (1942), No. 4, pp. 501-502).—Data on fungicidal efficiency include tests against barley covered smut, *Fomes annosus*, *Aspergillus niger*, fungus infections of the skin, *Botrytis tulipae*, *Venturia inaequalis*, rose mildew, and *Coccomyces hiemalis*. Tests against insects, mites, and other skin infections, and cecal coccidiosis of poultry are also reported.

**USGA reports on substitutes for mercury fungicides**, J. MONTEITH, JR. (*Golfdom*, 16 (1942), No. 5, pp. 28, 30, fig. 1).—In tests of over 100 chemicals, tetramethylthiuram disulfide proved of real value for controlling snow mold, brown patch, dollar spot, and other diseases of turf.

**"Thiosan"**—A new turf fungicide, C. HORN (*Golfdom*, 16 (1942), No. 5, pp. 13-14, figs. 2).—The effectiveness of this new fungicide (tetramethylthiuram disulfide), containing neither Hg nor any other metallic element, is said to have been demonstrated by tests on 18 playing greens in Delaware and New Jersey.

**Pythium root rot of grasses**, T. C. VANTERPOOL (*Sci. Agr.*, 22 (1942), No. 11, pp. 674-687, figs. 8).—Grown in the greenhouse in *Pythium*-infested soil from areas in wheat fields severely diseased with browning root rot, the common commercial grasses also became heavily attacked. The same pathogenic species, viz, *P. aristosporum*, *P. arrhenomanes*, *P. graminicola*, *P. tardicrescens*, and *P. volutum* are of major concern on both grasses and cereals, with *P. debaryanum* and its close allies less so. Under the same conditions, legume and flax roots were not attacked by the forms severely pathogenic on graminaceous hosts, but forms of the *P. debaryanum* group were isolated though the roots commonly showed little in the way of lesions. Field damage to grasses appears to be greatest in the early growth stages, suggesting the use of high-grade seed as an initial step in control. Further injury may occur in later growth periods when new roots are emerging from the crown. In the infested field soils used, phosphate-containing fertilizers, especially with ammonium phosphate, increased the growth of grasses considerably in pot tests when applied at seeding time. Applied alone, this phosphate usually had no effect or was slightly detrimental. The effects of various fertilizers in normal field soil during the establishment phase are also given. It is tentatively suggested that if grasses are to be grown in severely infested wheat fields which have given economical increases from phosphatic fertilizer amendments, at least trial strip applications of ammonium phosphate should be made. It is believed that more vigorous seedlings and a better stand will be thus secured, especially if the seeding is done on fallowed land, and an increase in the quality or nutritive value of the forage will result. There are 27 references.

**Viability of dusted wheat after storage**, G. T. S. BAYLIS (*New Zeal. Jour. Sci. and Technol.*, 23 (1941), No. 3A, pp. 126A-130A).—Both Agrosan G and Ceresan U. T. 1875A improved the field germination of Solid Straw Tuscan wheat after storage for 12 mo. Wheat samples of 16.7-12.8 percent moisture content

were included, and dusts were used at both standard and excess dosages. Injury from dusting occurred when wheat with 16.7 percent moisture was stored for 12 mo. in a closely lidded bin, but under such conditions field germination of nondusted wheat also declined substantially. Data are included relating to changes in moisture content of wheat during storage and to the relationship between field and laboratory germination tests of dusted grain.

**Heat inactivation of wheat mosaic virus in soils**, F. JOHNSON. (Ohio State Univ.). (*Science*, 95 (1942), No. 2476, p. 610).—This virus was inactivated in the soil when exposed to 50°–60° C. for 10 min.

**Third revision of the International Register of Physiologic Races of the Leaf Rust of Wheat (*Puccinia rubigo-vera tritici* (triticultura))**, C. O. JOHNSTON, H. B. HUMPHREY, R. M. CALDWELL, and L. E. COMPTON. (Coop. Kans. and Ind. Expt. Stas.). (*U. S. Dept. Agr., Bur. Plant Indus.*, 1942, pp. [1] + 20).—This revision (E. S. R., 81, p. 226) brings available information up to January 1942. Included are an analytical key for identifying the physiological races determined on the basis of their parasitic behavior on wheat varieties and a table showing the reactions of differential wheat varieties to these races.

**Raças fisiológicas da *Puccinia graminis tritici* em Portugal** [Physiologic races of *P. graminis tritici* in Portugal], B. D'OLIVEIRA and M. C. FILIPE DE SOUSA (*Agron. Lusitana*, 2 (1940), No. 3, pp. 243–252; *Eng. abs.*, p. 252).—Six physiologic races were found, viz, 14, 15, 24, 27, 40, and a new one described as 187. The reactions of the collection of Portuguese wheats to races 24, 27, and 40 are presented.

**Stem eelworm disease of french beans: First record in New South Wales**, R. D. WILSON (*Agr. Gaz. N. S. Wales*, 53 (1942), No. 2, pp. 95–99, figs. 5).—Infestation of French bean plants by *Anguillulina dipsaci* is reported, and a general discussion of this nematode and its control is given.

**Internal breakdown of table beets**, O. A. LORENZ ([*New York*] Cornell Sta. Mem. 246 (1942), pp. 42, pls. 7, figs. 5).—The experimental results here reported indicate that soil moisture has much to do with the availability to beet plants of boron applied to the soil. For example, with low soil moisture content, soil applications of borax at 300 lb. per acre injured table-beet plants very little, but with high soil moisture 100 lb. was toxic. The effect of low soil moisture in retarding the absorption of B was probably only temporary, since B again became available with increased moisture content. Plant growth was increased above that in solutions containing 0.01 p. p. m. B and 10 p. p. m. Ca either by increasing the B concentration without increasing that of Ca or by increasing the concentration of Ca without increasing that of B. When B increments at any Ca level were associated with increased growth, they were also associated with increased Ca absorption. However, it was indicated that growth could not have depended on Ca absorption in itself, probably depending rather on Ca utilization. The interaction between B and K was in the opposite direction from that between B and Ca. That is, B increments were more efficient in increasing growth at the higher than at the lower levels of K, whereas in the B–Ca experiments increments of B caused the greatest increase in growth at the lowest Ca levels. Absorption of K depended chiefly on its concentration in the nutrient solution. These results support the view that B aids the plant in absorbing cations, but B seems more closely associated with utilization than with absorption of Ca and K.

There were no consistent differences in dry weight as percentage of fresh weight between normal and break-down tissues. On the dry weight basis, ash, Ca, Mg, P, and Fe accumulated in considerable amounts in the areas of break-down tissue; K less so. Total and protein N were higher in affected

tissue, but there was little difference in soluble N. Total sugars, sucrose, and alcohol-soluble solids were higher in normal tissue, whereas reducing sugars and starch were higher in the break-down tissue. Microchemical studies showed B deficiency to be associated with reduction of pectic-staining materials in the intercellular spaces, and later a reduction in cellulosic-staining materials. B-deficient tissues of the roots had a lower protopectin:pectin ratio than normal tissues of the same beet. It is suggested that the effect of B deficiency may be to prevent the formation of certain compounds such as protopectins rather than to destroy compounds already formed. Possibly B acts as a catalyzer in forming protopectic substance such as calcium pectate. Anatomical symptoms of B deficiency were usually first noted in the parenchymatous tissues and vessels in the petioles of younger leaves.

**Cotton root rot studies with special reference to sclerotia, cover crops, rotations, tillage, seeding rates, soil fungicides, and effects on seed quality.** C. H. ROGERS (*Texas Sta. Bul.* 614 (1942), pp. 45, figs. 10).—Sclerotia of *Phymatotrichum omnivorum* were recovered to a depth of 8 ft. in the Blackland soils and in quantities of several million per acre in the first 3-4 ft. Reductions in sclerotial numbers after crop rotations and green manuring were scarcely large enough to account for partial control of root rot obtained, suggesting that the beneficial effect might have been on the active stage of the fungus in the soil or directly on the cotton plant. Microscopical studies indicated some structural difference between viable and nonviable sclerotia. In the usual cotton-corn-oats rotation with oats followed by summer catch crops of cowpeas and sorghum plowed under in late summer, the yield of lint cotton in 1941 was greater by 100 lb. per acre in the plats receiving this treatment than in continuous cotton plats and the amount of root rot was 20-30 percent less. Similarly, the yield from cotton following plowed-under Hubam stubble was twice as large as that from continuous cotton plats and root rot was reduced from 70 to 15-20 percent. Early plowing under of cotton plants in 1940 resulted in a yield increase of 120 lb. of seed cotton per acre in 1941 as compared with the usual late turning of the stalks.

Sesbania, guar, and certain selections of Brabham and Iron cowpeas were resistant and may prove valuable in rotations designed for root rot control and soil improvement. In a 3-yr. study, cotton was planted at rates of 2, 5, and 10 seeds per hill, in hills 18 in. apart and the stand thinned to not more than 2 plants per hill in all plats at time of chopping. The plats planted with the fewest seeds per hill had the least root rot at the end of the season. Subsoiling or tillage to 15 in. or more reduced the amount of root rot, but no outstanding yield increase was obtained. Soil treatment with certain fungicides (e. g., crude oil) was effective if applied sufficiently deep. Seed from plants killed early in the season by root rot had lower oil and protein contents and lower viability than that from plants escaping root rot during seed development. There are 26 references.

**Cotton seed disinfection in war-time.** A. S. BOUGHEY (*Nature* [London], 149 (1942), No. 3767, pp. 50-51).—As a substitute for seed treatment with mercurials, it was found that holding cottonseed for 48 hr. in four times its weight of irrigation water eliminated practically all traces of *Bacterium* (= *Phytomonas*) *malvacearum*. From laboratory studies it appeared that this effect was due to exposure of the pathogen to anaerobic conditions resulting from bacterial activity and O<sub>2</sub> absorption by the germinating seed.

**El tratamiento de la semilla de algodón con productos anticriptogámicos** [Cottonseed treatment with fungicides], M. A. DI FONZO (*Argentina Min. Agr., Junta Nac. Algodón, Bol. Mens.* No. 81-82 (1942), pp. 43-51, figs. 10).—

The effectiveness of various fungicides against seed-borne diseases of cotton was compared by seed treatment tests in the laboratory and field.

**Flax rust**, W. P. CASS SMITH (*Jour. Dept. Agr. West. Austral.*, 2. ser., 19 (1942), No. 1, pp. 56-63, figs. 4).—Though flax varieties for oil and for linseed have been grown in Western Australia for about 30 yr., large-scale commercial production has only been attempted during the current war. With the increase in culture, rust has made its appearance in epidemic form in at least one section. This paper reviews the local situation and summarizes data on the disease and its control.

**Stem-break and browning (*Polyspora lini*) of flax in New Zealand**, G. T. S. BAYLIS (*New Zeal. Jour. Sci. and Technol.*, 23 (1941), No. 1A, pp. 1A-8A, figs. 4).—The symptoms of this disease from two local areas are described. Among 19 flax varieties tested, 3 proved resistant and 1 almost immune. Seed-borne infection was eliminated by a 10-min. treatment of the seed in water at 126° F., and swelling of the mucilaginous seed coat during the process was avoided by freely dusting the seed with hydrated lime and adding 1 percent to the water.

**Seed treatment as an aid in the wartime production of peanuts**, H. C. BUCHA (*Agr. News Letter*, 10 (1942), No. 5, pp. 114-122).—Poor stands of peanuts, one of the chief obstacles to high yields, are usually due to seed decay in the soil. After reviewing data on seed treatment tests by others, the author presents the detailed results of greenhouse and field experiments with the sulfur compound 50 percent tetramethyl thiuram disulfide ("DuBay" 1205-FF) in which it compared very favorably with the organic mercurial Ceresan in preventing seed decay and materially increasing emergence. It appears that adoption of peanut seed treatment would provide a simple and inexpensive means of increasing farm income and at the same time aid in meeting the greatly heightened demand for peanut oil during the war.

**Dois virus no pimenteiro [Two virus diseases of pepper]**, M. DE LOURDES D'OLIVEIRA (*Agron. Lusitana*, 2 (1940), No. 3, pp. 209-223; *Eng. abs.*, pp. 221-222).—The viruses isolated from *Capsicum annuum* in two different parts of Portugal were those of tobacco mosaic and cucumber mosaic, identified by experimental inoculations and study of some of their physical and chemical properties. The symptoms, transmission, and control are discussed. There are 15 references.

**Nematode infection in Poa**, W. G. DORE (*Rhodora*, 44 (1942), No. 523, pp. 246-247, figs. 3).—Note on nematode infestation of *P. pratensis* in Nova Scotia.

**Trace-elements and "potato-sickness,"** C. ELLENBY (*Nature [London]*, 149 (1942) No. 3767, p. 50, fig. 1).—Results of the preliminary studies outlined lend support to the view that *Heterodera schachtii* is not the sole cause of the disease known as potato sickness. Planted on badly infested land, potatoes supplied with certain trace elements, particularly Zn, B, and Mn, far surpassed in growth and weight of crop those not so treated.

**Ring rot in volunteer plants**, R. BONDE. (Maine Expt. Sta.). (*Amer. Potato Jour.*, 19 (1942), No. 7, pp. 131-133).—In several years' field tests (1934-40) the ring rot bacteria failed to remain viable through the winter in the soil of certain fields that had produced badly diseased crops, but the disease was perpetuated in the field in infected tubers which survived the winter and produced volunteer plants. Such diseased plants may contaminate any disease-free stock that may be planted in the same soil.

**Plant nutrition and the hydrogen ion.—II, Potato scab**, R. A. SCHROEDER and W. A. ALBRECHT. (Mo. Expt. Sta.). (*Amer. Soc. Agron., Com. Fert. Min.*,

7 (1941), pp. 18-23).—Continuing this series (E. S. R., 87, p. 186), the authors found, in the light of the experimental data presented, that they were "forced to take the potato scab problem largely out of the category of pathology with the degree of soil acidity in control and to put it mainly into the category of plant nutrition with soil fertility at the controls. When the increased mobilization of plant nutrients, more particularly certain cations, in the presence of the hydrogen ion in contrast to lowered mobilization in hydrogen absence is appreciated, we shall be solving more rapidly some of the problems of so-called plant disease, of lowered crop yield, and of reduced crop quality. We shall arrive at these solutions not only by providing the supply of a well balanced soil fertility, but also by appreciating the presence of the hydrogen ion, by discontinuing to regard soil fertility mainly as single nutrient concepts, and by discontinuing to fight hydrogen presence in the soil by excessive carbonate applications. Only through the fuller understanding of the numerous interrelations between both the complex soil behaviors and the plant behaviors can crop production of the highest order in economic and nutritional aspects be attained."

The main virus diseases of the potato in Victoria, J. G. BALD and A. T. PUGSLEY (*Austral. Council Sci. and Indus. Res. Pam.* 110 (1941), pp. 40, pls. 4).—The authors summarize experiments and observations over a 5-yr. period on the virus diseases of Victorian potato varieties, including some properties and reactions of a number of the viruses and the distribution and incidence of these diseases in Victoria. There are 23 references.

The effect of potato virus X on growth and yield, J. G. BALD (*Austral. Jour. Sci.*, 4 (1942), No. 6, pp. 177-178).—If tobacco mosaic and similar viruses partly replace normal reserves of chromoprotein, the comparatively small effect they often have on host plant growth would become understandable. In infection tests with virus X in potato and *Datura stramonium* the results briefly described are said to be such as would naturally follow if virus multiplication were a partial substitute for the synthesis of chromoprotein or chlorophyll protein and if these proteins were stored up beyond the minimum requirements for photosynthesis as inert reserve material.

Preserving plant viruses in vitro by means of a simplified lyophile apparatus, T. P. DYKSTRA and H. G. DU BUY. (U. S. D. A. and Univ. Md.). (*Science*, 96 (1942), No. 2486, pp. 189-190, fig. 1).—The Y-virus and Canada streak virus of potato, extracted in CO<sub>2</sub> with the procedure and apparatus described, continued to produce 100 percent infection as long as 4 mo. after extraction and dehydration.

Transmission of potato virus Y by *Aphis rhamni* (Boyer), B. KASSANIS (*Ann. Appl. Biol.*, 29 (1942), No. 1, p. 95).

Investigations on potato root eelworm, *Heterodera rostochiensis* Wollenweber on the cyst population of a field over a series of years, H. W. and M. MILES (*Ann. Appl. Biol.*, 29 (1942), No. 2, pp. 109-114).—In the absence of the host there was a gradual decrease in the viability of the cysts, but the 7-yr. period between the potato crops of 1928 and 1936 proved insufficient to kill all cysts. Two crops of potatoes with a 3-yr. interval were enough to restore the cyst population to the previous level. The 7-yr. interval between crops was associated with the disappearance of all signs of "potato sickness" in the two subsequent crops.

Sorghum diseases and their control, J. O. MILLER (*Kans. State Col. Bot. M. Ctr.* 41 (1942), pp. 8, figs. 8).

Disease testing and initial seedling selection work at the Houma Station during 1940 and 1941, E. V. ABBOTT and E. M. SUMMERS. (U. S. D. A.). (*Sugar Bul.*, 20 (1942), No. 18, pp. 137-141).—This is a continuation of previous progress reports (E. S. R., 83, p. 505) on disease-testing and initial sugarcane

seedling selection work by pathologists at the U. S. Sugar Plant Field Station, Houma, La., including disease reactions of unreleased varieties at the test fields, recent test field introductions, total seedlings tested and new C. P. numbers assigned, seedling progeny tests, and Turkestan hybrid seedlings. With regard to the last, as the hybrids approach commercial type in the nobilization process the proportion of mosaic-resistant individuals is being materially increased.

**The hot water treatment of cane seed,** W. J. LUKE and C. W. EDGERTON (*Sugar Bul.*, 20 (1942), No. 18, p. 148).—Preliminary tests indicate the probability that sugarcane yields with certain varieties can be increased by treating the seed cane with hot water. On the basis of large-scale field tests and a number of small tests it was recommended that where equipment was available seed cane of the varieties C. P. 29-320 and C. P. 28-19 be treated for the September and October plantings, but insufficient information was available for definite recommendations as to other varieties.

**Alternaria on leaves of sunflower in India,** A. B. BOSE (*Jour. Indian Bot. Soc.*, 21 (1942), No. 3-4, pp. 179-184, figs. 2).—*A. tenuis*, causing a leaf spot of sunflower, is reported for the first time from India.

**Association of tobacco leafspot bacteria with roots of crop plants,** W. D. VALLEAU, E. M. JOHNSON, and S. DIAOHUN. (Ky. Expt. Sta.). (*Science*, 96 (1942), No. 2485, p. 164).—From experiments briefly reported, it appears that the causal bacteria of tobacco wildfire and angular leaf spot can maintain themselves on the roots of several unrelated crop plants for at least 6 mo. and can under certain natural conditions cause specific leaf spot diseases of several unrelated plants such as tobacco, tomato, morning-glory, and cowpea. These bacteria are believed to be common (but specific) organisms present on the roots, perhaps of native vegetation, which can and do, under special favorable circumstances, cause specific leaf spots of tobacco.

**Phytopathological classics, No. 7** (*Phytopathol. Classics No. 7* (1942), pp. 62, pls. 7).—This issue includes the following articles, with translations from the original German and preface and biographical sketches by J. Johnson: Concerning the Mosaic Disease of Tobacco, by A. Mayer; Concerning the Mosaic Disease of the Tobacco Plant, by D. Ivanowski; Concerning a Contagium Vivum Fluidum as Cause of the Spot Disease of Tobacco Leaves, by M. W. Beijerinck; and On the Etiology of Infectious Variegation, by E. Baur.

**Effect of infecting carrot plants with certain viruses on seedstalk development,** E. SAYED SAKR and H. C. THOMPSON. (Cornell Univ.). (*Plant Physiol.*, 17 (1942), No. 3, pp. 500-502, fig. 1).—Among carrot plants inoculated with six different viruses (10 plants each), signs of infection occurred only with cucumber mosaic and aster yellows viruses, potato latent virus and alfalfa, tobacco, and aucuba mosaic viruses failing to induce symptoms. Seedstalk development was induced in all plants inoculated with the aster yellows virus, in some cases followed by flower production but in none by setting of seed. There was no seedstalk development in any of the other plants.

**An analysis of market inspection reports on spoilage of cantaloups and related melons,** J. S. WIAINT (*U. S. Dept. Agr., Bur. Plant Indus., Plant Disease Rptr.*, 1942, Sup. 138, pp. 145-161).—An analysis of the information on mold and decay reported in 9,890 carlots of melons inspected at New York City during 1933, 1934, 1935, and 1941 included 3,294 carlots of cantaloups, 4,181 of Honey Dew melons, and 2,415 of Honey Ball and mixed melons combined. All originated in Arizona, California, or Colorado and together constituted about one-half of the melons unloaded at New York from those States during the 4 yr. A summary of the different decays and molds is tabulated by years for each type of melon. Specific decays cited on the inspection reports were, in order of their relative

importance, those due to *Rhizopus*, *Alternaria*, *Fusarium*, *Cladosporium*, and *Phytophthora*. Decays or molds, or both, were found in 4,400 carlots, an average of 4.7 percent of the melons in these cars being affected with decay and 4.8 percent with mold. Expressed in terms of all 9,880 carlots, 2.1 percent of all melons inspected were affected with decay and 2.1 percent with mold, or 4.2 percent total spoilage.

The results of 3,380 inspections of cantaloups and 574 of Honey Dew melons made at a large number of markets (1922-28) are also summarized. The melons originated in a number of States and represented only a very small part of those shipped therefrom to the inspection markets during the period. Decay was reported in 879 carlots or 22.2 percent of the total inspected. An average of 10.7 percent of the melons were affected per carlot. Expressed in terms of all 3,380 carlots, an average of 2.4 percent of the melons inspected were reported decayed.

**Growth stimulation of peas by tetrachloro-para-benzoquinone, a fungicidal seed protectant,** G. L. McNEW. (N. Y. State Expt. Sta.). (*Science*, 96 (1942), No. 2483, pp. 118-119).—Data obtained under controlled conditions (with diseases absent) indicated that tetrachloro-*p*-benzoquinone (under trade name Spergon) serves in the dual capacity of seed protectant and growth stimulant when applied to pea seed. As a growth stimulant for peas, the material should therefore pay dividends irrespective of disease conditions. There is also good circumstantial evidence that lima beans and sweetpotatoes may be similarly stimulated. These observations are deemed of considerable fundamental significance, since they reveal a promising new field of study into fungicides.

**Influence of controlled environment and nutrition on the resistance of garden pea to *Fusarium* wilt,** W. T. SCHROEDER and J. C. WALKER. (Wis. Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 5, pp. 221-248, pls. 4, figs. 10).—Under controlled nutrition and temperature in sand artificially infested with microconidia and hyphal fragments of *F. oxysporum pisi* race 1, the optimum temperature for disease development in peas was 27°-30° C. instead of 21° as previously reported for infested soil, but air temperature had relatively little influence. When grown in the same nutrient solution (with carbohydrate added) used in the sand culture of the host, the fungus grew best at 28°. Within the range studied, severity of disease development in susceptible plants appeared directly proportional to temperature. The greatest progress of the fungus up the stem occurred in plants growing at the 24° and 21° sand temperatures. Besides the other symptoms in susceptible plants, the lower internodes were significantly greater in diameter than in uninfected control plants. Disease development in homozygous resistant plants varied from off color and very slight incurving of the lower stipules and leaflets at the low temperatures and low nutrient concentration to severe wilting at the very highest concentration and optimum temperature. At high temperatures and low nutrient concentration diseased resistant plants were similar to diseased susceptible plants at the low temperature.

The disease development in either resistant or susceptible plants at various concentrations of nutrient solution depended on the sand temperatures. Using four nutrient solutions differing only in total salt concentration, the time required for complete wilting in susceptible plants at 21° varied directly with the concentration, but in resistant plants it was most severe in the weakest solution and none occurred at the higher concentrations. At 27° disease development was most severe at the highest concentration and least so at the lowest, and no differences in symptoms were observed between susceptible and resistant plants. At the lowest concentration, resistant plants developed a very severe slow wilting, whereas susceptible plants approached the rapid wilting occurrent at the highest

concentration. No differences in fungus growth rates in culture were observed that could account for the differences noted in disease development above described. Extensive cortical and stelar penetration of the roots and stelar penetration above the first and second internodes were found, and more pronounced reactions to the fungus were noted in resistant plants at the high temperatures than in susceptible plants at either high or low temperatures. Cross inoculations of susceptible and resistant varieties of tomato, pea, and cabbage with their respective *Fusarium* wilt fungi under conditions of high temperatures and low nutrient sand culture indicated that the break-down in pea-wilt resistance could be accomplished only with the pea-wilt organism. There are 24 references.

**The release of auxin from isolated leaf proteins of spinach by enzymes,** S. G. WILDMAN and S. A. GORDON (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 6, pp. 217-228, fig. 1).—Auxin was shown to be associated with proteins isolated from spinach leaves, capable of release by enzymatic hydrolysis and obtainable from both cytoplasmic and chloroplastic proteins. The cytoplasmic proteins were separated into two fractions by isoelectric precipitation, more auxin being obtained from one than from the other. Diffusion tests indicated the similarity between the leaf auxin and that released from proteins by enzymatic hydrolysis, and both appeared to be of lower molecular weight than indoleacetic acid. Evidence is presented that the auxin released from leaf proteins of spinach is not a result of bacterial contamination. There are 16 references.

**Breeding for tomato variety resistant to bacterial cancer *Aplanobacter michiganense*** E. F. SMITH, K. N. YATZYNNINA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 32 (1941), No. 5, pp. 372-373).—Promising progress is shown by the first 2 yr. of a breeding program for resistance to bacterial canker (*Phytophthora michiganensis*) in hybrids of tomato with *Lycopersicon pimpinellifolium*. Among five species of the genus tested for resistance, only *L. pimpinellifolium*, used in these crosses, proved resistant.

**Macro-element nutrition of the tomato plant as correlated with fruitfulness and occurrence of blossom-end rot,** C. B. LYON, K. C. BEESON, and M. BARRENTINE. (U. S. D. A.). (*Bot. Gaz.*, 103 (1942), No. 4, pp. 651-667, figs. 11).—In sand cultures of 1,044 tomato plants using 87 different nutrient solutions, variations in amounts of Ca and nitrate in the medium resulted in general in greater differences in fruitfulness over wider ranges in concentration than did the other elements tested. Greatest fruitfulness occurred in treatments relatively high in nitrate and low in sulfate and phosphate in the anion triangle and in those relatively high in Ca and low in Mg and K in the cation triangle. The percentage of diseased fruits on each plant increased with decreasing Ca concentrations, this correlation being largely independent of that of Mg and K. No correlation with any anion was observed. Fruits produced under treatments where the rot was most severe were low in Ca and high in K and Mg. The occurrence of blossom-end rot was thus definitely associated with Ca nutrition. There are 25 references.

**Tree troubles during a wet summer,** P. P. PIRONE (*New Jersey Stas. Nursery Disease Notes*, 15 (1942), No. 2, pp. 5-8).—As a result of the abnormally wet summer of 1942, several diseases occurring ordinarily as sporadic invaders have become common in New Jersey and may be expected to become more widespread during the fall and in 1943. Among them are basal rot (*Phytophthora cambivora*), shoestring root rot (*Armillaria mellea*), and various leaf diseases. Certain observations are also presented on the production of aerial roots on large trees, attributed to the frequent rains.

**The effects of leafhopper feeding injury on apparent photosynthesis and transpiration of apple leaves,** G. E. MARSHALL, N. F. CHILDERS, and H. W.

**BRODY.** (Ind. and Ohio Expt. Stas.). (*Jour. Agr. Res.*, 65 (1942), No. 6, pp. 265-281, figs. 5).—Injury to Stayman Winesap apple leaves by several species of apple leafhoppers (*Typhlocyba* spp.), grape leafhoppers (*Erythroneura* spp.), and the potato leafhopper (*Empoasca fabae*) was accompanied by a more or less marked reduction in apparent photosynthesis and transpiration, the former usually being affected sooner and to a greater extent. A given number of potato leafhoppers proved more detrimental to leaf metabolism than an equal number of apple or grape leafhoppers. Cross sections of injured leaves showed that the mesophyll-feeding types of leafhopper (*Typhlocyba* spp. and *Erythroneura* spp.) removed the contents of the cells in the palisade layers, whereas the spongy mesophyll cells were not significantly affected unless the leaf had been severely injured. The results indicate that apparent photosynthesis and transpiration of apple leaves may be reduced early in the growing season when the leafhopper population is moderately low, and when this occurs the capacity of the injured leaves to function normally is permanently impaired. Early control of these insects is therefore important.

**Factors affecting distribution and severity of black root rot of apple trees, J. S. COOLEY.** (U. S. D. A.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 6, pp. 299-311).—Black root rot of apple is distributed from Pennsylvania to Georgia and westward to Arkansas, but is unknown outside the United States. Its distribution may depend partly on the soil being warm enough for the pathogen (*Xylaria mali*) to thrive, and local distribution is apparently affected by certain conditions adverse to the host. Experimental infection was successful when the inoculum was infected apple twigs, but when a mass of mycelium from an agar culture was used it was not. Wounding was not necessary for infection. In agar cultures one isolate made fair growth at 15° C., but its optimum was about 25°. Roots of stored apple seedlings were infected at 15.5°. Inoculations with 27 isolates indicated a wide variation in pathogenicity. As shown by inoculations of apple, pear, plum, cherry, and peach seedlings, only the apple showed undoubted susceptibility. In tests during 3 or 4 successive years on 19 own-rooted standard apple varieties, 30 seedling clones, and seedlings of 9 named varieties of apples, analysis of variance showed only slight significance for variety in own-rooted varieties, and in the own-rooted seedling clones and variety seedlings there was no significance for variety. Statistical analysis of the infection data (1936-38) showed a significant correlation between infection and high seasonal temperature. The longevity of the fungus in infected apple roots varied. In several experiments the living fungus could not be found a few months after the death of the host, but in some natural infections it survived the host by several years.

**Apple scab and bitter rot in Missouri, M. A. SMITH.** (U. S. D. A.). (*Missouri State Hort. Soc. Proc.*, 1939-40, pp. 91-97).—A general discussion of these two diseases, with particular reference to their occurrence and control in Missouri.

**Apple scab and its control at Glasnevin in 1939, 1940 and 1941, R. McKAY** ([*Irish Free State*] *Dept. Agr. Jour.*, 39 (1942), No. 1, pp. 46-79, pls. 6, fig. 1).—The detailed results of spraying experiments and seasonal observations on apple scab for the 3 yr. are reported.

**Bacterial diseases of stone-fruit trees in Britain.—VIII, Bacterial canker of peach, H. WORMALD** (*Brit. Mycol. Soc. Trans.*, 25 (1942), pt. 3, pp. 246-249, pl. 1).—The organism isolated from the bacterial canker of a peach tree described, when inoculated into peach, plum, and cherry branches, produced typical cankers. It is referred to *Pseudomonas* (= *Phytomonas*) *mors-prunorum*.

**A progress report on the yellow-leaf disease of sour cherry**, E. J. RASMUSSEN and D. CATON (*Mich. State Hort. Soc. Ann. Rpt.*, 71 (1941), pp. 100-105).—This slow-acting virus disease, present in Michigan for a least 20 yr., is of economic importance because it causes premature defoliation, progressive reduction in spur growth, reduced yields, and shortening of the profitable life of the orchard. Sprays, fertilizers, or culture practices have no apparent effect on the disease. It is transmitted by budding, but the method of orchard transfer has not been proved, though some evidence points to leafhoppers as vectors. Montmorency selections appear to vary in susceptibility. Propagation of nursery trees from disease-free high-producing strains or selections promises to become an important control measure.

**Peach X-disease or yellow-red virosis**, C. F. TAYLOR. (W. Va. Expt. Sta.). (*Mountaineer Grower*, 13 (1942), No. 138, pp. 15-16).—A brief summary of the present status of this disease, thus far not reported from West Virginia.

**Control of X disease of peaches by killing chokecherry weed with ammonium sulfamate**, E. M. HILDEBRAND and D. H. PALMITER. (Cornell Univ. and N. Y. State Expt. Sta.) (*Agr. News Letter*, 10 (1942), No. 3, pp. 73-75, fig. 1).—It is claimed that if peach trees are purchased from reliable nurseries, if young plantings are isolated for a minimum of 500 ft. from chokecherries, and if all chokecherries within 500 ft. of bearing orchards are destroyed, X disease as it is known in the eastern United States will cease to be a menace to peach culture.

**Kill chokecherries to save peaches from X disease**, D. H. PALMITER and E. M. HILDEBRAND (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, pp. 2, 11, fig. 1).—Herbicidal sprays are seen as the best means of destroying the wild hosts of this virus disease.

**Currant leaf spot held in check with bordeaux spray**, R. F. SUIT (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, p. 5, fig. 1).—Two applications of 3-3-100 bordeaux applied when the fruit is about half grown and again after harvest were found to check defoliation and insure adequate protection against yield losses.

**Studies in bacteriosis.**—XXV, Studies on a bacterium associated with leafy-galls, fasciations and "cauliflower" disease of various plants—pt. 4, The inoculation of strawberry plants with *Bacterium fasciens* (Tilford), M. S. LACEY (*Ann. Appl. Biol.*, 29 (1942), No. 1, pp. 11-15, pl. 1).—Attempts to produce this disease by inoculating *B. (=Phytophthora) fasciens* into plants grown from runners gave inconclusive results, only 25 percent developing some signs of infection and the majority of these recovering. However, inoculations in seedling strawberry plants gave definite positive results, abnormal growth being produced in 76 percent of them. This organism caused gall production on young plants in the absence of wounds.

**Banana leaf spot: When to spray and why**, R. LEACH (*Kingston, Jamaica: Dept. Agr.*, 1942, pp. [1]+6, pls. 2).—This is an informative leaflet.

**Manganese and zinc deficiencies in coastal citrus trees**, R. J. BENTON (*Agr. Gaz. N. S. Wales*, 53 (1942), No. 2, pp. 90, 94, fig. 1).—A note on these deficiencies observed in central coastal areas of New South Wales which responded to combination sprays containing both Zn and Mn.

**"Dry root rot" disease of citrus trees**, F. C. LOEST (*Farming in So. Africa*, 17 (1942), No. 196, pp. 420-424, figs. 5).—A root disease found responsible for the retrogression and death of many citrus trees throughout the Union of South Africa was shown to result from infection by *Diplodia natalensis*. Contributing factors and prevention and control methods are briefly discussed.

**Brown spot of passion fruit** (*Agr. Gaz. N. S. Wales*, 53 (1942), No. 2, pp. 93-

94, figs. 2).—A note on *Alternaria passiflorae* infection of leaves and fruits, and on control.

Enfermedad de la "tinta" del castaño [The ink disease of chestnut], P. U[QUIJO LANDALUZE] (*Estac. Fitopatol. Agr. La Coruña Pub. 14* (1941), pp. 31–38, figs. 15).—This paper reports a study of the disease due to *Phytophthora cambivora* in the Spanish Province of La Coruña, including isolation of the pathogen, inoculations into the host tree, and studies of the life history and morphology of the fungus in culture.

The effect of a mold, *Trichoderma lignorum*, on loblolly pine sapwood, M. S. CHIDESTER. (U. S. D. A.). (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 134–138, figs. 2).—The experimental results reported indicate that wood-inhabiting strains of *T. lignorum* cause a slight reduction in some of the strength properties of pine sapwood.

Carotenoids of telial galls of *Gymnosporangium juniperi-virginianae* Lk., B. L. SMITS and W. J. PETERSON. (Kans. State Col.). (*Science*, 96 (1942), No. 2487, pp. 210–211).

Recent developments in white-pine blister rust control in the Northwest, E. L. JOY (*Northwest Sci.*, 16 (1942), No. 3, pp. 55–58).—A review.

Some resupinate polypores from the region of the Great Lakes, XIII, D. V. BAXTER (*Mich. Acad. Sci., Arts, and Letters, Papers*, 27 (1941), pp. 139–162, pls. 11, figs. 4).—The recent emphasis on aviation has focused attention on types of wood suitable for training planes and plane parts, and among the softwoods Sitka spruce (*Picea sitchensis*) is of prime importance and white spruce (*P. glauca*) less so. Except for certain conspicuous species, however, the common fungi on these spruces have not been critically investigated. The present contribution (E. S. R., 85, p. 358) deals primarily with *Trametes serialis* and *T. alaskana* n. sp., together with allied species of each fungus, and considers their hosts, geographic distribution, cultures, and the decays induced. It is deemed clear from the records given that comparative studies of the species of *Trametes* in culture and of those closely related are necessary, and the variation found among isolates from different regions makes such studies all the more imperative.

Decay in red-stained jack pine ties under service conditions, C. W. FRITZ and E. A. ATWELL (*Canada Dept. Mines and Resources, Lands, Parks, and Forests Branch, Forest Serv., Forest Prod. Labs. Cir. 58* (1941), pp. [2]+19, pls. 7).—Red-staining fungi were not found responsible for decay of either creosoted or untreated ties under track conditions, in treated ties remaining viable but dormant and in untreated ties being gradually killed by secondary fungi. After 10 years' service, untreated ties were in an advanced stage of decay by secondary fungi, the prevalent rot being of the brown cubical type and due to several distinct fungi, with *Lenzites saeplaria* the dominant species. Creosote did not sterilize the ties, but it reduced the viability of the red-staining fungi and proved a great protection to the ties. With the passage of years, however, checks opened up the creosoted shell and permitted the entrance of secondary fungi. A detailed account of the study is given.

Treating fence posts with chromated zinc chloride, W. C. NETTLES. (Clemson Agr. Col.). (*Agr. News Letter*, 10 (1942), No. 3, pp. 65–66, pl. 1).—A note on preservation of fence posts against termites, fungi, and various decays, with directions for treatment.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

[Contributions in economic zoology and entomology] (*Jour. Council Sci. and Indus. Res. [Austral.]*, 15 (1942), No. 1, pp. 3–9, 37–54, 56–80, figs. 3).—

Contributions presented include the following: Further Observations on the Relation of Tail Length to the Incidence of Blowfly Strike of the Breech of Merino Sheep, by J. H. RICHES (pp. 3-9); Attempted Transmission of *Anaplasma marginale* Theller by Biting-Flies, by I. M. and M. J. MACKERRAS and C. R. MULHEARN (pp. 37-54); The Preparation and Examination of Faecal Cultures for the Differentiation of Larvae of Sheep Nematodes, by H. V. WHITLOCK (pp. 56-58); The Use of Mineral Oils and Tar Oils for Wheat Weevil [Rice Weevil and Red Flour Beetle] Control, by J. S. FITZGERALD, F. N. RATCLIFFE, and F. J. GAY (pp. 59-71); Investigations on the Locust (Grasshopper) Problem, by K. H. L. KEY (pp. 72-77); and Oriental Peach Moth Investigations—General Statement, July 1941 (pp. 77-80).

**History, policy, and program of the Huntington Wildlife Forest Station,** R. T. KING, W. A. DENCE, and W. L. WEBB (*Roosevelt Wildlife Bul.* [Syracuse Univ.], 7 (1941), No. 4, pp. [1]+388-505, pls. 2, figs. 25).

**Flight and running speeds of birds,** C. COTTAM, C. S. WILLIAMS, and C. A. SOOTER (*Wilson Bul.*, 54 (1942), No. 2, pp. 121-131).—The results of timings made during the course of field work in various parts of the West of a number of birds whose flight or running speeds had never been recorded and additions to the limited data on record for others are brought together and summarized in tables. The authors' records were made by automobile, from which two or more observers usually checked the speeds.

**Parasites of the American coot (*Fulica americana*) in central Iowa,** R. L. ROUDABUSH. (Iowa Expt. Sta. et al.). (*Iowa State Col. Jour. Sci.*, 16 (1942), No. 4, pp. 437-441).—An annotated list of the ecto- and endo-parasites of the American coot in central Iowa, together with information on the number and percentage of hosts infested and references to the literature.

**Ecology and management of the mourning dove (*Zenaidura macroura* (Linn.)) in southwest Iowa,** H. E. MCCLURE (*Iowa State Col. Jour. Sci.*, 16 (1941), No. 1, pp. 93-95).

**Insect food of the rock wren,** G. F. KNOWLTON and F. C. HARMSTON. (Utah Expt. Sta.). (*Great Basin Nat.*, 3 (1942), No. 1, p. 22).—An examination of the stomach contents of the rock wren (*Salpinctes obsoletus obsoletus*), a species that is common in the semidesert areas frequented by a number of important insect pests in Utah, has given proof that it feeds upon the beet leafhopper, false chinch bug, Say stinkbug, army cutworm, grasshoppers, and many other pests.

**Feeding habits of *Bufo marinus*,** J. F. ILLINGSWORTH (*Hawaii. Ent. Soc. Proc.*, 11 (1941), No. 1, p. 51).—Examination of 53 stools of the giant toad (*B. marinus*) in Kaimuki during 5 weeks following March 1, 1940, revealed the Surinam roach to have been the principal food, it varying from 40 to as high as 90 percent of the entire contents. During the period the Chinese rose beetle *Adoretus sinicus* Burm. was on the wing some stools ran as high as 40 to 50 percent of their remains. The Pheidole ant (*Pheidole megacephala*) at times comprised from 10 to 20 percent of the castings. Other insects found were grain beetles (Tenebrionidae), black grass bugs (*Geotomus pygmaeus*), black wasp (*Odynerus* ?), Fuller rose beetle, one honeybee, and one sweetpotato hornworm. The author concludes that the toads are destined to be an important check upon the Surinam roach, which has an important bearing in the Tropics, as it is the intermediate host of the eye worm of chickens.

**Field book of snakes of the United States and Canada,** K. P. SCHMIDT and D. D. DAVIS (*New York: G. P. Putnam's Sons*, [1941], pp. XIII+365, pls. [35], figs. 103).—Following a brief preface and the introduction (pp. 3-77), is the main part of this work which consists of a systematic account of the snakes

of the United States and Canada, including a key to the genera. The work includes 4 colored plates and 103 drawings by A. A. Enzenbacher and 82 photographs from life. Ten pages are devoted to references to the literature.

**Venomous snakes:** Some Central American records; incidence of snake-bite accidents, H. C. CLARK (*Amer. Jour. Trop. Med.*, 22 (1942), No. 1, pp. 37-49).—In reporting upon investigations conducted it is pointed out that domestic animals at large on the range are exposed by day and night to snake bite. Mention is made of a report that over a period of 3 yr. snake bite in Texas was responsible for an annual loss of cattle valued at more than 1 million dollars.

**General entomology,** S. W. FROST (*New York and London: McGraw-Hill Book Co.*, 1942, pp. X+524, [pl. 1], figs. 406).—This work, intended as an advanced text, is presented in 23 chapters, each accompanied by a copious bibliography. Field keys to the immature forms of the orders of insects exclusive of eggs and pupae and to the common groups of lepidopterous and coleopterous larvae, material on classifications of insects, and a list of general entomological texts and other important references are given in an appendix.

**Zoology and entomology:** Control of insect pests (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, pp. 6, 7).—A practical account by C. Dorman of work with storage insects, boll weevil, and cucumber and melon pests.

[Entomological investigations by the New York State Station] (*New York State Sta. Rpt.* 1942, pp. 35-51, 58).—Progress is noted (E. S. R., 86, p. 506) on insecticides, fruit and vegetable insect investigations, insects attacking nursery stock and ornamental plantings, biological control of injurious insects, and the potato leafhopper and the hopvine borer as hop pests.

**Entomology,** C. E. PEMBERTON (*Hawaii. Sugar Planters' Assoc. Ptd. Rpts.*, 61 (1941), *Expt. Sta. Com. Rpt.*, pp. 21-27).—The findings, especially in the field of insect control for the year ended September 30, 1941, are noted.

**Insects of Guam, I** (*Bernice P. Bishop Mus. Bul.* 172 (1942), pp. V+218, pls. 10, figs. 10).—This contribution presents the results of studies of insects collected during a survey conducted in that island in 1936 by O. H. Swezey and several associates under the auspices of the Hawaiian Sugar Planters' Association. The insect pests which were found on various crops were listed with respect to food plants in the contribution which has been noted (E. S. R., 84, p. 358). The findings as reported by specialists, together with descriptions of many new species, are arranged by orders and include Odonata, Thysanoptera, Homoptera, Neuroptera, Lepidoptera, Coleoptera, Strepsiptera, Hymenoptera, and Diptera. The list is said to contain about 50 species not known to occur in Hawaii.

**Several important insect pests of cotton.**—I, Relation of population to migration. II, Insecticidal studies for their control, J. C. GAINES. (*Texas Expt. Sta.*). (*Iowa State Col. Jour. Sci.*, 17 (1942), No. 1, pp. 63-65).—This is a report of work conducted over a period of years in the Brazos River bottoms near College Station, Tex., with the boll weevil, cotton flea hopper, bollworm, and flower thrips.

**The effect of insect control on the yield and quality of cotton prematurely killed by cotton root rot,** S. E. JONES. (*Tex. Expt. Sta.*). (*Iowa State Col. Jour. Sci.*, 16 (1941), No. 1, pp. 82-84).—In the experimental work reported it was found that low yields from plants prematurely killed by root rot were not materially increased by controlling the flea hopper or boll weevil under the insect conditions existing during the years 1937-39, inclusive. Those plants produced only a small amount of low quality cotton when there was no insect damage. The factor which determines the profit to be made from controlling insects on land where cotton dies from root rot is the yield from living plants,

regardless of the percentage dying early in the season. If the yield from living plants is sufficient for profitable cotton production and insects are damaging the crop, control measures should be used.

**Report of fruit insect work in 1939**, L. JENKINS, H. E. BROWN, C. W. WINGO, W. W. SMITH, and L. HASEMAN. (Univ. Mo.). (*Missouri State Hort. Soc. Proc.*, 1939-40, pp. 97-99).—The work of the year with the codling moth, oriental fruit moth, and fruit tree leaf roller is reported.

**On the estimation of forest insect damage, with particular reference to *Dendroctonus piceaperda* Hopk.**, R. E. BALCH (*Jour. Forestry*, 40 (1942), No. 8, pp. 621-629).

**Two important pests of hickory reproduction in the Southeast**, J. A. BEAL and C. L. MASSEY (*Jour. Forestry*, 40 (1942), No. 4, pp. 316-318).—The numerous dead and dying terminal shoots of young hickory trees which came to attention in the Duke Forest in 1939 were found to be largely the result of attack by the twig girdler and the hickory spiral borer *Agrilus arcuatus torquatus* Lec. A small number of specimens of the twig pruner was also found causing damage to hickories. The character and amount of damage to young hickory stands by both species and the results of a study of egg and larval mortality of the twig girdler are reported. Parasites, predators, and associated insects are listed for both species.

**Attractants and repellents for insects**, [I], II, E. G. THOMSEN and M. H. DONER (*Soap and Sanit. Chem.*, 18 (1942), Nos. 4, pp. 97-99, 105; 5, pp. 95-96, 105).

**What kinds of light attract night-flying insects most? least?** L. C. PORTER (*Gen. Elect. Rev.*, 44 (1941), No. 6, pp. 310-313, figs. 3).—The results of an investigation of the relative attraction of night-flying insects, including such as enter unscreened porches and/or annoy man, to both equal-wattage lamps (100 w.) and equal brightness lamps (standard, readily available), of various colors (including white, yellow, natural amber, flame-tint, amber-orange, and red), are reported, the number and weight of insects collected at lights of such colors being detailed in tables by families. The insects were attracted more or less by all colors. Photographs are given of piles of insects collected which, as pointed out, do not represent the true value of the lamp attraction since they show the size of insects rather than the numbers. It is indicated that for equal amounts of light, ordinary red light attracts the smallest number of insects, especially of the small gnats that pass through window screens, but red may not attract the lowest weight of insects. It is noted that red light is not a satisfactory color to live or work under, and that for practical purposes yellow is preferable from the standpoint of the size of insects attracted. Use of lower-wattage lamps is considered to be the most effective way to reduce the number of insects attracted. The work was conducted cooperatively by the General Electric Company at Cleveland and the Ohio Experiment Station at Wooster.

**Response of insects to color, intensity, and distribution of light**. H. L. GUI, L. C. PORTER, and G. F. PRIDEAUX. (Ohio Expt. Sta. et al.). (*Agr. Engin.*, 23 (1942), No. 2, pp. 51-58, figs. 22).—This is a detailed report of the work noted above. The details are given in tables and graphs, together with reproductions of photographs. Lights of all colors tested were found to attract insects to a greater or lesser degree, and none was found to repel insects. The colors on which comparable data are available arrange themselves in order of least to most attractiveness to insects as red, yellow, white, and blue. Bare lamps attract many more insects than do lamps contained within deep-bowl type reflectors or reflector and projector type bulbs. By the utilization of lights of the proper kind and the correct distribution of light, few insects were attracted to the

test area and some may have been drawn away from it. Yellow light, when compared with white light of the same candlepower and brightness, proved to be approximately 66 percent less attractive to insects. It was shown that even though a 15-w. white lamp was used v. a 75-w. yellow, the white lamp still caught more insects. The color produced by the gold fluorescent light was much less attractive to insects than blue fluorescent light.

**Studies of contact insecticides.—XVI, Penetration of oils into insect eggs:**

(a) Influence of oil characteristics. (b) Influence of age of egg and of species. R. L. BLICKLE (*New Hampshire Sta. Tech. Bul. 79 (1942), pp. 14, figs. 3*).—In continuation of these studies (E. S. R., 86, p. 508), insect eggs were placed in oil saturated with a dye, removed from the oil after definite time intervals, and sectioned. Of the insect eggs tested, penetration of oil was most rapid with eggs of the American cockroach, less rapid with eggs of the Colorado potato beetle, and still less rapid with eggs of the Mexican bean beetle. Low-viscosity petroleum oils penetrated more rapidly than those with high viscosity, while glycerides having the same viscosity as some petroleum oils exhibited somewhat slower penetration. Those petroleum oils of low unsulfonatable residue were observed to penetrate more rapidly than corresponding oils of higher unsulfonatable residue. Apparently refined glycerides penetrated more rapidly than crude. Penetration time decreased with increased temperature above 25° C., but below 25° increase in penetration time was not marked and occurred only with oils of higher viscosity. When immersed in oils for long periods the eggs collapsed, while those placed in distilled water for the same period gained weight.

Some new facts about oil sprays and other dormant treatments containing oil, P. J. CHAPMAN. (N. Y. State Expt. Sta.). (*Mich. State Hort. Soc. Ann. Rpt., 70 (1940), pp. 14–20*).

**All-purpose insect spray, E. M. SEARLS.** (Univ. Wis.). (*Soap and Sanit. Chem., 18 (1942), No. 5, pp. 97, 99, 101, figs. 3*).—It is pointed out that an odorless type AA grade spray made with a highly refined oil base within the distillation range of kerosene may be considered an all-purpose fly spray under average conditions. Such a spray may be used under all conditions where an oil base spray may be used at all. It is sufficiently potent to kill hiding insects as well as flies.

Some internal effects of dinitrophenols on insects, G. B. VIADO (*Iowa State Col. Jour. Sci., 16 (1941), No. 1, pp. 146–147*).

**Application of the aerosol to fumigation.—I, Stabilization of a naphthalene aerosol, W. N. SULLIVAN, L. D. GOODHUE, and J. H. FALES.** (U. S. D. A.). (*Pests, 10 (1942), No. 6, pp. 18–20*).—Report is made of toxicity tests against the housefly in the Peet-Grady chamber, in which naphthalene was vaporized both alone and in the presence of smoke from a burning mixture containing cornstarch and sodium nitrate. The effective period of dispersed naphthalene was greatly lengthened by vaporization in the presence of the smoke. This increased effectiveness seems to be due to adsorption of the insecticide on the inert particles. The presence of the inert particles changes the character of the deposit and the rate of crystallization, as well as the size of the crystal. Instead of being collected mostly on the floor, the naphthalene was deposited more uniformly on all surfaces regardless of position. The difference in mortality between the lots of flies exposed to naphthalene with and without smoke was greater in covered than in open cages. A list of 11 references to the literature is included.

**Chronic toxicity of derris, A. M. AMBROSE, F. DEEDS, and J. B. MCNAUGHT.** (U. S. D. A. et al.). (*Indus. and Engin. Chem., 34 (1942), No. 6, pp. 684–689*,

*figs. 4*).—Existing data on the acute and chronic toxicity of derris are summarized, accompanied by a list of 11 references. The results of a study of the chronic toxicity of derris which includes a different strain of albino rats maintained on a different basic diet from that formerly used (E. S. R., 80, p. 369) are presented. The quantity of total extractives and the qualitative and quantitative composition of the extractives were found to be more important factors in the chronic toxicity of derris samples than is the rotenone content. Evidence of liver injury has been found in albino rats receiving daily in the diet a concentration of derris or cube corresponding to 75 parts per million parts of diet. It is pointed out that variations in composition of derris and cube necessitate caution in making sweeping generalizations regarding the toxic properties of derris and cube on the basis of studies on a few samples.

**Lower concentrations of rotenone**, H. F. WILSON and R. L. JAMES. (Univ. Wis.). (*Soap and Sanit. Chem.*, 18 (1942), No. 3, pp. 93-95, 117).—The data presented, details of which are given in tables, reveal that the rotenone content of agricultural dusts may be safely reduced with a view to conserving the available stock. Early tests indicate that with compatible diluents and optimum application methods significant reductions in rotenone content can be safely made with no loss in kill.

**Industrial fumigation against insects**, E. A. BACK and R. T. COTTON (*U. S. Dept. Agr. Cir.* 369, rev. (1942), pp. 64, *figs. 38*).—A revision (E. S. R., 75, p. 80).

**A dry bait for grasshopper control**, L. C. PAUL (*Canad. Ent.*, 74 (1942), No. 5, pp. 77-78).—In experimental tests with nymphal and adult grasshoppers in Saskatchewan and Manitoba during 1940 and 1941 a bait consisting of dry bran sprayed with sodium arsenite was as effective as the standard wet bran-sawdust bait. In both years the tests were made with *Melanoplus mexicanus* (Sauss.) and in 1941 with the clear-winged grasshopper also. It was found that the dry bran bait did not lump or mold over a period of several weeks. When used it was thoroughly dry and could not readily be distinguished from the original untreated bran. The bait spread well, especially with a wind, when, because of its relative lightness, it carried farther than the wet baits. It was prepared by spraying sodium arsenite (8 lb. as  $As_2O_3$  per gallon) directly upon dry bran at the equivalent of 1 qt. of concentrated poison to 100 lb. of bran. By using a spray gun that worked on an air pressure of 40 lb. it was possible to distribute the siruplike concentrated sodium arsenite in a very fine mist. The formation of droplets of fluid on the walls of the apparatus was almost entirely prevented by spraying the poison into the air stream which carried the bran just as the bran entered a large box receptacle; air circulation for better distribution of material was accomplished by placing a fan in this box.

**Pyrethrum vs. roaches**, F. L. CAMPBELL. (Ohio State Univ. et al.). (*Soap and Sanit. Chem.*, 18 (1942), Nos. 5, pp. 90-93, 103, 105, *fig. 1*; 6, pp. 119, 121, 123, 125, 127, 141).—Presented with a list of 41 references to the literature cited.

**The genus *Hesperotettix* in Utah** (Orthoptera: Locustidae; Cyrtacanthacrinae), W. W. HENDERSON. (Utah State Agr. Col.). (*Great Basin Nat.*, 3 (1942), No. 1, pp. 9-21, *figs. 3*).

**Fecundity, longevity, and parthenogenesis of the American [cock]roach** (*Periplaneta americana* L.), J. T. GRIFFITHS, JR., and O. E. TAUBER. (Iowa Expt. Sta.). (*Physiol. Zool.*, 15 (1942), No. 2, pp. 196-209).—In the investigations conducted by the authors parthenogenesis was found to occur in 9 egg capsules formed by 3 out of 25 unmated females of the American cockroach. The phenomenon occurred in 4.5 percent of the well-formed, seemingly normal

capsules produced by virgin females. Unmated females produced many malformed egg cases, which were not retained and were not tested for viability. Increased egg production is correlated with decreased longevity. Females in the first group lived an average of 181 days, those in the second group 218, and virgin females lived 295 days. The average adult life span for the selected group of cockroaches was 225 days for the females and 200 days for the males. Female adulthood varied from 90 to 708 days and that of the male from 91 to 362 days. A maximum of 18 nymphs was found to emerge from 1 egg capsule, but the average number from 121 cases was 12. The incubation period over moist sand was 53 days at room temperature, which fluctuated between 17° and 28° C., and 40 days at 29°.

**The effect of temperature upon the development of cockroaches**, G. E. GOULD. (Ind. Expt. Sta.). (*Ind. Acad. Sci. Proc.*, 50 (1940), pp. 242-248).—This contribution supplements data on the temperature-development relationship (E. S. R., 84, p. 361) and summarizes findings on six species of cockroaches occurring in homes in Indiana. The three species infesting buildings, namely, the German cockroach, American cockroach, and oriental cockroach, showed a decided similarity in the temperature requirements for development. The temperature range from 74° to 83° F. was the most favorable for incubation and nymphal development. The brown-banded roach required higher temperatures for normal development, while the Pennsylvania woods roach *Parcoblatta pennsylvanica* DeG. responded to lower temperatures. Acceleration of development of all species continued up to 84° and in some cases even higher, although higher temperatures were detrimental to capsule production and shortened the lives of adults.

**Roach testing: A progress report describing a new method of testing roach sprays**, E. R. MCGOVAN and J. H. FALES. (U. S. D. A.). (*Soap and Sanit. Chem.*, 18 (1942), No. 3, pp. 101, 103, 105, 107, 117, figs. 2).

**A new Frankliniella from Florida (Thysanoptera)**, J. R. WATSON (*Fla. Ent.*, 25 (1942), No. 2, pp. 17-18, figs. 2).—Under the name *F. bratleyi* a thrips taken on bulbs of tuberose at Gainesville is described as new.

**A discussion of researches on the sugar-cane froghopper (Homop.: Cercopidae)**, A. PICKLES (*Trop. Agr. [Trinidad]*, 19 (1942), No. 6, pp. 116-123).—Following the brief introduction, a historical summary, chronologically arranged, is presented. The data are given under the headings of cultivation and manuring, insecticidal methods, biological control, varietal resistance, difficulties met with in froghopper investigations, and suggestions for future investigations. Insecticidal control is said to provide the best means at present of controlling froghopper outbreaks, and the use of "Cyanogas," followed by pyrethrum, is suggested for this purpose. A list of 44 references to the literature is included.

**Protecting plants against the insect vector of aster yellows, G. M. LIST** (Colo. State Col.) (*Jour. Colo.-Wyo. Acad. Sci.*, 2 (1940), No. 6, p. 47).—Complete protection from aster yellows, which is transmitted only by the leafhopper *Macrostelus divinus* (Uhl.), was obtained through the use of a 3-ft. muslin fence erected about the plats, 82 percent of the check plants in the open garden having been infected in 1938 and 52.06 percent in 1939.

**Host plant records of Cercopidae in North America north of Mexico (Homoptera)**, K. C. DOERING (*Jour. Kans. Ent. Soc.*, 15 (1942), Nos. 2, pp. 65-72; 3, pp. 73-92).

**New Psyllidae from Puerto Rico, with notes on others (Homoptera)**, J. S. CALDWELL (*Jour. Agr. Univ. Puerto Rico [Univ. Sta.]*, 26 (1942), No. 2, pp. 28-33, figs. 6).—Four new species are described, with notes on two others. Figures are included to aid in identification.

The host relation of the cotton flea hopper, E. HIXSON (*Iowa State Col. Jour. Sci.*, 16 (1941), No. 1, pp. 66-68).

*Rhamnus alnifolia* L'Her., a winter host of *Aphis abbreviata* Patch, one of the aphids feeding upon potato foliage, R. P. GORHAM (*Canad. Ent.*, 74 (1942), No. 5, p. 96).—The aphid survey conducted in New Brunswick during the past 8 yr. has shown that the species *A. abbreviata* occurs quite commonly in a number of places where no species of the common European buckthorn (*R. cathartica*), long known as a winter host plant upon which its eggs are deposited in the autumn, is known to grow. Search for a native species of buckthorn (*R. alnifolia*) that is a common winter host plant in the State of Maine resulted in its discovery in wet pasture land east of Grand Falls in Victoria County, where migrants of this aphid were clustering thickly upon the leaves and stems and oviposition was beginning. A later survey revealed the presence of this host in limited abundance in several places on other farms in the districts infested with aphid eggs. *R. frangula*, a recently introduced European hedge plant in York County, New Brunswick, was also found to serve as a winter host plant for this aphid.

The apple mealybug *Phenacoccus aceris* Sig. and its control by dormant sprays, J. MARSHALL (*Sci. Agr.*, 22 (1942), No. 12, pp. 727-732).—A brief account of this mealybug, which under certain conditions causes considerable losses in fruit districts of Nova Scotia and British Columbia, particularly through its excretion serving as a medium for development of sooty fungus on the fruits, is followed by a report of control work extending over a period of 3 yr. Control has been most readily and economically accomplished by the use of a dormant or delayed dormant application after the immature females have left their wintering cocoons and moved to the twigs and fruit spurs to resume feeding. "Dormant petroleum oil (California crude) of 108 sec. Saybolt viscosity at 100° F. has been more effective than a more viscous oil of 223 sec. or less viscous oils of 44 to 32 sec. From the standpoint of economy, however, an oil of 44 viscosity (Diesel oil) seems preferable to 108 viscosity type. A 6-percent application of Diesel oil has been as effective as a 4-percent application of 108 viscosity oil and costs but two-thirds as much. A mixture of petroleum oil and lime-sulfur appears to have a considerable residual effect that is lacking in oil alone. The greater cost of such a mixture, however, appears to outweigh this advantage. Oil solutions containing 1 or 2 percent dinitrocresol or dinitrocyclohexylphenol were more effective than oil alone. Addition of oxalic acid to lower the pH value of the spray mixture apparently increased the effectiveness of such oil solutions. Water solutions of sodium dinitrocresylate and sodium dinitrocyclohexylphenate proved to be effective against the apple mealybug and less expensive than oil emulsions. The dinitrocyclohexylphenol salt is somewhat objectionable to apply."

The Canadian apple mealybug *Phenacoccus aceris* Signoret and its allies in northeastern America, G. J. RAY (*Canad. Ent.*, 74 (1942), No. 7, pp. 118-125, figs. 27).—This contribution includes an account of the economic importance and taxonomy of *P. aceris*, which first gained entrance from Europe into Maine and has spread into Nova Scotia and British Columbia to become a major pest of apple, cherry, and to some extent currant. A key to and notes on other species of the genus *Phenacoccus* of northeastern America and notes on the parasite *Allotropa utilis* Muesebl. are included.

Status of the friendly fungus parasites of armored scale-insects, E. W. BERGER (*Fla. Ent.*, 25 (1942), No. 2, pp. 26-29).

The relationship of ants and other organisms to certain scale insects on coffee in Puerto Rico, M. R. SMITH. (U. S. D. A.). (*Jour. Agr. Univ. Puerto Rico [Univ. Sta.]*, 26 (1942), No. 2, pp. 21-27).—Fourteen species of ants were

noted attending scale insects on coffee, the 3 most common being the fire ant, the little fire ant, and *Bruchymyrmex heeri obscurior* For. The hemispherical scale and the green scale were the most important scales, while *Encyrtus infelix* (Embleton) was the most common parasite. This parasite while preparing to oviposit often stroked the scale with her antennae, causing the scale to void honeydew which was lapped up by the wasp. Ingestion of honeydew by ants is described. Certain entomogenous fungi, especially *Cephalosporium lecanii*, appeared to be the principal factors regulating the abundance of coffee scales. Shade, coolness, and moisture favored these fungi, and scales were accordingly less abundant in the normal shady locations.

Seasonal history of the margarodid scale *Matsucoccus bisetosus* Morrison occurring on ponderosa and Jeffrey pines in California (Homoptera: Coccoidea: Margarodidae), H. L. MCKENZIE. (U. S. D. A.). (*Microentomology*, 7 (1942), No. 1, pp. 19-24, figs. 2).—This contribution relates to a scale insect of importance because of its apparent association with decadence in both young and mature ponderosa and Jeffrey pines. *M. bisetosus* attacks members of the so-called pitch- or hard-pine group of trees, including such species as *Pinus ponderosa*, *P. jeffreyi*, *P. sabiniana*, *P. contorta*, and *P. scopulorum*. It is commonly found feeding in twig axils and on the stems of twigs and branches, as well as on the trunks of young pines, and appears to be associated with a necrosis and resining in the twig axils. It is believed that this type of injury may be responsible for the gradual decadence and death of small twigs, and that these dying twigs may ultimately contribute to large branch killing. Excessive branch killing undoubtedly affects the vigor of the host tree. The species is rather widely distributed throughout the pine stands extending from Oregon into California, Arizona, and Colorado.

The mineola moth or destructive prune worm, W. E. SHULL and C. WAKELAND (*Idaho Sta. Bul.* 242 (1941), pp. 7, figs. 7).—The pyralid moth *Mineola scitulella* Hulst, first discovered in Idaho in 1925, is probably now generally present in all prune-growing areas of southwestern Idaho. In the spring overwintering larvae destroy many buds and blossoms of prunes by boring into the unopened buds and eating the floral parts. First-generation larvae feed almost entirely in green prunes, causing them to shrivel and drop. Second-generation larvae attack the fruit before harvest and often occur in packed prunes. First-generation moths start emergence about May 15, while those of the second generation start emergence in July. A few third-brood larvae are produced. Best direct control found is a dormant-type oil emulsion containing pyrethrins, composed of 2.75 pt. of pyrethrum extract and 4 gal. of emulsified oil in 96 gal. of water, applied 2 to 6 days after 95 percent of the overwintering larvae have emerged from their hibernacula.

Control of orange tortrix, A. M. BOYCE. (Calif. Citrus Expt. Sta.). (*Calif. Citrog.*, 27 (1942), No. 8, p. 219, figs. 3).—In supplementing the earlier account of orange tortrix control (E. S. R., 81, p. 818), reference is made to biological studies conducted by A. J. Basinger at the Citrus Experiment Station which have shown that in the intermediate and interior areas there are usually two fairly uniform generations each year. In the coastal areas there are probably three or more generations which overlap considerably, i. e., all stages of the insect may be found at any time of the year. In the warmer areas the two generations differ greatly in the length of their life cycles. The first generation of the year develops in approximately 3 mo., from about the middle of February to about the middle of May. The second generation requires approximately 9 mo. Thus it is evident that the cooler months of the year are most favorable for rapid development of the larvae.

Injury on navels as reflected by fruit drop usually occurs only in the fall and winter seasons, while on Valencias it also occurs throughout the summer. However, during the past several years the greatest amount of injury to Valencia fruits has taken place throughout the summer season. Within recent years Valencias have been commonly held on the trees throughout the summer and into the early fall seasons. Because of this fact the total loss in dropped fruits due to relatively light infestations of the orange tortrix has been greater than formerly. While only a few fruits per tree may drop each week due to tortrix injury the total amount of dropped fruits per tree throughout the entire summer season often represents a considerable loss.

Experimental evidence and commercial usage have shown that this pest can be satisfactorily controlled by cryolite applied as a dust or as a spray. When it is applied as a dust an amount of the dust mixture should be applied to furnish 0.5 lb. of actual cryolite per mature tree. Cryolite may also be satisfactorily incorporated in DN-dust for the combined control of the orange tortrix and the citrus red mite. Furthermore cryolite may be incorporated in DN-sulfur dust, thereby affording a single dust mixture for the combined control of orange tortrix, citrus thrips, and the citrus red mite. The use of cryolite as a spray solely for control of the orange tortrix is seldom practicable. Cryolite is not compatible with lime-sulfur, although it may be used with wettable sulfur.

In the control of orange tortrix on navel oranges a cryolite dust mixture applied during the latter portion of May and early June not only prevents the drop of fruit in the fall and winter seasons but also largely eliminates the scarring by the small tortrix larvae between the buttons of the young fruits.

**Achieving 3 percent worm damage, E. GOULD** (*Mountaineer Grower*, 13 (1942), No. 138, pp. 7-9, 11-13, 15).—Report is made of the clean-up program applied in a large commercial orchard in West Virginia in which, due in large part to ineffective spraying, the codling moth population had built up and its control in many other orchards throughout the area had become increasingly difficult. Other factors responsible for this build-up included weather conditions during the several years preceding that were unusually favorable to the moth, the omission of second-brood sprays due to the spray residue limitations, under-equipment, improper timing of spray applications, ineffective application, and the use of less toxic insecticides. A table given which shows the amount of spray materials used during the years 1935-41, inclusive, gives evidence of the recognized seriousness of the increasing losses being caused by the pest. By 1935 the losses became so serious that an increased control effort was necessary. The results of the steps taken to reduce the losses in this orchard are shown in the tabulated summary. The cost of spray materials per acre which increased from \$8.32 in 1935 to \$13.89 in 1938 and \$23.65 in 1939 resulted in a reduction of the infested fruit from 50 percent in 1938 to 20 percent in 1939 and 10 percent in 1940. In 1941 the cost of materials was only \$11.97 per acre and the infestation had been reduced to approximately 3 percent. Estimated on an orchard basis, there were 47,000 bu. more uninjured fruit produced in 1941 than in 1938 and at no increased cost. There was every reason to believe that this light infestation could be held at the present low level by careful effective use of lead arsenate.

**Codling moth studies, E. GOULD** (*Mountaineer Grower*, 12 (1941), No. 128, pp. 33-35, 37-38).

**Correlation of sugar yields with the percent of joints bored by *Diatraea saccharalis* (F.)—sugarcane borer studies, I, J. W. WILSON** (*Fla. Ent.*, 25 (1942), No. 2, pp. 19-24, fig. 1).

**Entomological work: Progress report, B. L. MITCHELL and E. O. PEARSON** (*Empire Cotton Growing Corp., Expt. Stas. Prog. Rpts., 1940-41, pp. 166-187, figs. 5*).—Investigational work of the year with the red bollworm *Diparopsia castanea* Hmps. is reported.

**Protecting market sweet corn from the European corn borer, W. A. BAKER, D. D. QUESTEL, and C. H. BATCHELDER** (*U. S. Dept. Agr. Leaflet 225 (1942), pp. 7, figs. 4*).—A practical account.

**Tomato fruitworm control, J. L. HOERNER.** (Colo: State Col.). (*Jour. Colo.-Wyo. Acad. Sci., 2 (1940), No. 6, pp. 44-45*).—Of the six insecticides tested against the tomato fruitworm in the Arkansas Valley, Colo., a dust composed of 50 percent cryolite and 50 percent talc gave the best control, with 1.9 percent for the first picking, 4 for the last picking, and 2.3 percent wormy for the season average for 1938. Of the seven insecticides tested in 1939, cryolite and talc again gave the best control, followed by corn meal and cryolite broadcast over the plants, which gave almost equal control. At the second picking on September 11 the untreated plats gave 1.3 percent, the last picking October 9 5.9, and the season average 3.3 percent wormy. The two liquid sprays tested gave a higher percentage of wormy tomatoes than the untreated plats.

**Mineral-oil treatment of sweet corn for earworm control, G. W. BARBER** (*U. S. Dept. Agr. Cir. 657 (1942), pp. 16, figs. 6*).—A practical account.

**Proceedings and papers of the twelfth annual conference of the California Mosquito Control Association, edited by H. F. GRAY** (*Calif. Mosquito Control Assoc., Ann. Conf., Proc. and Papers, 12 (1941), pp. [3]+143, figs. 5*).—The proceedings of this conference (*E. S. R., 85, p. 647*), held at Berkeley, Calif., December 15-16, 1941, are reported. The symposium on encephalitis included Relationship of the St. Louis and the Western Equine Viruses of Encephalitis to Man and Animals in California, by B. F. Howitt (pp. 3-22) (*E. S. R., 87, p. 566*); Newer Developments in Knowledge of Insect Hosts and Vectors of Western Equine and St. Louis Encephalitis, by W. C. Reeves (pp. 23-36); and Animal Reservoirs, General Epidemiological Summary, and Possible Control Measures for the American Summer Encephalitides, by W. M. Hammon (pp. 37-51) (all Univ. Calif.), each of which is followed by discussions. Military mosquito control in World War I is discussed by S. B. Freeborn (pp. 56-61), Federal aid in mosquito control work by R. H. Creel (p. 62), and Mosquito Breeding and Control in the Vicinity of Military Zones, by R. F. Peters (pp. 62-69); A Review of Selected Literature Pertaining to Mosquitoes in 1940-1941, by W. C. Reeves (pp. 75-98) (Univ. Calif.); Changes in Legislation Affecting Mosquito Control Operations, by H. F. Gray (pp. 100-110); and Mosquito Breeding in Certain Cemeteries in Alameda County, California, by T. F. Kelley (pp. 111-121) are presented. The symposium on operating problems (pp. 123-136) includes discussion on power spraying by R. Bendel, larvicides by E. C. Robinson, mosquito fish by A. M. Emerick, annexation by H. Lilley, controlled re-flooding by H. Pangborn, rice field control by F. M. Butler, and cash basis fund by H. F. Gray.

**Mosquito light trap catches from ten Iowa cities, 1940, J. A. ROWE.** (*Iowa Expt. Sta.*). (*Iowa State Col. Jour. Sci., 16 (1942), No. 4, pp. 487-518, figs. 9*).

**Emergence habits of the Clear Lake gnat, A. W. LINDQUIST and C. O. DEONIER.** (*U. S. D. A.*). (*Jour. Kans. Ent. Soc., 15 (1942), No. 4, pp. 109-120, figs. 2*).—This is a contribution on the emergence of this gnat from Clear Lake, Calif. An account of this pest by Herms has been noted (*E. S. R., 78, p. 80*).

**New Dolichopodidae from Utah and Colorado (Diptera), F. C. HARMSTON and G. F. KNOWLTON.** (*Utah Expt. Sta.*). (*Canad. Ent., 74 (1942), No. 5, pp. 80-85, figs. 10*).

**New North American Tachinidae belonging to the genera *Microchaetina* and *Hypenomyia*, with key to the known species (Diptera),** H. J. REINHARD. (Tex. Expt. Sta.). (*Canad. Ent.*, 74 (1942), No. 5, pp. 88-91).

**Hawaiian Sarcophagidae,** H. DE SOUZA LOPES (*Hawaii. Ent. Soc. Proc.*, 11 (1941), No. 1, pp. 53-56).—Six species representing the genera *Ravinia*, *Hystriocnema*, and *Sarcophaga* are reported from Hawaii.

**Zinc oxide:** A new larvicide for use in the medication of cattle for the control of horn flies, W. G. BRUCE. (U. S. D. A.). (*Jour. Kans. Ent. Soc.*, 15 (1942), No. 3, pp. 105-107).—Report is made of experiments conducted to determine the value of zinc oxide in preventing the development of larvae of the hornfly in cattle droppings. When various quantities of the chemical mixed with bran were fed to cattle the minimum effective dose was 1.5 gm. per 100 lb. weight of the animal. This dose rendered the droppings unfavorable for the development of hornfly larvae for 24 hr. beginning 20 hr. after administration. When zinc oxide was mixed directly with the droppings the minimum lethal dose was 0.01 gm. for each 100 gm. of droppings.

**Acidified nicotine sprays for horn flies on cattle,** W. G. BRUCE. (U. S. D. A.). (*Jour. Kans. Ent. Soc.*, 15 (1942), No. 4, pp. 120-123).—In experiments on the toxicity of nicotine sprays for the horn fly, nicotine lactate, an aqueous solution of nicotine containing 0.5 percent of nicotine and 1.0 percent of lactic acid, and the combination of nicotine sulfate and acetic acid were effective, but the latter was objectionable because of its disagreeable odor. When certain acids were incorporated in the nicotine sprays the toxicity was prolonged, and the spray was considerably more effective against horn flies than when no acids were added.

**Bionomics and morphology of the black onion fly *Tritoxa flexa* (Wied.) (Diptera: Ortalidae),** H. C. MANIS (*Iowa State Col. Jour. Sci.*, 16 (1941), No. 1, pp. 96-98).—A digest of a thesis on *T. flexa*, which in Iowa is as serious a pest of onions as is the onion maggot in the onion-growing localities of Pleasant Valley, St. Ansgar, and Clear Lake.

**Tests with various chemicals for the control of white grubs in forest nurseries of the Carolinas,** H. R. JOHNSTON and C. B. EATON. (U. S. D. A. et al.). (*Jour. Forestry*, 40 (1942), No. 9, pp. 712-721).—Investigations commenced in 1934 with the view to developing a satisfactory means of controlling white grubs (*Phyllophaga* spp.) in forest nurseries of the Southeast revealed acid lead arsenate as too injurious to pine seedlings to be used for such a purpose. In later tests certain other chemicals were found to be more satisfactory, carbon disulfide being more effective than the other materials.

**Notes on beetles related to *Phyllophaga* Harris, with descriptions of new genera and subgenera,** L. W. SAYLOR (*U. S. Natl. Mus. Proc.*, 92 (1942), No. 3145, pp. 157-165, pl. 1).—The data presented and the conclusions drawn are the result of a critical study of 543 species of phyllophagan beetles from North, South, and Central America and the West Indies.

**Japanese beetle continues on offensive in New York,** E. H. WHEELER (*Farm Res. [New York State Sta.]*, 8 (1942), No. 4, p. 12).—A practical account

**Japanese beetle control in Indiana,** F. N. WALLACE (*Ind. Acad. Sci. Proc.*, 50 (1940), pp. 16-22).

**Biology of the squash blister beetle,** W. R. HORSFALL. (Ark. Expt. Sta.). (*Jour. Kans. Ent. Soc.*, 15 (1942), No. 3, pp. 93-99).—A study of the life cycle of the squash blister beetle *Henous confertus* Say in Arkansas, where it was a pest of importance in the northwestern part of the State in the summer of 1939 and of less importance the following year, is reported. In addition to squash,

flowers of several species of cucurbits and those of alfalfa and the western daisy are preferred sources of food. Ripe tomato fruits are also injured.

**The flatheaded apple tree borer (*Chrysobothris femorata* (Olivier))**, F. A. FENTON (*Oklahoma Sta. Bul.* 259 (1942), pp. 31, figs. 12).—Under Oklahoma conditions for 1935 and 1936, 89.9 and 87.2 percent, respectively, of the flatheaded apple tree borers completed their life cycles in 1 yr., 8.9 and 12.1 percent required 2 yr., and 1.2 and 0.7 percent 3 yr. Emergence from infested wood begins early in May and continues until early August. Adult survival under laboratory conditions averages 26 days. The adults feed on tender bark and may bite through leaf petioles. Females begin oviposition in from 4 to 8 days after feeding and prefer weak trees, inserting the eggs in cracks or wounds. Hatching occurs in 6 to 8 days, and larvae develop in the cambium layer. Larvae overwinter in the xylem, and the majority pupate in the spring. The pupal stage lasts from 8 to 14 days. Trees or tops of trees die as a result of girdling by this insect. The peak of abundance in Oklahoma was reached in 1936 and 1937. After this, natural agencies caused the borer to be scarce. Tree paints are not recommended for control. Best protection resulted from the use of spiral tree wraps extending a few inches below ground level, put in place early in May and removed about October 1.

**A revision of the North American species of buprestid beetles belonging to the tribe Chrysobothrini**, W. S. FISHER (*U. S. Dept. Agr., Misc. Pub.* 470 (1942), pp. 275, figs. 126).—This publication deals with 7 species of *Actenodes* and 115 species of *Chrysobothris*, of which 7 new species are described. The important synonymy, a description, the type locality, distribution, and host plants if known are given for each species. Notes and records are included for all the species in these genera found on the mainland of America, north of Mexico, as well as those occurring in Lower California. Mention is made of unrecognized and fossil species. Numerous figures are given to aid in the determination of the different species.

**Larval characteristics of certain elm bark infesting Coleoptera**, P. P. WALLACE and R. L. BEARD. (Conn. [New Haven] Expt. Sta.). (*Canad. Ent.*, 74 (1942), No. 5, pp. 86-87, figs. 3).

**Cotton or boll weevils**, J. L. WEBB (*U. S. Dept. Agr., Misc. Pub.* 484 (1942), pp. II+16, figs. 10).—A practical account, written especially for boys and girls, which supersedes Miscellaneous Publication 35 (E. S. R., 61, p. 156).

**Factors affecting the usefulness of honeybees in pollination**, G. H. VANSSELL. (Coop. Univ. Calif.). (*U. S. Dept. Agr. Cir.* 650 (1942), pp. 32, figs. 10).—Honeybees constituted 82 percent of blossom visitors and were practically the only distributors of pear pollen in the Camino district of California. Emasculated blossoms were visited frequently. A wide range in the quantity of nectar secreted and its sugar concentration was noted in different species of plants. Simultaneously blossoming plants must compete for insect visitors. Bees may go a mile and a half or more from well established colonies in search of nectar and pollen. One bee visited 84 pear blossoms to obtain her full load of pollen. It was estimated that on a good flight day 822,720 bees issued from 16 colonies in one pear orchard. Strong overwintered colonies surpassed package bees in population, flight activity, and amount of pollen gathered, and 5-lb. packages were more effective than smaller units.

**One year and two year old queens**, E. BRAUN (*Amer. Bee Jour.*, 82 (1942), No. 8, pp. 356-357).—A contribution from the Dominion Experimental Farm, Brandon, Manitoba.

**Growth factor requirements of *Bacillus* larvae** White, A. G. LOCHHEAD (*Jour. Bact.*, 44 (1942), No. 2, pp. 185-189).—It was found that *B. larvae*, hereto-

fore successfully cultivated only on media containing addenda of "natural" substances, grows well on a medium containing salts-sugar solution, peptone, and thiamin. Thiamin completely replaced the growth factor effect of such addenda as vegetable extract, yeast, or egg yolk. Other growth factors, namely, biotin, vitamin B<sub>6</sub>, pantothenic acid, inositol, nicotinic acid, and riboflavin, were without effect, nor did they increase the effect of thiamin in promoting growth either singly or in combination.

**Biological control of black scale, H. S. SMITH.** (Calif. Citrus Expt. Sta.). (Calif. Citrog., 27 (1942), No. 10, pp. 266, 290-291, figs. 7).—Report is made of progress of black scale control following an extended field survey of the black scale situation in all of southern California, which has shown that in the coastal areas, including all of Santa Barbara, Los Angeles, and Orange Counties and most of Ventura and San Diego Counties, black scale populations have in the past two seasons been the lowest in many years. Almost no insecticidal treatment has been necessary to combat this scale in these areas during that period. While in certain more interior areas a few medium to heavy infestations occur and in certain areas there are many heavily infested groves, the almost unbelievably low populations of black scale in southern California as a whole are most striking. The establishment of the black scale parasite *Metaphycus helvolus* is considered mainly responsible for this control.

**Biological control of black scale in southern California, H. S. SMITH.** (Calif. Citrus Expt. Sta.). (Citrus Leaves, 22 (1942), No. 7, pp. 5-7, figs. 6).—Essentially noted above.

**Mortality of reproduction defoliated by the red-headed pine sawfly (Neodiprion lecontei Fitch), J. A. BEAL** (Jour. Forestry, 40 (1942), No. 7, pp. 562-563).—Observations on the killing of young pine trees as a result of defoliation by the red-headed pine sawfly are reported. Additional information on relative survival and susceptibility of shaded and unshaded trees is also presented. The observations were conducted during a local outbreak of this pest in some of the young stands of shortleaf pine (*Pinus echinata*) and loblolly pine (*P. taeda*) in the Duke Forest in 1939.

**A comparative study of the influence of temperature on the development of certain sawflies after hibernation in the cocoon, A. W. A. BROWN and L. DAVIAULT** (Sci. Agr., 22 (1942), No. 5, pp. 298-306, figs. 10).—A study was made of four species of *Neodiprion* and two each of *Pikonema* and *Pristiphora* to determine the characteristic reaction of the various species to the conditions of temperature and humidity to which they are subjected in the laboratory. The results obtained in the course of this study represent 2 yr. of experimental work carried on with some 10,000 cocoons as a basis for further comparative studies of thermal requirements. The findings, which are summarized in a series of graphs for each of the eight species studied, are considered to warrant the following conclusions: "(1) In most cases the value of the thermal constant is slightly higher for females than for males. Values for the theoretical threshold are nearly the same for both sexes, varying either way (2) As a class, the genus *Neodiprion* is characterized by a high theoretical threshold and a comparatively low thermal constant. In other words, this group requires higher temperature to start development but emergence follows in a relatively shorter time. (3) The highest theoretical thresholds—and lowest thermal constants—are exhibited by *N. lecontei* Fitch and *N. dubiosus* Schedl. Both of these species show a preference in the field for open-grown trees, where the ground is rapidly heated in the spring by isolation. . . . (4) The optimum temperature, as far as survival is concerned, lies in the vicinity of 22° C. (72° F.) for the species of *Neodiprion* studied; for those of the genera *Pristiphora* and *Pikonema*, it is in general lower. (5) By con-

trast, the genus *Pikonema* is characterized by a low theoretical threshold and a high thermal constant. Indeed, the theoretical threshold of *P. dimmockii* is less than 1° above the freezing point. . . (6) Cocoons of *Pristiphora geniculata* have temperature characteristics resembling those of *Pikonema*, but the material of *Pristiphora ericksonii*, perhaps in contrast to some established opinions, exhibited the high theoretical threshold and lower thermal constant characteristic of *Neodiprion*."

Recently discovered mite on citrus, E. A. MCGREGOR. (U. S. D. A.). (*Calif. Citrog.*, 27 (1942), No. 10, p. 270, figs. 5).—Through feeding within the bracts, *Tarsonemus bakeri* Ewing causes the tips of citrus buds to become brown and dead. In certain orchards in San Diego County this minute mite and the larger bud mite (*Eriophyes sheldoni* Ewing) are present on the same trees, but the malformations of the foliage and fruits caused by the latter are rather easily distinguished from the distortion associated with the tarsonemid mite. *T. bakeri* has been observed on Eureka and Lisbon lemon, navel and Valencia orange, and on grapefruit. Its distribution includes six counties and involves a north-and-south extension of about 155 miles. This mite seems to be closely associated with and may be instrumental in spreading the *Alternaria* fungus, which is known to be the direct or contributing cause of black rot, center rot, end rot, break-down, and similar conditions.

Mites and apple maggot, R. HUTSON (*Mich. State Hort. Soc. Ann. Rpt.*, 70 (1940), pp. 11-14).

Orchard mites and the mealy bug problem, W. S. HOUGH (*Mountaineer Grover*, 12 (1941), No. 128, pp. 10-11, 13).

Ticks collected on the Pama (Iowa) Indian Reservation, with notes on other species, G. W. EDDY and C. R. JOYCE. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 16 (1942), No. 4, pp. 539-543).—Report is made upon the Ixodoidea known to occur in Iowa.

A new species of tick found on shrews, J. D. GREGSON (*Canad. Ent.* 74 (1942), No. 8, pp. 137-139, figs. 9).—An ixodid collected in all stages from shrews in some 10 localities in British Columbia is described as new under the name *Ixodes soricis*. The species in all its stages appears to be specific to shrews, these animals being but rarely parasitized by *I. angustus* Neum., the adult, nymphal, and larval stages of which were found on squirrels, rabbits, moles, rats, mice, chipmunks, and dogs.

Life history studies on two trematodes of the subfamily Notocotylinae. E. C. HERBER (*Jour. Parasitol.*, 28 (1942), No. 3, pp. 179-196, figs. 25).—This contribution deals with life history studies on two species of trematodes parasitic in mammals and birds which have been completed experimentally, namely, *Quinqueserialis quinqueserialis* and *Notocotylus stagnicolae* n. sp. The definitive hosts of *Q. quinqueserialis* are *Ondatra zibethicus*, *Microtus pennsylvanicus*, and *Zapus hudsonius*. The definitive hosts of *N. stagnicolae* are *Gallus domesticus*, *Anas domestica*, *Querquedula discors*, *Mergus merganser*, and *Aegialitis semipalmata*.

## ANIMAL PRODUCTION

Livestock production, W. H. PETERS (*New York and London: McGraw-Hill Book Co.*, 1942, 1 ed., pp. VIII+450, figs. 101).—General directions are given for the production, breeding, feeding, management, and judging of beef and dairy cattle, swine, sheep, goats, horses, and mules.

Problems in feeding and management of livestock (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, pp. 5, 6).—Results are briefly reported by C. Dorman on studies of natural breeding and artificial insemination of mares; corn, oats,

barley, and sweetpotato meal for finishing pigs; cottonseed meal feeding with charcoal and minerals for pigs; cottonseed cake, oats, barley, dried sweetpotatoes, soybean-sorghum silage, and kudzu hay for finishing and wintering beef cows; pastures and vitamins for laying hens; egg coolers; and one mash for chickens of all ages.

The physiological approach to livestock nutrition problems, L. A. MAYNARD. (Cornell Univ.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 179-188).—There are pointed out contributions of the physiologist to the fundamental nutrition problems, including the importance of dietary interrelationships in protein, carbohydrate and fat metabolism, and the role of minerals and vitamins, natural and synthetic. The soundness and promise of the physiological approach to livestock nutrition problems is emphasized.

Calories in wartime, E. G. RITZMAN (*New Hampshire Sta. Cir.* 62 (1942), pp. 16).—Conclusions based on many years' results of cooperative research between the station and the Nutrition Laboratory of the Carnegie Institute showed that the returns that may be expected from livestock will depend on the proportion of available nutrients above maintenance requirements. Material savings of concentrates for animals may be made by a better exploitation of forage possibilities. Examples with timothy hay, oats, and soybeans, cut at optimum stages for feed value, are presented. Adequate amounts of proteins and energy alone are not necessarily sufficient for young animals.

Direct methods of computing rations, B. H. SCHNEIDER. (W. Va. Expt. Sta.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 246-255).—Six direct methods of computing livestock rations which eliminate part or all of the trial-and-error element in compounding feeds are presented. It is suggested that the trial of these methods under many practical and experimental conditions may develop the best method applicable to all conditions.

The nutritive value of animal proteins: The biological values of fishmeal, whale and fishmeal, meatmeal, meat and bonemeal, crayfishmeal, and white fishmeal, B. A. DU TOIT and D. B. SMUTS (*Onderstepoort Jour. Vet. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 191-198).—Biological values were ascertained with six rats each over a period of about 1 week after a low nitrogen ration and transition period, of 94 for whitefish meal, 81 for crayfish meal, 71 for fish meal, 67 for meat meal, 67 for meat and bonemeal, and 63 for whale and fish meal.

The relative efficiency of urea as a protein substitute in the ration of ruminants, B. C. JOHNSON, T. S. HAMILTON, H. H. MITCHELL, and W. B. ROBINSON. (Univ. Ill.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 236-245).—Digestion and metabolism experiments were carried out with 16 growing lambs, comparing the nitrogen utilization from soybean meal, casein, and urea as supplements of roughly 10, 12, and 14 percent crude protein to a basal ration. These results showed that additions of urea to produce the equivalent of 12 percent crude protein induced a retention of nitrogen that was not improved by further urea additions, although it was improved by raising the crude protein content of the ration. Conversion of urea in the paunch does not proceed at a sufficiently rapid rate to comply with the protein requirements in the growing lamb. The utilization in digestion of urea nitrogen was enhanced by available sugar such as corn molasses. Nitrogen from soybean meal was somewhat better utilized than nitrogen from casein. The biological value of the nitrogen in the rations containing 10-12 percent crude protein generally varied within a few percent from 60, suggesting that a considerable portion of the protein utilized by the ruminant is micro-organismal regardless of the nature of the

nitrogenous constituents consumed. For the study there was employed a basal ration consisting of redtop hay and corn with the various supplements.

**Studies on carotene in relation to animal nutrition, I, II, P. A. SESHAN and K. C. SEN** (*Jour. Agr. Sci. [England]*, 32 (1942), No. 2, pp. 194-216).—Two papers in this series are presented.

**I. The technique of carotene estimation in feeding stuffs** (pp. 194-201).—A modified method of estimating carotene content of plant material is suggested, which involves a combined aqueous and alcoholic potash hydrolysis before extracting. This method proved relatively efficient.

**II. The development and distribution of carotene in the plant and the carotene content of some common feeding stuffs** (pp. 202-216).—The absence of sunlight caused poor development of carotene in plants grown under artificial conditions. In the growth of corn and barley there were increases in the former to 58.4 mg. per kilogram and 31.4 in the latter at 12 days of age. At 3 weeks field growth the cereal plants had increased materially but declined thereafter. The carotene contents of green fodder plants and dry feeds commonly used in cattle rations are presented.

**The carotene content of some South African feeds, III, S. J. MYBURGH** (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 199-210).—Further studies (E. S. R., 85, p. 801) of the carotene content of samples of six grasses taken at monthly intervals from three areas on South African ranges are presented. The calculated intake of carotene by 800-lb. cattle did not indicate a carotene deficiency of cattle on the ranges.

**Digestibility studies with ruminants.—IX, Associative digestibility of grains: Wheat bran, gluten feed, and soybean oil meal, C. J. WATSON, J. A. CAMPBELL, W. M. DAVIDSON, C. H. ROBINSON, and G. W. MUIR** (*Sci. Agr.*, 22 (1942), No. 9, pp. 561-570).—Continuing this series (E. S. R., 87, p. 257), the calculated digestibility of a grain mixture of wheat bran, gluten feed, and soybean meal was practically the same as that determined by the amounts of each ingredient fed to five steers.

**The ensilage of citrus fruit pulp, A. BONDI** (*Empire Jour. Expt. Agr.*, 10 (1942), No. 38, pp. 89-92).—Citrus fruit pulp was ensiled in barrels without serious deterioration for as long as 8 mo. and without the addition of acid preservatives. The composition of orange and grapefruit pulp before and after ensiling is given.

**Sugarcane silage, shocked sugarcane, and carpet grass as roughages for wintering the beef herd, W. G. KIRK and R. M. CROWN** (*Florida Sta. Bul.* 373 (1942), pp. 19, figs. 4).—Storing shocked sugarcane with butts on the ground against upright supports proved practical, but it should not be stacked more than 20 ft. deep for more than a few weeks. Cows wintered on the shocked sugarcane were in a thriftier condition and gave advantageous gains over those wintered on sugarcane silage or on carpet grass pasture with cottonseed meal fed as a supplement. In three experiments shocked sugarcane proved superior to the silage in chemical composition and the gains made by lots of about 10 cows. On combining 3-yr. results, the rations of sugarcane silage, shocked sugarcane, and carpet grass pasture, fed with about 2 lb. of cottonseed meal daily, were found to produce respective average losses per cow of 44, 4, and 78 lb. A preliminary test of 1 yr. showed similar results.

**Forest grazing and beef cattle production in the Coastal Plain of Georgia, H. H. BISWELL, B. L. SOUTHWELL, J. W. STEVENSON, and W. O. SHEPHERD** (*Coop. U. S. D. A.*). (*Georgia Coastal Plain Sta. Cir.* 8 (1942), pp. 25, figs. 10).—A survey of 106 farms in the Coastal Plain region of Georgia, where cattle are raised and where forest ranges are used for grazing, showed that forest lands

contributed a large part of the yearlong sustenance. The breeding cows usually lost considerable weight on the range after October 15. Calf crops of 40-70 percent were produced. Profitable beef cattle production in the region may occur with tick eradication and better management, and breeding. For grazing cut-over forest lands certain management practices and burning seem to need attention.

**Maximum beef production from mountainous summer range in Utah,** L. A. STODDART (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, pp. 6-7, figs. 5).—The important features of beef cattle management on Utah mountain ranges are briefly presented. Results of 6-yr. grazing at different intensities with suggestions on the economics of the practices are included.

**Beef improvement begins at home,** F. MCKENZIE (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, p. 2, fig. 1).—Plans of the station for finding superior blood lines of beef cattle for the State are presented.

**More beef from the same number of cattle on Nevada ranches,** C. A. BRENNEN and C. E. FLEMING (*Nevada Sta. Bul.* 162 (1942), pp. 13, figs. 4).—It is suggested that in a well planned program of breeding, feeding, and grazing cattle to increase production, calves should be dropped near the start of the grazing season and kept gaining by supplemental feeding of hay and temporary pastures until marketing.

**Purchasing feeder cattle,** G. A. BRANAMAN (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 65-68, fig. 1).—It is concluded that "under present war emergency conditions, it is important to buy on a strict grade basis with definite concern for the price ceilings in effect for each grade of beef."

**Legume silage vs. corn silage vs. legume hay for fattening calves,** G. A. BRANAMAN and G. K. DAVIS (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 13-16).—In a 196-day feeding experiment with 3 lots of 10 400-lb. calves each, average daily gains of 1.95, 1.84, and 2.08 lb. were made by groups receiving legume hay, corn silage, and legume silage, respectively, with beet pulp molasses. The gains in weight and market finish were superior for those fed molasses legume silage to those receiving legume hay. Less shelled corn was required with corn silage than by the cattle in either of the other two lots. Returns per head, including pigs, were calculated considerably greater for the legume silage and corn silage groups.

**The importance of body weight in selection of range ewes,** C. E. TERRILL and J. A. STOEHR. (U. S. D. A.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 221-228).—The yearling fall weights over a 15-yr. period of 758 ewes of Rambouillet, Columbia, and Corriedale breeds were found to be an indication of the number and weights of lambs produced in the succeeding 4 yr. The ewes of each breed were classified into 3 groups by weight, and selection on the yearling body weight had about the same effectiveness, from 13 to 15 lb. of lamb weaned per year, in the 4 yr. regardless of the breed. Lifetime body weights of ewes were inversely proportional to the weights of the lambs produced. Lifetime production of fleece weight was in favor of the heavier ewes, but there was practically no difference in the lifetime fleece length.

**Relationship between weanling and yearling fleece characters in range sheep,** E. M. POHLE. (U. S. D. A.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 229-235, fig. 1).—The length of staple and percentage of clean wool produced by 170 yearling Rambouillet ewes could be predicted from these characters in the weanling fleeces from the formula  $Y = a + Xb_{.1}$ , wherein Y refers to the yearling values and X those for the weanling animals. Fineness and density showed limited predictive value. One sample was essentially as good as two for estimating clean yield, density index, and staple length, but four samples were

materially more reliable than two samples for predicting yearling fleece length in the Columbias.

**A study on the possibility of cystine synthesis in the rumen of sheep together with the effect of cystine supplementation on the nitrogen utilization of lucerne in young stock,** D. B. SMUTS, B. A. DU TOIT, and J. G. v. d. WATH (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 181-190).—The biological value of rumen ingesta from sheep was shown in experiments on rats to be greater than that of alfalfa. The biological value of the rumen ingesta was significantly enhanced when supplemented with cystine. In studies with mature sheep, the inclusion of cystine in an alfalfa ration did not influence biological value, although this was increased about 10 percent in growing sheep.

**The digestibility of citrus feeds,** A. BONDI and H. MEYER (*Empire Jour. Expt. Agr.*, 10 (1942), No. 38, pp. 93-95).—In digestive experiments with sheep the feeding value of orange pulp silage was about 16 percent higher than that of whole cull oranges. It should be noted that the citrus feeds are relatively low in protein.

**The feeding of western lambs,** W. G. KAMMLADE, E. K. FAULKNER, and U. S. GARRIGUS. (Ill. Expt. Sta.). (*Sheep and Goat Raiser*, 22 (1942), No. 12, pp. 16-18, fig. 1).—No indication was obtained of a benefit in lamb production from additions of cobalt or a mineral mixture to the ration of shelled corn and alfalfa hay with corn silage and soybean meal in a 90-day feeding experiment. In all of the 5 lots of about 45 lambs each, average daily gains were similar. More economical gains were made with corn silage and a protein supplement than with alfalfa hay because of the higher cost of the latter roughage. The 91 lambs not ready to market at the end of the feeding experiment were half shorn and half unshorn. During a 35-day feeding period those shorn made average daily gains of 0.22 lb., whereas those unshorn made average daily gains of 0.20 lb. Calculation of the returns from 7.9 lb. of wool produced by the shorn lambs and the sale of the meat showed no definite advantage of shearing lambs before feeding.

**The lipids of the duodenal mucosa of swine during the absorption of fat,** R. REISER. (N. C. Expt. Sta.). (*Jour. Biol. Chem.*, 145 (1942), No. 1, pp. 109-114).—Analyses of the alcohol-ether extract of the mucosa of five 225-lb. Duroc-Jersey pigs after 48 hr. fasting in comparison with the mucosa of similar pigs 2 and 3 hr. after consumption of 200 and 300 gm. of cottonseed oil showed no changes in the phospholipid or cholesterol content of the mucosa during absorption. About 2.5 percent of the duodenal mucosa of the fasting pig was made up of free fatty acid. After ingestion of oil 5 hr. the free fatty acid content was practically doubled. No triglycerides were present during fasting and only small amounts during the absorption period.

**Vitamin A in swine feeding,** W. D. ALBRIGHT and L. D. FRASER (*Canada Dept. Agr. Pub.* 736 (1942), pp. 16, figs. 10).—In five experiments on varied rations Yorkshire shotes developed staggering gaits and diverse symptoms characterized as A-avitaminosis. These symptoms were prevented and largely cured by feeding Pilchardene and green or cured alfalfa. Normal development was made for a time on the vitamin A-deficient ration and the attacks were irregular.

**Vitamin A studies with rats and pigs,** R. BRAUDE, A. S. FOOT, K. M. HENRY, S. K. KON, S. Y. THOMPSON, and T. H. MEAD (*Biochem. Jour.*, 35 (1941), No. 5-6, pp. 693-707, fig. 1).—Supplements of varying forms of carotene products were administered to pigs. Appreciable amounts of vitamin A were found in the livers at slaughter of pigs which had received high levels of  $\beta$ -carotene in the

diet. There was essentially no vitamin A in the livers of controls or pigs which had received zeaxanthin or low levels of the  $\beta$ -carotene. Considerable amounts of A were found when vitamin A ester or vitamin A alcohol had been fed. Similar tests with rats showed that much the same results were obtained. Zeaxanthin was biologically inactive in both species. Pigs made less efficient use of  $\beta$ -carotene than rats.

**Factors affecting farm horse power efficiency**, L. H. BLAKESLEE and R. S. HUDSON (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 25-28).—Studies of the feed requirements and selling price of draft horses sired by Percheron and Belgian stallions showed that the use of pasture and roughage offered an economical method of production and there was little difference in the selling price. In the study 28 colts were raised to 3 yr. of age on rations containing grain and hay. Groups wintered on these feeds were compared with other groups having access to a haystack and winter pasture without grain. Two colts were stall fed, which proved costly, and the individuals were more subject to deformities.

**Coffee grounds in animal rations**, W. KING WILSON (*Nature [London]*, 149 (1942), No. 3778, pp. 361, 362).—In one experiment of 4 mo. duration a ration in which about 10 percent of the concentrates were replaced by fresh spent coffee grounds was fed to a group of 10 adult rabbits. The average gains of the control group were 4.7 oz. during this period as compared with 3.1 oz. by the experimental group. Little difference was shown in the proportion of fertile does in the two groups.

**Factors affecting profits in the poultry enterprise**, C. FRISCHKNECHT (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, pp. 1, 11, figs. 2).—A discussion of the general principles of poultry production with special reference to the war program.

**Time- and labor-saving equipment for the laying house**, D. C. KENNARD and V. D. CHAMBERLIN (*Ohio Sta. Spec. Cir.* 51, rev. (1942), pp. 16, figs. 16).—This is a revision with amplification of the text and illustrations of the circular previously noted (E. S. R., 80, p. 115).

**The problem of moisture in poultry house litter**, T. B. CHARLES, A. E. TEPPER, W. T. ACKERMAN, B. W. FRENCH, R. C. DUBGIN, and R. B. HALPIN (*New Hampshire Sta. Bul.* 338 (1942), pp. 30, figs. 11).—Observations on the moisture conditions, mortality, egg production, and related factors of poultry in 10 pens and an experimental plot house over a 3-yr. period with different kinds of litter and ventilation showed that the pen litter increased in moisture to a maximum of about 50 percent during the less favorable winter weather in February and March, with a gradual decrease in litter moisture thereafter until it again averaged about 20 percent in June. Peat moss possessed the highest moisture absorptive capacity and the greatest retention of absorbed water of any of the litters studied. The least water absorptive capacity of any of the litters studied was shown by sand and gravel. Other litters in the study included shavings, sawdust, chopped hay, sugarcane, oat hulls, and straw, separately and mixed. The moisture content of desirable poultry pen litters should not exceed 40 percent. Additions of fresh relatively dry litters to poultry pens during the winter months did not result in a continued dry litter condition. Newly added litter picked up moisture rapidly and in a few weeks reached the moisture level of old litter. Neither egg production nor mortality was related to the moisture present. It was estimated that each hen consumed approximately 22.6 gal. of water per year. Prevention of water spilling, warming floors, and insulation helped to maintain dry litters.

**The hydrogen ion concentration in avian digestive tracts, D. S. FARNER.** (Univ. Wis.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 445-450).—Statistical analysis of the H-ion concentration of the digestive tracts of chickens, pigeons, ducks, pheasants, and turkeys showed the gizzard to have an acidity of pH 2.00-2.60. This was significantly more acid than the duodenum and large intestine in the different species, which ranged from 5 to 7. There was a tendency for the acidity to decrease with progression from the duodenum through the ileum. The pH of the intestinal tracts was obtained by the quinhydrone electrode.

**The comparison of corn, milo, and hegari in the diet of laying hens, J. C. HAMMOND.** (U. S. D. A.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 410-415).—The number and interior quality of eggs produced by 19 lots of 25 laying hens each showed that either 53 percent of yellow milo or hegari were equal to equivalent amounts of white corn in a well balanced ration. Equal results were also obtained in hatchability of eggs, egg size, and live weight. In a fair diet containing no animal protein hatchability of the eggs was reduced with hegari to about 15 percent as contrasted with about 50 percent in hatchability with white corn and 40 percent with yellow milo. Neither fertility nor physical composition of the eggs was affected by the divergent dietary treatments which included rations with and without dried skim milk and alfalfa leaf meal. Eggs from pullets fed a corn and alfalfa leaf meal diet retained a high percentage of thick whites after 18 days' storage at 75° F.

**Gross values of combinations of soybean oil meal with pilchard fish meal or meat meal, C. I. DRAPER and M. RHIAN.** (Wash. Expt. Sta.). *U. S. Egg and Poultry Mag.*, 48 (1942), No. 8, pp. 466-468, 475-476).—When added to a cereal ration containing 8 percent protein, sufficient protein feeds to give an 11-percent protein ration gave the following results in fattening: Casein 100, pilchard fish meal 109, soybean meal 85, and meat meal 33. With as much as equal parts of pilchard fish meal and soybean meal the chicks gained well and utilized the feed as efficiently as with casein. With meat meal alone or with soybean meal the efficiency of the protein supplement was reduced.

**The value of dogfish meal as a protein supplement, M. RHIAN, J. S. CARVER, R. W. HARRISON, and W. S. HAMM** (*Washington Sta. Bul.* 416 (1942), pp. 24).—Employing the method of protein evaluation for chicks previously noted (E. S. R., 82, p. 377), comparison of the protein value of 18 fish meals showed dogfish meal prepared by dry rendering methods commercially and experimentally to have little value as a protein feed. On the other hand, wet process meal prepared experimentally had relatively high apparent gross protein values, comparable to those obtained with pilchard fish meal and soybean meal. There was no significant difference in dogfish meals unpreserved and preserved with 0.1-1.0 percent formaldehyde. Similar results were obtained for formaldehyde treated and untreated casein. Good care and speed of handling were essential if high quality dogfish products were to be produced. When formaldehyde was used as a coagulant there was a tendency to lower the gross protein value. The urea content of the wet process dogfish meal was not detrimental to their feeding value except as it affected the usual determination of the protein content. Unadulterated commercial dogfish meals of very high protein content, especially with large amounts of urea, were likely to be dry process meals.

**Chick feeding experiments with solvent-extracted tung oil meal, L. L. RUSOFF, N. R. MEHRHOF, and R. S. MCKINNEY.** (Fla. Expt. Sta. and U. S. D. A.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 451-454, fig. 1).—No evidence of toxicity was noted from solvent-extracted tung oil meal fed as 4.9, 9.6, 14.1, and 18.5 percent of a cereal ration with alfalfa leaf meal and meat scrap to 5 lots of 9 12-day-old chicks for 5 weeks. The meal was unpalatable, resulting in reduced weekly

gains and feed consumption. As the percentage of the tung oil meal increased gains decreased.

**Fat absorption in the laying hen**, R. M. CONRAD and H. M. SCOTT. (Kans. Expt. Sta.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 407-409).—Differences between the fatty acid content of portal blood and heart blood of laying hens, which received an egg-yolk meal 4-7 hr. before treatment, showed that in the laying hen most of the fatty acids were absorbed by way of the portal system rather than by the lymphatic system. The study was conducted in two experiments with blood drawn from the portal vein and the heart for 15 hens in each experiment receiving fat and 4 and 6 controls.

**Creatine formation in the chick**, H. J. ALMQUIST, E. MECCHI, and F. H. KRATZER. (Univ. Calif.). (*Jour. Biol. Chem.*, 141 (1941), No. 2, pp. 365-373).—With methods previously employed (E. S. R., 87, p. 838), the authors obtained results with chicks suggesting that glycine or arginine are specific biological precursors of creatine. In their absence the muscle creatine became very low and profound weakness developed as contrasted with the effects produced by methionine deficiency which did not reduce muscle creatine below normal.

**Effect of biotin on reproduction in the domestic fowl**, W. W. CRAVENS, E. E. SEBESTA, J. G. HALPIN, and E. B. HART. (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 1, pp. 101-104, fig. 1).—There was a reduction from about 80 percent hatchability of eggs on normal rations to less than 20 percent in 6 weeks on a purified diet. The missing factor was supplied by additions of 5 percent whey concentrate, 3 percent kidney residue, or 15  $\mu$ g. of biotin per 100 gm. of ration. These results demonstrate clearly the need of chicks for biotin (E. S. R., 87, p. 409).

**Hatching ability of poultry.—II, Texture of egg shells in relation to hatching power**, E. W. HENDERSON (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 41-47).—Continuing this series (E. S. R., 86, p. 667), despite an unexpected good hatchability of one lot of eggs with porous shells from hens selected for high egg production, there was found to be a significant relation between the shell texture and the hatchability among 2,398 eggs produced by Barred Rock and White Leghorn hens. The conclusions were derived from  $X^2$  tests and coefficients of correlation.

**The effects of dubbing White Leghorn males**, W. F. LAMOREUX and D. G. JONES. (Cornell Univ.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 437-444, fig. 1).—When cockerels were reared under proper conditions with access to sunlight, there were no significant differences in body weights, size of the testes and pituitaries, and production of semen or gonadotropic hormones as a result of removal of the comb and wattles. Undubbed birds with large combs showed that certain equipment such as feeders and fountains interfered with feed consumption, and that this was reflected in live weight. The study was conducted with 4 groups involving a total of 147 White Leghorn  $\delta$ s with combs and wattles removed at 8-12 weeks of age from half of them, in comparison with undubbed  $\delta$ s.

**Rearing geese on grass alone and with supplementary feeding**, M. M. WRIGHT and F. J. DUDLEY (*Harper Adams Util. Poultry Jour.*, 27 (1942), No. 7, pp. 135-137).—In studies with three lots of goslings little advantage resulted from feeding concentrates until 1 mo. before marketing. Restriction of supplementary feeding to the final 4 weeks of the feeding period tended to reduce the fat of the carcasses (E. S. R., 87, p. 841).

**The development of perosis in turkey poults and its prevention**, R. J. EVANS, E. I. ROBERTSON, M. RHIAN, and L. A. WILHELM. (Wash. Expt. Sta.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 422-429, figs. 2).—In a study of perosis in

turkeys, 180-day-old poultz were fed in 12 groups for 8 weeks on rations supplying varying percentages of protein and minerals with perosis scores of the birds ascertained. In a second experiment 7 groups of 15 poultz each were fed similar rations for 8 weeks with choline, soybean meal, pea meal, fish meal, and liver meal supplements to ascertain the effects of these materials on perosis. The general results showed that perosis in these poultz was produced either by a manganese or choline deficiency. Severe perosis was effectively prevented by 0.2 percent choline or 15 percent liver meal. Some protection was afforded by 15 percent soybean meal or 13 percent herring fish meal, but 15 percent pea meal gave no benefit. The incidence of perosis was increased by increasing or decreasing the protein from 22 percent. The three symptoms of perosis indicated by Wilgus et al. (E. S. R., 78, p. 91) are described and illustrated.

### DAIRY FARMING—DAIRYING

The chemical composition of Michigan-grown hays as fed to dairy cattle.—I. The carotene content, A. C. BALTZER, C. F. HUFFMAN, and C. W. DUNCAN (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 8-15).—The carotene content of 46 samples of clover, alfalfa, timothy, and other grasses mixed for first and second cutting hays per unit weight from different counties of Michigan are tabulated. These results show that there were only 5 samples among this group that contained less than 10  $\mu$ g. of carotene per gram of dry matter. The amounts of hays containing different carotene doses necessary to furnish the requirement of carotene for younger and older calves and 1,000-lb. cows were calculated. The carotene contents during the growing season were found to be high during the fast-growing period and decreasing markedly with maturity.

Limited-grain feeding and all-year pasture for dairy cows, C. E. WYLIE and L. R. NEEL (*Tennessee Sta. Cir.* 78 (1942), pp. 8, figs. 4).—In 4-yr. trials with approximately seven Jersey cows on each ration, comparison was made of 1 lb. of concentrates to 3 lb. of milk and the same amounts and kinds of concentrates to 6 lb. of milk. The results showed that the second group was pastured 346 days as contrasted with 198 days. The milk and fat production for the full-fed group were greater, but the estimated income per cow per year in the half-fed group was \$82.59 as contrasted with \$78.96 in the full-fed animals. Results of similar studies are reviewed.

Investigations to aid Mississippi dairymen (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, pp. 5, 6).—Brief results are given by C. Dorman on the relation of bitterness to flavor of cheese, on minerals, and on vitamins in feeds for dairy cows.

Dairy cattle judging, A. B. NYSTROM (*U. S. Dept. Agr., Farmers' Bul.* 1769, rev. (1942), pp. [21]+29, figs. 21).—A revision (E. S. R., 77, p. 236).

Relation of volume of daily milk production to ascorbic acid content of cow's milk, A. D. HOLMES, F. TRIPP, E. A. WOELFFER, and G. H. SATTERFIELD. (Univ. N. C. et al.). (*Food Res.*, 7 (1942), No. 2, pp. 111-117).—The studies of the ascorbic acid content of Guernsey and Holstein milk (E. S. R., 86, p. 522) showed that the volume of the milk produced had little influence on the amount of ascorbic acid found in the milk. However, the total daily ascorbic acid production was related to the milk secreted. As lactation advanced the total output of ascorbic acid decreased.

Effect of water bacteria on quality of dairy products, W. B. SABLES. (Univ. Wis.). (*Natl. Butter and Cheese Jour.*, 33 (1942), No. 7, pp. 14, 16).—Difficulties from gas-forming, proteolytic and other organisms from water may cause de-

fects, if allowed to grow, in the quality of cream, butter, and cheese. Various bacteria from water sources are identified.

**Thermophilic bacteria in milk and a simple remedy against them, M. J. PRUCHA.** (Univ. Ill.). (*Milk Plant Mo.*, 31 (1942), No. 4, pp. 38-39).—Thermophilic bacteria, the types which tolerate pasteurization temperatures, are discussed from the standpoint of their prevalence. Such bacteria result from a lack of cleanliness, which may be traced to the farm or the milk plant.

**The problem of controlling rancidity in milk, N. P. TARASSUK.** (Univ. Calif.). (*Milk Plant Mo.*, 31 (1942), No. 4, pp. 24-25).—A brief review is given of the role of lipase in milk as a factor in the development of rancidity, as reported by Krukovsky and Herrington (E. S. R., 81, p. 413).

**Method of sampling an important factor in determining homogenization efficiency of milk, G. M. TROUT and M. V. SCHEID** (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 16-22).—Comparison of five methods of obtaining the upper 100 cc. sample of milk homogenized at 1,000 and 2,500 lb. pressure showed that sampling with a filter pump or by decanting was more reliable than when a pipette was used. Difficulty was encountered with the cream siphon in obtaining the correct volume. Differences in the fat content of samples obtained by the different methods served as a measure of the adequacy of homogenization. Twenty-four bottles of milk were used for comparison of each of the methods of sampling.

**Stability of fat emulsion in commercial homogenized milk, G. M. TROUT and M. V. SCHEID** (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 22-25, fig. 1).—Homogenized milk collected from four milk plants over a 3-mo. period failed to qualify in nearly half of the 200 samples for homogenization as defined in public health standards. Quart bottles were allowed to stand 48 hr. at 40° F. before testing for differences in the fat content of the top layer and the rest of the milk.

**Studies relating to soft curd milk, J. C. MARQUARDT.** (N. Y. State Expt. Sta.) (*Milk Dealer*, 31 (1942), No. 8, pp. 27-28, 72).—Homogenization was shown to increase the uniformity of the curd strength and fats, solids, and ash contents of three top layers of milk as compared with normal unhomogenized samples. In all cases homogenization increased the setting time.

**Developments in the pasteurization of churning cream, E. L. JACK.** (Univ. Calif.). (*Jour. Milk Technol.*, 5 (1942), No. 1, pp. 44-47).—Pasteurization of churning cream at 180°-185° F. for a short period to destroy enzymatic activity as soon as possible is recommended.

**Experiments in freezing cream for storage, G. M. TROUT.** (Mich. Expt. Sta.). (*Canad. Dairy and Ice Cream Jour.*, 21 (1942), No. 7, pp. 22-23).—Storage of cream pasteurized and frozen at different temperatures and homogenized at contrasting pressures showed that it could be safely stored for 12 mo. if properly produced and processed without off-flavors. Storage of frozen cream seemed to offer possibilities.

**Studies on surface taint butter, I-V** (*Sci. Agr.*, 22 (1942), Nos. 5, pp. 277-286; 6, pp. 347-355, fig. 1; 7, pp. 438-447, pl. 1, figs. 5; 8, pp. 461-464; 9, pp. 552-560).—The results of several experiments are reported.

**I. Odour production by *Pseudomonas putrefaciens*, H. Wolochow, H. R. Thornton, and E. G. Hood** (pp. 277-286).—Attempts to identify the precursors of the surface taints in Alberta creamery butters in 1919 were unsuccessful, but 24-hr. growth of the organism, *P. putrefaciens*, in several culture media at room temperatures produced the characteristic odor. The cultural characteristics and odor produced by the organism at different temperatures are described.

**II. An odourous compound in skim milk cultures of *Pseudomonas putrefaciens***

test, W. L. Dunkley, G. Hunter, H. R. Thornton, and E. G. Hood (pp. 347-355).—Distillation of acidified skim milk cultures of *P. putrefaciens* showed the presence of formic, acetic, butyric and isovaleric acids. The sweaty feet odor of the skim milk cultures was related chemically to these conditions.

III. *Some further characteristics of Pseudomonas putrefaciens*, H. Wolochow, H. R. Thornton, and E. G. Hood (pp. 438-447).—Cultural and morphological characteristics of *Pseudomonas* strains in different media are described.

IV. *Distribution and taxonomy of Pseudomonas putrefaciens*, H. Wolochow, H. R. Thornton, and E. G. Hood (pp. 461-464).—The isolation of *P. putrefaciens* from soil and water in Alberta is noted.

V. *The growth of Pseudomonas putrefaciens in butter*, H. Wolochow, H. R. Thornton, and E. G. Hood (pp. 552-560).—At no time in over 300 churnings was it possible to induce surface taints in butter, but it was regularly produced when the butter wash water was contaminated with this organism.

Merits of churned cultured buttermilk, C. L. ROADHOUSE. (Univ. Calif.). (*Canad. Dairy and Ice Cream Jour.*, 21 (1942), No. 8, pp. 54, 56).—A churned cultured buttermilk containing 1-2 percent milk fat did not whey off, had butter granules, was pleasing in flavor, and was produced with skim milk and cream. The skim milk and cream were pasteurized and mixed and permitted to stand before bottling.

Conditions necessary for maintaining quality of year-old vacuum-canned Cheddar cheese, N. S. GOLDING. (Wash. Expt. Sta.). (*Natl. Butter and Cheese Jour.*, 33 (1942), No. 7, pp. 10-12, figs. 2).—There are reported data on the production of a high quality vacuum-canned year-old Cheddar cheese when stored at 52° F. In contrasting studies cans were stored at 62°, 68°, and 74°, respectively. Tests were made of the pressures in the cans at 5-day intervals and the cheese scored. There seemed to be little to be gained in producing fully mature high-quality American Cheddar cheese if it were to be spoiled by high temperatures in the retail store or in the household.

Lehrbuch der Emmentalerkäserei [Textbook of Swiss cheese], A. PETER, edited by E. ZOLLIKOFER (Bern: K. J. Wyss Erben, 1942, 8. ed., pp. VIII+160, figs. 46).—General principles of cheese manufacture are presented in this eighth edition (E. S. R., 64, p. 376).

Technical literature of ice cream for 1941, A. LEIGHTON. (U. S. D. A.). (*Ice Cream Rev.*, 25 (1942), No. 9, pp. 26-28, 52, 54, 56-62).—A comprehensive review, including a classified bibliography of 261 references.

Sugars in ice cream, C. D. DAHLE. (Pa. State Col.). (*Ice Cream Rev.*, 25 (1942), No. 9, pp. 24-25, 44).—Various sweetening agents that may be used in ice cream manufacture are discussed as to their effects on the sweetness and freezing of the product.

Use of corn syrup solids in ice cream, J. W. KNECHTGES and H. H. SOMMER. (Univ. Wis.). (*Ice Cream Rev.*, 25 (1942), No. 11, pp. 22-23, 62-64, figs. 2).—Studies of the effects of different percentages of sucrose and substitutes on the freezing point and acidity of ice cream are presented. Corn sirup lowered the freezing point less than sucrose unless the replacement was made at the rate of 5 lb. corn sirup to 4 lb. sucrose. As much as 25-33½ percent of the sucrose could be replaced in ice cream mixes without interfering with the taste, body, texture, melting behavior, or whipping ability. No significant differences in consumer preference were noted when 4 percent sucrose was replaced by 5 percent corn sirup in the mix containing 16 percent sucrose.

Corn syrup solids—their use in ice cream, J. W. KNECHTGES and H. H. SOMMER. (Univ. Wis.). (*Ice Cream Trade Jour.*, 38 (1942), No. 7, pp. 14-15, 42-45, fig. 1).—Same as above.

**Conserving chocolate coating, J. H. EMB.** (Ohio State Univ.). (*Ice Cream Trade Jour.*, 38 (1942), No. 4, pp. 28, 63, fig. 1).—General directions for the conservation of chocolate and its use for dipping ice cream bars are given.

**Substitutes for coconut fat in dipping chocolate, J. J. SCHEURING and P. H. TRACY.** (Univ. Ill.). (*Ice Cream Rev.*, 25 (1942), No. 12, pp. 23, 38, 40).—A number of experiments were conducted in which part of the coconut oil in the chocolate coating of ice cream bars was replaced by domestic oils and fats, singly and in combination. These results indicated that 8–15 percent low-melting point fats and 10–25 percent high-melting point fats were used successfully as substitutes for coconut oil. The best coating was produced with a combination of 5 percent each of hydrogenated and unhydrogenated soybean oils. A satisfactory substitute coating was made from 10 percent cocoa, 40 percent powdered sugar, and 35 percent hydrogenated and 15 percent unhydrogenated soybean oil.

**Reducing oiling off of frozen cream used in ice cream, J. C. HENING.** (N. Y. State Expt. Sta.). (*Ice Cream Trade Jour.*, 38 (1942), No. 7, pp. 20, 48–51).—Studies of the influence of pasteurization and cooling of cream on oiling-off showed that when milk is held cold prior to separation oiling-off of the frozen material is reduced, as contrasted with cream heat treated even though the viscosity is increased. There were no significant differences in the whipping properties of such cream. In carrying out these studies samples of milk were pasteurized at 145° F. for 30 min., 150° for 20 min., 160° for 15 min., 170° for 10 min., and 180° for 5 min. Following this procedure one half was cooled to 80° and separated, but the other half was cooled to 40° and held at that temperature for 20–24 hr. Later it was warmed to 80°–85° and separated.

**Stabilizers, H. H. SOMMER.** (Univ. Wis.). (*Canad. Dairy and Ice Cream Jour.*, 21 (1942), No. 7, pp. 58, 60).—A brief account of stabilizers used in ice cream manufacture and how they work, together with the needs of many of these substances for war purposes.

## VETERINARY MEDICINE

**The relationship between nutrition and disease in farm animals, L. P. DOYLE.** (Ind. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 100 (1942), No. 780, pp. 208–209).

**Nature of *Elmeria nieschulzi* growth-promoting potency of feeding stuffs.—III, Pantothenic acid, E. R. BECKER and L. SMITH** (*Iowa State Col. Jour. Sci.*, 16 (1942), No. 4, pp. 443–449).—It was found in further work (E. S. R., 87, p. 270) that when a particular ration, restricted in vitamin B<sub>1</sub>, vitamin B<sub>6</sub>, and pantothenate, and possibly certain other accessory food factors, was employed as "basal" the addition of calcium pantothenate effected moderate increases in the numbers of oocysts eliminated during *E. nieschulzi* infections. The additional supplement with vitamin B<sub>6</sub> was evidenced by a still further and more marked increase in oocyst counts. The addition of vitamin B<sub>1</sub>, or of both vitamins B<sub>1</sub> and B<sub>6</sub>, to the ration already supplemented with pantothenate did not result in the marked decrease in numbers of oocysts eliminated so characteristic of the B<sub>1</sub>+B<sub>6</sub> supplement to the ration lacking pantothenate supplement. Thus, pantothenate supplement counteracts the coccidium-inhibiting effect of the vitamin B<sub>1</sub> and B<sub>6</sub> supplement.

**Intravenous and subcutaneous administration of alkali-treated bovine serum albumin to man and lower animals, H. A. DAVIS and A. G. EATON.** (La. State Univ.). (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 246–248).—Alkali-treated bovine serum albumin, when administered by vein or by other parenteral routes, was found not toxic to human beings, dogs, rabbits,

guinea pigs, or mice and to possess little or no antigenicity. It was shown to be capable of raising and maintaining the blood pressure of dogs subjected to severe hemorrhage. It is pointed out that these findings suggest that alkali-treated bovine serum albumin may prove useful as a substitute for blood in man.

**Clinical findings in encephalitis (western equine),** J. D. ADAMSON and S. DURO (*Canad. Pub. Health Jour.*, 33 (1942), No. 6, pp. 288-300, figs. 4).

**The pathology of western equine encephalomyelitis: 18 human cases, Manitoba epidemic, 1941,** T. L. QUONG (*Canad. Pub. Health Jour.*, 33 (1942), No. 6, pp. 300-306, figs. 8).

**Western equine encephalomyelitis in infants,** H. MEDOVY (*Canad. Pub. Health Jour.*, 33 (1942), No. 6, pp. 307-312, fig. 1).

**Swine erysipelas infection in man,** L. VAN ES (*Nebraska Sta. Res. Bul.* 130 (1942), pp. 34, figs. 5).—This contribution, which supplements the author's report of investigations of swine erysipelas in pigs (*E. S. R.*, 88, p. 103), reviews the present knowledge of it as a human disease (erysipeloid), describing its more salient features, and examining them from epidemiological, clinical, pathological, and prophylactic viewpoints. Within the past decade it has spread throughout Nebraska's swine population and become a major problem of preventive medicine. A list of 115 references to the literature is included.

**The affinity of Newcastle disease virus to the influenza virus group,** F. M. BURNET (*Austral. Jour. Expt. Biol. and Med. Sci.*, 20 (1942), No. 2, pp. 81-88).—Report is made of the activity of the virus of Newcastle disease of fowl after inoculation by various routes in the chick embryo. In nearly every respect there is a striking resemblance to the behavior of well-adapted strains of influenza virus. Infected amniotic or allantoic fluids agglutinate red cells from several species; the reaction closely resembles the Hirst phenomenon with influenza virus and is specifically neutralized by immune serum. There is no serological relation between Newcastle disease virus and influenza viruses. After intranasal inoculation in mice Newcastle disease virus produces influenza-like consolidation of the lungs, sometimes fatal. Ferrets show no temperature response after administration of high titer Newcastle disease virus, but may develop a significant antibody response.

**Rickettsia-like organism from normal Dermacentor andersoni Stiles,** E. A. STEINHAUS (*Pub. Health Rpts. [U. S.]*, 57 (1942), No. 37, pp. 1375-1377).—Under the name *Rickettsia dermatrophila* an organism occurring spontaneously in the tissues of the tick *D. andersoni* is described as new. It cannot be cultivated on various artificial media, but is readily maintained by serial passage in incubating fertile chick eggs. The egg fluids, which constantly contain large numbers of organisms, were used as the transfer medium. It is nonpathogenic for laboratory animals and various rodent hosts of *D. andersoni*, and inoculated animals are not subsequently immune to Rocky Mountain spotted fever or American "Q" fever.

**Studies on staphylococcal toxins,** L. W. SLANETZ. (N. H. Expt. Sta.). (*Jour. Bact.*, 43 (1942), No. 1, pp. 105-106).

**On the isolation and growth of a bacteria-free strain of Trichomonas fetus in Minnesota,** M. D. SCHNEIDER. (U. S. D. A.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 787, pp. 245-247).—A bacteria-free strain of *T. fetus* was isolated in Minnesota through the use of a thermostable semisolid medium and a Glaser-Coria "V" tube. It is recommended that for bacteria-free isolation the material be taken from a direct vaginal wash of an infected cow, immediately washing the trichomonads by centrifugation and concentrating them to a small volume of 1 to 2 cc. of liquid medium. The washing seems to increase the motility of the trichomonads, thereby making the chance of isolation more

likely. Comparative microscopic examinations of vaginal wash material showed that in washing the sample thus taken by centrifugation and concentrating to a small volume one is more apt to be positive of the diagnosis. An eggshell modification was introduced for routine use in the sodium citrate and sodium carbonate mediums. Suggestions are made for preventing evaporation of the liquid parts of the medium when cultures are to be incubated for periods longer than 1 mo. *T. foetus* grows well under partially anaerobic conditions.

Studies pertaining to the antibacterial activity of sulfathiazole and its methyl derivative, R. D. MUIR, V. J. SHAMLEFFER, and L. R. JONES (*Jour. Bact.*, 44 (1942), No. 1, pp. 95-110, figs. 2).—Sulfathiazole and sulfamethylthiazole have been found to display practically identical bacteriostatic activities in vivo and in vitro under the conditions obtaining in the experiments reported. "The antibacterial activity of the thiazole drugs is significantly greater in the synthetic medium herein employed than in an ordinary nutrient broth. Viable cell counts made from cultures in synthetic media containing sulfathiazole reveal an initial lag phase in drug activity which is followed by a prolonged period of bacteriostasis. Similar cell counts made from nutrient broth cultures likewise exhibit an initial lag phase in drug action followed by a period of increase, logarithmic in character but reduced in tempo. Para-aminobenzoic acid and a few closely related compounds as well as a variety of bacteriological peptones and other commonly used ingredients of ordinary culture media were found to possess antisulfathiazole activity when tested under standardized conditions."

Synthetic phenol disinfectants, J. VARLEY (*Soap and Sanit. Chem.*, 18 (1942), No. 6, pp. 109-112).—It is shown from the results of intraperitoneal injection of a 1 : 10 aqueous dilution of disinfectants including liquor cresolis compositus, 50 percent cresylic disinfectant, and two newly developed types of synthetic phenol (coefficient 5) germicides that the first two mentioned are definitely more irritating to the skin of rabbits than the two types of synthetic phenol germicides. One of the synthetic phenol germicides appears to be the best material and the one most unlikely to cause dermatitis.

Evaluation of germicidal properties of sodium hydroxide and alkaline washing compounds, C. R. ARNOLD and M. LEVINE (*Iowa State Col. Jour. Sci.*, 16 (1942), No. 4, pp. 519-538, figs. 4).

Special report on diseases of cattle (*U. S. Dept. Agr., Bur. Anim. Indus.*, 1942, rev. ed., pp. VII+507, pls. 50, figs. 24).—A new edition of this work (*E. S. R.*, 51, p. 84) in which many of the parts have been revised by new contributors.

Some common diseases of cattle, G. H. CONN (*New York: Orange Judd Pub. Co.*, 1942, pp. 176, [figs. 36]).

Lesions of the Purkinje network of the bovine heart as a result of potassium deficiency, J. F. SYKES and L. A. MOORE. (*Mich. Expt. Sta.*). (*Arch. Pathol.*, 33 (1942), No. 4, pp. 467-471, figs. 3).—It was shown that rations low in potassium when fed to calves produced degenerative changes in the Purkinje fibers of the heart. These changes were accompanied by alterations in the electrocardiograms of the animals. The Purkinje fibers presented in varying degree a granular appearance. Vacuolation of the fibers was also observed in some instances.

Chronic bloat associated with a papilloma of the reticulum, A. F. SELLERS. (*Minn. Expt. Sta.*). (*Cornell Vet.*, 32 (1942), No. 3, pp. 321-325, figs. 2).—Report is made of the findings in a 2- to 2.5-year-old Holstein female that had suffered from an attack of coccidiosis with concomitant diarrhea from 6 mo. of age.

Arteriosclerosis in a clinical case of bovine Johne's disease, R. GIFFORD, D. F. EVELYTH, and W. GIFFORD. (*Ark. Expt. Sta.*). (*Vet. Med.*, 37 (1942), No. 10, pp. 416-420, figs. 8).—Report is made of a case of advanced arteriosclerosis in

a 3-year-old Hereford cow. The possible relationships of Johne's disease and other factors as predisposing influences are considered.

**Treatment of infectious keratitis in cattle,** M. W. EMMEL (Univ. Fla.). (*North Amer. Vet.*, 23 (1942), No. 3, p. 204).

**Intramammary injection of homogenized oil-sulfanilamide in the treatment of bovine mastitis,** J. C. KAKAVAS (Univ. Del.). (*Jour. Bact.*, 44 (1942), No. 2, pp. 262-263).—It was found in the treatment of bovine mastitis that sulfanilamide could be introduced into the udder of a cow very readily by properly suspending the drug in light liquid petrolatum. One lb. of sulfanilamide is added to 900 cc. of light liquid petrolatum and mixed thoroughly by means of a mechanical mixer. The mixture is then passed through a homogenizer, resulting in a thin uniform creamy suspension which remains stable. One cc. of the homogenized oil-sulfanilamide contains 0.378 gm. of sulfanilamide. In streptococcal mastitis the dosage recommended for an average size udder is 40 cc. of the homogenized product given daily for 4 days. If the infection persists the treatment may be repeated with safety. In staphylococcal mastitis the dose recommended is 80 cc. of the product given daily for 4 days and repeated if indicated. The homogenized oil-sulfanilamide as used in these experiments was well tolerated and no contraindications have been manifested in the cases treated. There was no appreciable decrease in milk production during or after treatment. When 103 cows, 100 infected with *Streptococcus agalactiae* and 3 with *S. uberis*, were treated for streptococcal mastitis by intramammary injections with homogenized oil-sulfanilamide, the bacteriological findings indicated cures were effected in 92 cows and partial or no improvement in 11. Of the 265 quarters treated, 251 were cured and 14 were not.

**The role of gramicidin in bovine mastitis therapy,** W. J. MULCHINOCK (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), No. 4, pp. 95-101).—Following a brief review of the literature, the details of three experiments are reported. They show gramicidin to be an effective agent in the treatment of bovine mastitis caused by *Streptococcus agalactiae*.

**Studies in the epidemiology of Q fever.**—IX, The role of the cow in the transmission of human infection, E. H. DERRECK, D. J. W. SMITH, and H. E. BROWN (*Austral. Jour. Expt. Biol. and Med. Sci.*, 20 (1942), No. 2, pp. 105-110, fig. 1).—In this further contribution (E. S. R., 87, p. 111) it is shown that cattle are susceptible to Q fever, and in the endemic area natural infection occurs among them. It is probable that the cows become infected from the animal reservoir by means of ticks (other than *Boophilus annulatus microplus* Can.), and that they can then transmit the infection to humans either directly from their tissues or indirectly from the crushed tissues or feces of their ticks.

**Experiments on the transmission of rinderpest through the agency of *Tabanus orientis*, with remarks on the feeding habits of this fly,** H. R. KAPUR (*Indian Jour. Vet. Sci. and Anim. Husb.*, 11 (1941), No. 2, pp. 84-93, figs. 2).—Of two healthy bulls that were subjected to bites of wild *T. orientis* flies partially fed on rinderpest-infected animals, one developed typical symptoms of the disease, which eventually progressed to a fatal issue. Observations on the feeding habits of *T. orientis* have shown that the fly seldom takes more than one complete feed in captivity but that under field conditions it usually continues to feed until it is fully engorged. These facts make it impossible for this fly to play any important role in the spread of rinderpest. The virus of rinderpest is viable in the body of the fly for a minimum period of 30 hr. and inert at 48 hr.

**Clinical observations in bovine trichomoniasis,** A. T. and R. GILYARD (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 787, pp. 276-278).

**Experimental infestation with *Fischoederius elongatus* in a calf at Madras.** S. N. VAIDYANATHAN (*Indian Jour. Vet. Sci. and Anim. Husbandry*, 11 (1941), No. 3, p. 243).

**Lungworms of domestic sheep and bighorn sheep in Wyoming.** R. F. HONESS (*Wyoming Sta. Bul.* 255 (1942), pp. 24, figs. 27).—In the investigation conducted two species of lungworms were found infesting bighorn sheep in Wyoming, namely, *Protostrongylus rushi* Dikmans 1937 and *P. frosti* n. sp. Of these, *P. frosti* was the more serious, its damage to lung tissue, while not dependent completely upon a nutritional-bacterial complex, being irreparable. No special pathology was observed for *P. rushi*. It is pointed out that *Dictyocaulus filaria* is the only lungworm known to infest domestic sheep in Wyoming.

**Observations on *Babesia foliata* n. sp. from a sheep.** H. N. RAY and K. RAGHAVACHARI (*Indian Jour. Vet. Sci. and Anim. Husbandry*, 11 (1941), No. 3, pp. 239-242, pl. 1).

**Phenothiazine as an anthelmintic for sheep.** V. E. WHITEHURST, JR., and L. E. SWANSON. (Fla. Expt. Sta.). (*Jour. Anim. Sci.*, 1 (1942), No. 3, pp. 256-259).—The experiments reported led to the conclusion that phenothiazine may be effectively administered to sheep grazed on grain crops. Doses of 25 gm. per adult sheep, given at monthly intervals, were effective in controlling stomach worms in sheep. The drug was not toxic or objectionable when given with feed. No serious staining of the wool was observed from the use of phenothiazine.

**The foot-worm disease in deer of the northern Rocky Mountain region.** R. M. DeNio and R. M. WEST. (U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 7, pp. 540-543, figs. 2).—Report is made of the recent discovery of an important disease of deer and elk in the northern Rocky Mountain region. This disease is known to occur mainly in western Montana but may have a far wider distribution. Frequently diagnosed erroneously as foot rot due to *Actinomyces necrophorus*, it was found by W. M. Rush in 1933 to be caused by the footworm parasite *Onchocerca cervipedis*, previously classified as *O. flexuosa*. The affection is confined almost entirely to whitetail and mule deer; 19 percent of 424 deer examined were infected. The highest rate of occurrence is in adult animals, and 69 percent of the infected adults were males. The life history of this organism has not been studied and its mode of transmission is unknown, consequently control measures have not yet been attempted.

**Photosensitization produced in pigs by phenothiazine.** W. E. SWALES, W. D. ALBRIGHT, L. FRASER, and G. W. MUIR (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), No. 6, pp. 169-172).—The data presented show that phenothiazine may induce photosensitization and other toxic reactions in pigs. It is suggested that pigs treated with this chemical should be protected from direct sunlight for at least 3 days afterward. Pigs less than 70 days of age should not be treated with phenothiazine.

**Cell changes in gall bladder as an aid in the diagnosis of hog cholera.** W. H. BOYNTON, G. M. WOODS, F. W. WOOD, and N. H. CASSELLBERRY. (Univ. Calif. et al.). (*Vet. Med.*, 37 (1942), No. 7, pp. 288-290, figs. 2).—A study conducted with a view to expediting the diagnosis of hog cholera resulted in the finding that the nuclei of both the glandular and epithelial cells of the gall bladder stained very sharply and distinctively, inclusion bodies being observed in the nuclei of many of the glandular cells. These bodies stained a deep magenta and were easily differentiated from the nucleoli, which stained a light blue. In all the non-cholera cases the glandular and epithelial cells failed to take the stain readily. Thus, a manifestly different and easily discernible microscopic picture can be obtained from the gall bladder scrapings of cholera-infected pigs.

**Crystal violet vaccine for the prevention of swine fever, T. M. DOYLE** (*Vet. Jour.*, 98 (1942), No. 3-4, pp. 51-64).—The author has found that the immunity conferred by crystal violet vaccine for the prevention of hog cholera is complete by about the twelfth day and persists under laboratory conditions for at least 10 mo. Vaccinated pigs did not transmit the infection to in-contact pigs. Repeated lots of vaccine of a reasonably uniform potency were prepared.

**Sulfaguanidine in the treatment of infectious enteritis in swine, H. C. H. KEENKAMP and M. H. ROEPKE** (Univ. Minn.). (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 268-269).—The treatment with sulfaguanidine of 133 swine affected with infectious enteritis in both the acute and chronic form generally checked the diarrhea, with the feces returning to normal consistency by the fourth or fifth day. About 92 percent of the animals recovered, 7.5 succumbed, and 0.75 percent made no improvement. This preliminary work suggests that an effective dose lies within the range of 0.165 to 0.33 gm. per kilogram of body weight (7.5 to 15 gm. per 100 lb.). In preliminary toxicity trials no evidence of ill effects was noted with dosages below 0.66 gm. per kilogram of body weight. The daily dose was divided between morning and evening and administered in capsules or mixed with small amounts of feed. The treatment was continued for 3 or 4 days after the condition became normal.

**A new *Salmonella* type, J. J. MONTEVERDE** (*Nature* [London], 149 (1942), No. 3732, p. 472).—The name *S. bonariensis* is suggested for a new *Salmonella* type isolated by the author in Buenos Aires from the mesenteric gland of a normal pig. Its characteristics are described.

**The use of *Brucella abortus* vaccine in fistulous conditions in horses, H. SUMNER** (*Vet. Rec.*, 54 (1942), No. 26, pp. 257-258).—Reference is made to the successful use of Nator B dead *B. abortus* vaccine in 4 cases of poll evil and 6 cases of fistulous withers without any other treatment or untoward results of any kind. All but 2 of 15 succeeding cases of quittor, including 10 reactors to the agglutination test for *B. abortus*, when treated with a dead vaccine made a complete recovery. Agglutinins were present in 2 cases in a dilution of 1:10 only, 3 cases in 1:20, 4 in 1:40, and 1 in 1:80. The vaccine is given subcutaneously and the dose repeated every 5 to 8 days until recovery takes place. The period of treatment with vaccine averaged 6 weeks. No local medication was applied. No constitutional reaction has been observed when the dead vaccine is employed.

**The relationship of St. Louis encephalitis virus to the equine encephalitis problem, with notes on results of inoculation of horses with St. Louis encephalitis virus, M. S. SHAHAN, L. O. MOTT, R. L. KNUDSON, O. L. OSTEN, and L. T. GILTNER** (U. S. D. A.). (*Vet. Med.*, 37 (1942), No. 8, pp. 339-345, figs. 2).—This contribution, presented with a list of 19 references to the literature cited, reports upon intracerebral inoculations of 14 horses with St. Louis encephalitis virus. Eight horses that recovered from inoculation with St. Louis encephalitis virus were found to be immune on reinoculation. Three horses which recovered from St. Louis encephalitis virus were susceptible to intracerebral inoculation of western equine encephalomyelitis. The St. Louis virus did not appear in the blood in amounts demonstrable by mouse inoculation following the intracerebral inoculation of the horses. Differences in the symptoms observed in horses inoculated with St. Louis encephalitis and western equine encephalomyelitis viruses are pointed out. The results of a limited number of in vitro neutralization tests of blood serum collected from horses injected with St. Louis encephalitis virus are given.

**The anthelmintic activity of Ficin in dogs, T. J. BROOKS, JR., and H. W. BROWN** (Univ. N. C. et al.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 787, pp. 250-253).—In a series of eight dogs the enzyme "Ficin," obtained from

the latex of *Ficus dollaria* grown in Brazil, was found to be 100-percent effective in removing *Ascaris* spp. from the intestinal tract. It was 96-percent effective against *Trichuris dispar*, 13.6 percent effective against *Ancylostoma caninum*, and totally ineffective against *Dipylidium caninum*. It also appeared to have no effect on the microfilariae of *Dirofilaria immitis*, or on *Diectophyme renale*, either in the kidney or in the body cavity.

**Distemper studies in ferrets, II-V** (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), Nos. 6, pp. 176-181; 7, pp. 204-207; 8, pp. 234-238; 9, pp. 262-267).—Four further contributions are reported (E. S. R., 87, p. 571).

II. *Tissue vaccines prepared from viscerotropic distemper virus*, E. A. Watson and L. M. Heath (pp. 176-181).—A vaccine prepared from composite formalized ferret tissues, exclusive of spleen, indicated higher immunizing properties than a vaccine prepared from spleen tissue alone. Vaccines prepared from various formalized ferret tissues indicate immunizing properties in all tissues tested except heart and brain. The immunizing values of the various tissue vaccines were in the following order: Trachea-lung and kidney, gall-urinary bladders and stomach, and liver and spleen. Heart and brain tissues were worthless as vaccines. Vaccinated ferrets were more susceptible to infection by contact exposure than by the subcutaneous inoculation of virus.

III. *Tissue vaccines prepared from neurotropic distemper virus*, L. M. Heath and E. A. Watson (pp. 204-207).—It was found that formalized tissue suspensions composed of either brain tissue alone or composite tissues from ferrets manifesting symptoms of distemper protected ferrets against homologous or heterologous strains of virus when inoculated subcutaneously. The formalized brain suspension, however, gave no protection against homologous virus in brain suspension inoculated intracerebrally, while the formalized composite tissue gave 50 percent protection against similar infection. No evidence was found to indicate that the immunizing properties of tissue vaccines were correlated with the presence of inclusion bodies in the tissue from which vaccines were prepared.

IV. *Protective, therapeutic, and aggressin properties of composite tissue vaccine*, E. A. Watson and L. M. Heath (pp. 234-238).—The authors found that the minimum period required to establish immunity with the tissue vaccine employed against subcutaneous infection was 5 days, while a period of 8 days was necessary when infection was by contact. The tissue vaccine employed indicated no therapeutic action on the course of the disease after infection by either the subcutaneous inoculation of virus or by contact. The experiment furnished no evidence that the vaccine contained aggressin properties.

V. *Immunizing and therapeutic properties of anti-distemper serum*, L. M. Heath, E. A. Watson, and P. J. G. Plummer (pp. 262-267).—It was apparent that passive immunity against contact exposure was of short and varied duration, the length of which was apparently dependent on the interval between serum treatment and exposure. The shorter the interval, the longer was the immunity. Active immunity was established when antiserum was administered simultaneously and as late as 3 days after the subcutaneous inoculation of virus. This type of immunity was, however, less evident when ferrets were exposed to infection by contact before serum treatment. There are no curative properties in the antiserum when administered in a single dose after the appearance of visible symptoms.

**Histologic adaptation of the fox encephalitis virus**, R. G. GREEN and J. C. BARTON. (Univ. Minn.). (*Jour. Bact.*, 44 (1942), No. 2, p. 253).—The finding of the distribution of inclusion bodies indicates that the fox encephalitis virus is adapted primarily to growth in vascular endothelium and grows secondarily in pia-arachnoidal cells and hepatic cells. This virus does not seem adapted

to invasion of nerve cells. The symptoms of encephalitis appear to be caused by destruction of the cerebral vascular endothelium.

The pathology of Chastek paralysis in foxes, a counterpart of Wernicke's hemorrhagic polioencephalitis of man, C. A. EVANS, W. E. CARLSON, and R. G. GREEN. (Univ. Minn. et al.). (*Amer. Jour. Pathol.*, 18 (1942), No. 1, pp. 79-91, pl. 1).—This contribution is presented with a list of 14 references to the literature.

Two larval cestodes from the muskrat, D. J. AMEEL. (Kans. State Col. et al.). (*Amer. Micros. Soc. Trans.*, 61 (1942), No. 3, pp. 267-271, figs. 7).—A list is given of the helminth parasites, including percentages of infection per species, that were found on examination of 252 muskrats taken during the trapping seasons of 1928 and 1929 largely from southern and central Michigan. This is followed by descriptions of two unidentified larval cestodes.

Woolly-pod or broad-leaved milkweed (*Asclepias eriocarpa*) poisoning of rabbits, E. L. VAIL (*North Amer. Vet.*, 23 (1942), No. 8, pp. 539-542).—The woollypod or broad-leaved milkweed here considered, which grows in many sections of California and in abundance in southern California, proved to be poisonous to domestic and western cottontail rabbits. The leaves and stems, fresh or air-dried, and the latex of this plant are all poisonous to the rabbit. The most marked symptoms are progressive anterior and, to a lesser degree, posterior paralysis. The rabbits at first assume a "humped" position, later become prostrate and comatose. Following coma, death occurs within a few hours. The autopsies reveal congested blood vessels and a hemorrhagic condition in practically all vital organs. Rabbits seldom eat the plant except when it is mixed with hay or straw. The air-dried plants lose much of their objectionable odor and taste, thus becoming more palatable to domestic rabbits unaccustomed to fresh, green feed.

Observations of mortality during the course of poultry breeding operations in Canada, S. S. MUNRO (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 787, pp. 256-259, figs. 2).

Coccidiosis in chickens, C. A. HERRICK and J. G. HALPIN (*Wisconsin Sta. Spec. Bul.*, rev. 1942, June, pp. 2).—A mimeographed revision of the practical account noted (E. S. R., 77, p. 546).

The periodicity of oocyst discharge in coccidial infection of chickens, P. P. LEVINE (*Jour. Parasitol.*, 28 (1942), No. 4, pp. 346-348, fig. 1).

Preservation of avian malaria parasites by low-temperature freezing, R. D. MANWELL and G. JEFFERY (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 222-224).—Report is made of the successful preservation of seven species of avian malaria plasmodia for periods up to 90 days by low-temperature freezing. Very rapid freezing and thawing seem of more importance than the occurrence of fairly considerable temperature variations. For maintaining stocks of malaria for research or class use this method of preservation has much potential importance. It is probable that all species of plasmodia can be preserved in this way equally well, and it does not appear that different stages of the parasite are much differently affected.

Chemotherapy and avian malaria, A. BISHOP (*Parasitology*, 34 (1942), No. 1, pp. 1-54).—This summary of knowledge of the subject is presented with a nine-page list of references to the literature cited.

Pullet disease: A cholera-like disease of poultry, J. F. RYFF and H. J. STAFSETH. (Mich. Expt. Sta.). (*Vet. Med.*, 37 (1942), No. 7, pp. 294-296, figs. 2; *abs. in Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, p. 71).—A practical account of the choleralike disease of young chickens and turkeys, reported upon by Jungherr and his associates at the Connecticut Storrs Experiment Station (E. S. R., 86, p. 96), which may in its various manifestations resemble botulism,

leucosis, fowl typhoid, and other bacterial affections. Work by the authors with *Escherichia coli* indicates that colon organisms are merely secondary invaders and not the cause of pullet disease.

**Pullorum like infection of fowl**, A. R. YOUNIE (*Canad. Jour. Compar. Med. and Vet. Sci.*, 6 (1942), No. 6, pp. 172-173).—A further report is made of the affection of fowls indistinguishable in history and symptoms from pullorum disease previously noted (E. S. R., 85, p. 827).

**Twenty-second annual report of pullorum disease eradication in Massachusetts**, H. VAN ROEKEL ET AL. (*Massachusetts Sta. Control Ser. Bul.* 112 (1942), pp. 11).—In further eradication work with pullorum disease (E. S. R., 86, p. 391), during the 1941-42 testing season 687,824 samples (662,715 chickens and 5,109 fowl other than chicken) were tested. In 368 chicken flocks, 653,080 birds were tested and of these 591,628 were in nonreacting flocks. The percentage of positive tests was 0.27. No reactors were detected among tested birds in 5 of 13 counties. The marked increase (99,153) over the previous season in the number of birds in nonreacting flocks reveals further progress in the establishment and maintenance of pullorum-free flocks.

**A preliminary report on a method of vaccination against Ranikhet disease [of poultry]**, J. R. HADDOW and J. A. IDNANI (*Indian Jour. Vet. Sci. and Anim. Husband.*, 11 (1941), No. 2, pp. 113-121).

**Certain nutritional requirements of the fowl cestode *Raillietina cesticillus* (Molin) as demonstrated by short periods of starvation of the host**, W. M. REID. (Kans. Expt. Sta. et al.). (*Jour. Parasitol.*, 28 (1942), No. 4, pp. 319-340, figs. 2).—Observations upon short starvation periods of chickens infected with *R. cesticillus* (E. S. R., 86, p. 383) having led to the conclusion that profound changes must be induced in these parasites by lack of proper food in the gut of the host, a more comprehensive study was made by using the combination of starvation and chemical analyses of worms removed from starved and control hosts. It was found that 20 hr. of host starvation is sufficient to reduce the glycogen content of *R. cesticillus* to about one-eleventh of its normal level. "This reduction in the glycogen store is believed to be responsible for the loss of strobilae in starvation because insufficient muscular energy is available to counteract the action of peristalsis. A daily fluctuation occurred in the glycogen level of tapeworms in the gut of chickens under normal feeding habits from 7.14 percent at 6 p. m. to 3.68 percent at 6 a. m. It is thought that this fluctuation, which is dependent upon the presence of available food material in the host gut, explains the release of proglottids only at certain hours during the day. These findings afford proof of the importance of glycogen in the metabolism of cestodes. The mean percentage composition of *R. cesticillus* removed from the fowl under normal feeding conditions at 6 p. m. was found to be 79.46 percent water, 6.51 percent glycogen, 3.2 percent ether-soluble extract, 1.14 percent nitrogen, and 2.36 percent ash content. Compared with other work, the percentage of water is considerably lower than that in the other forms which have been completely analyzed, with correspondingly high glycogen, nitrogen, and ash values for this worm.

"Crowding of *R. cesticillus* in heavy infections causes a dwarfing in the size [of] the cestodes as measured by weight. The diminished carbohydrate level in the host intestine due to food consumed by the worm does not appear to be sufficient to produce this effect. Proglottid counts supplemented with rather complete infection data are of value in estimating the number of worms in a living fowl—information of value in anthelmintic and certain other experimental fields."

A two-page bibliography is included.

"Field experiments in the use of sulfur to control lice, fleas, and mites of chickens, M. W. EMMEL (*Florida Sta. Bul.* 374 (1942), pp. 8, fig. 1).—In reporting further (*E. S. R.*, 77, p. 858) the author presents the results of a series of field experiments aimed at determining the value of sulfur in the control of ecto-parasites of the fowl. Chicken lice (the large and small body louse, shaft louse, and fluff louse) were completely eradicated from 10 farm flocks by feeding 5 percent of dusting sulfur in the regular mash for a period of 3 weeks and scattering sulfur over the soil in the yards at the rate of 2 lb. per 100 sq. ft. Sticktight fleas were completely controlled by a similar procedure in 8 farm flocks. Combined infestations of lice and fleas were controlled successfully on 7 farms by the same procedure. Sulfur getting onto external parts of the birds appears to be the important factor in this means of control. The common chicken mite was controlled successfully on 8 farms by dusting sulfur about the house and on the litter, dropping boards, and nesting material.

The efficacy of phenothiazine for the removal of the cecal worm of chickens, R. W. ALLEN, L. OLIVIER, and H. O. PETERSON. (*U. S. D. A.*). (*Vet. Med.*, 37 (1942), No. 10, pp. 412-415, figs. 5).—In the experimental work reported, details of which appear in table form, phenothiazine administered for 4 consecutive days at daily dose rates of 0.05, 0.1, and 0.5 gm. removed 12.6, 91.7, and 99.8 percent, respectively, of the mature or nearly mature *Heterakis gallinae* from naturally infected chickens. Of the three dosages tested, 0.5 gm. was the most effective. The drug has no significant lethal effect on the unexpelled worms, and on the basis of the weight data there was no evidence to indicate that it affected the chickens adversely.

Some effects of feeding phenothiazine to chickens in various amounts, L. G. NICHOLSON and E. C. McCULLOCH. (*Wash. Expt. Sta.*). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 786, pp. 205-209, figs. 7).—In experimental work the prolonged medication of hens over a period of 85 consecutive days with 1 gm. per day of phenothiazine, which is twice the maximum recommended single therapeutic dose, exerted a deleterious effect upon body weight, egg production, and hemoglobin concentration, and perhaps mortality of the hens. Four of the six hens receiving this amount of phenothiazine, which averaged approximately 0.505 gm. per kilogram per day for 85 days, or a total of 42.8 gm. per kilogram, survived. When six hens were given 0.5 gm. per day, which is the maximum recommended single therapeutic dose, for 85 consecutive days no significant effect was observed upon body weight, egg production, or hemoglobin concentration, and all survived. The feeding of mash containing 2,000 gm. of phenothiazine per ton for 61 days had no deleterious effect upon body weight, egg production, or hemoglobin concentration.

Phenothiazine vs. hemoglobin in chickens, B. MERIWEATHER (*Vet. Med.*, 36 (1941), No. 7, pp. 374-375, fig. 1).—In determining the toxic effect of phenothiazine upon the blood of fowl, a fine-powdered commercial form was administered to four groups of nine birds each, members of the first group receiving 0.5 gm. each, the second 1 gm., the third 2.5 gm., and the fourth 5 gm. The hemoglobin average was determined for each group of birds, using a Dare's hemoglobinometer in all the determinations, the readings on each bird being made at intervals of 24, 48, 72, and 96 hr. after dosing. A drop in the hemoglobin content amounting to approximately 2 gm. per 100 cc. of blood resulted, the decrease being most noticeable 48 hr. after administration, after which a gradual rise in hemoglobin occurred. The decrease in hemoglobin of birds receiving 10 times the therapeutic dose did not differ materially from that in birds receiving the normal dose, possibly due to the fact that a large part of the drug was eliminated unchanged in the feces when large doses were adminis-

tered. It is pointed out that while the anemia is of considerable duration in the Equidae it is evanescent or of no consequence in the fowl.

**Cochlosoma rostratum** from the turkey, E. McNEIL and W. R. HINSHAW. (Univ. Calif.). (*Jour. Parasitol.*, 28 (1942), No. 4, pp. 349-350).

Two new *Salmonella* types with related specific antigens, P. R. EDWARDS and D. W. BRUNER. (Ky. Expt. Sta.). (*Jour. Immunol.*, 44 (1942), No. 4, pp. 319-324).—The first of two new species, isolated from the liver of one of a group of poults affected with a fatal disease and represented by the antigenic formula (VIII):1, (v) . . . -1, 6 . . . , is described under the name *S. amherstiana*. The second, isolated from a child affected with gastroenteritis and from normal human carriers and represented by the antigenic formula [I], IX, XII . . . :1, z . . . -1, 5 . . . , is described under the name *S. javiana*. Attention is called to the complexity of the phases containing antigen 1.

**Heterakis isolonche** Linstow (1906) in a pheasant, with remarks on tuberculosis and gapeworms, F. R. BEAUDETTE. (N. J. Expt. Stas.). (*Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 787, pp. 274-275).—Report is made of the finding of *H. isolonche* in an emaciated golden pheasant found dead on a farm near New Brunswick, N. J. This nematode is the cause of nodular or verrucose typhilitis of pheasants.

Reducing coccidiosis in California valley quail during captivity, C. M. HERMAN and J. JANKIEWICZ (*Calif. Fish and Game*, 28 (1942), No. 3, pp. 148-149, fig. 1).—Fifteen California valley quail (*Lophortyx californica*) infected heavily with coccidia (*Eimeria* spp.) at the beginning of the experiment were kept in elevated wire-bottomed cages. Daily examinations showed a gradual reduction, and by the end of 1 week very few oocysts could be found in the material from any of these birds, indicating that the larger number of parasites more likely to injure the health of the birds is maintained only with continual reinfection.

The protozoan blood parasite *Haemoproteus lophortyx* O'Roke in quail at the San Joaquin Experimental Range, California, C. M. HERMAN and B. GLADING (*Calif. Fish and Game*, 28 (1942), No. 3, pp. 150-153, figs. 3).—Data are presented upon a survey of blood smears from valley quail in the San Joaquin Experimental Range from September 1937 to September 1940. *H. lophortyx* infection was found in 84.3 percent of the 503 quail examined. Intensity of infection has been tabulated by the number of parasites present per 10,000 red blood cells. A greater percentage of infection was noted in birds under 1 yr. of age than in adults during all months of examination except in August and September, when the reverse was true.

Occurrence of psittacosis-like infection in domestic and game birds of Michigan, B. EDDIE and T. FRANCIS, JR. (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 291-295).—Complement-fixation tests with the virus of meningo-pneumonitis in Michigan revealed that 61 of 100 pigeons reacted with the antigen, 41 of them in dilutions of 1:32 or greater. Pigeon serum fails to give the cross-reaction with lymphogranuloma venereum antigen which is commonly seen with human serum. Reactions of variable intensity were obtained with 22 of 100 serums from domestic turkeys, with 5 of 24 serums from domestic ducks, and, in the lowest dilution only, with 9 of 45 chicken serums. No reactions were observed with the serums of 90 wild fowl.

## AGRICULTURAL ENGINEERING

Recent findings in agricultural engineering, R. W. TRULLINGER. (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 6, pp. 181-185, fig. 1).—This is a review of the agricultural engineering work of the State experiment stations in 1941.

Under the heading of machinery and power are taken up better use of tractors and power equipment, more efficient tillage methods and equipment, better mechanical planting and fertilization of field crops, mechanical harvesting, weed-control equipment, spraying and fumigating equipment, and orchard heaters. The topic erosion and runoff control methods and equipment covers much of the work of the State stations in cooperation with the U. S. D. A. Soil Conservation Service. The discussion of rural electrification deals with farm freezing units, electric pig and lamb brooders, electricity in dairy farming, and electric fencing. Under the head of farm structures are included better farm homes, poultry-production structures, and crop storages.

**Engineering contribution to war program in agriculture, H. L. BROWN** (*Agr. Engin.*, 23 (1942), No. 7, p. 231).—This is a brief general discussion noting the place of soil conservation measures, increased use of electricity, and farm machinery in the expanding food production program.

**Improving efficiency of farm labor to meet wartime demands, E. W. LEHMANN and H. P. BATEMAN.** (Univ. Ill.). (*Agr. Engin.*, 23 (1942), No. 9, pp. 277–280, figs. 2).—Some of the topics taken up are training of operators and repairmen, extending the use of machines, improving tractor efficiency and economy, an engineering approach to selection and effective use of power and machinery units, an accident and fire prevention program, and plans to carry out the program.

**Agricultural engineering in India, M. VAUGH and M. D. STRONG** (*Agr. Engin.*, 23 (1942), No. 7, pp. 230–231, figs. 2).—The authors give a very brief account of the primitive agriculture of the Indian farmer and of the “first and only agricultural engineering course in southern Asia.”

**Irrigation water supply system capacities, C. V. GIVAN.** (Univ. Calif.). (*Agr. Engin.*, 23 (1942), No. 9, pp. 281–283, figs. 2).—The author presents a graphic method for determining time and quantity of irrigation required from the rate-of-loss curve, water-holding capacity of the top 6 ft. of soil, and the time required to saturate this known capacity of the top 6 ft. at a continuous supply rate of 1 cu. ft. per second. The graphs shown apply to a prune orchard at Davis, Calif., on a Yolo loam capable of holding 0.83 ft. of readily available moisture in the top 6 ft. Under the soil and climatic conditions specified moisture contributions from rainfall between the time in March when transpiration began and the end of October are not considered important.

This graphical method of accounting for changes in the soil-moisture regimen has not been applied to other problems where rates of loss and soil-moisture capacity are different. It is believed, however, that the method can be used to solve even more complicated problems of this type, and might be useful in determining the rates at which any material should be supplied from one or more sources for storage in a series of places where it is required that stored material be available at all times during which it is to be withdrawn from each storage place at known rates of withdrawal.

**A short method of determining volume of run-off from water-stage recorder charts, T. L. COPLEY.** (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 6, pp. 189, 192, figs. 2).—By the new method the area under the runoff graph is divided into horizontal rather than vertical intervals, and the discharge rate for each interval is multiplied by the average length or duration of the strip to secure the interval and total discharge. In using this method it is necessary first to determine the height of the horizontal interval to be used. For charts with a  $\frac{1}{2}$ -gauge height ratio for small plats a 0.02-ft. stage is suggested for accurate reading, since this will be a small division on the chart. The narrower the strip the greater the accuracy obtained and also the greater the amount of

calculation. It is pointed out that only total volume of runoff can be determined by this short method. When hydrographs are to be prepared or rates of runoff or infiltration determined, the conventional method must be used.

**Preparing brush land for pastures, R. H. MEANS** (*Mississippi Sta. Cir. 108* (1942), pp. 7, figs. 6; also in *Miss. Farm Res. [Mississippi Sta.] 5* (1942), No. 9, pp. 1, 8, figs. 5).—The author reports the clearing of land abandoned for from 2 to 20 yr. at a cost of \$2.38 per acre, the original clearing being done by hand labor with axes, followed by burning of the brush in place and subsequent mowing to keep down sprouts. Mowing two or three times per year was found sufficient. Satisfactory pasture was obtained. Clearing at the cost reported involved the use of labor at 10 ct. per hour, and for this and other reasons mentioned no approximation of the average cost throughout the State could be made. It is believed, however, that much land abandoned from cultivation can be prepared for pasture at a not prohibitive cost.

**Soil admixtures for earth walls, R. L. PATTY.** (S. Dak. State Col.). (*Agr. Engin.*, 23 (1942), No. 9, pp. 291–294, figs. 5).—At least 80 percent of all soil types, as they will be found on farms over the United States, will be satisfactory for use in rammed earth walls. Two-thirds of these could be used just as they are dug providing the outside surface of the wall is to be protected with stucco or plaster. The other one-third will need at least a small proportion of sand added, even though they are to be plastered. A recommended admixture of sand will make a high percentage of these walls good enough to stand indefinitely as bare walls. For farm buildings no admixtures other than sand are necessary. The sand will make a high-quality soil and the wall may be left standing for a year or two. If it begins to roughen too much it will be in the right condition for stuccoing.

Cinders can be substituted for sand as an admixture to a low-quality soil. Cinders reduced shrinkage and cracking of the wall like sand and reduced the strength in the same proportion. They can be used up to one measure of cinders to one of soil if the wall is to be plastered. Portland cement greatly increased the strength of rammed earth walls when the sand content of the soil was high, but only slightly when the sand content was low. Five percent of portland cement by volume was found insufficient for weather resistance, but 10 percent may prove satisfactory. Snow and ice damaged earth walls containing portland cement admixtures (soil-cement walls) when left in contact with them, and the damage to soil-cement walls was definitely greater than to plain rammed earth walls. Fiber admixtures when well distributed through a soil increased the strength of the wall slightly. Asphalt emulsion has shown very satisfactory results as a stabilizing admixture for earth walls. It lends itself well to adobe-type construction in which the oil can be mixed into puddled soils or mud.

Plating or veneering rammed earth walls with the same soil stabilized with a dependable admixture proved a satisfactory process.

**Terrace construction by plowing, D. E. SPRINGER** (*Agr. Engin.*, 23 (1942), No. 9, pp. 284, 286, figs. 4).—Some of the advantages of plow-constructed terraces are that the equipment required is available on most average-sized farms in the Corn Belt; the tractor and plow are generally in good condition, and there is no extra work for a farmer to get ready; terraces are constructed more economically with a plow than with some of the conventional terracing machines; one man can do the job—an important factor in a time of farm labor shortage; a farmer uses the same methods for maintenance as for construction; and farmers who practice contour farming can easily build terraces without special assistance. Laying out contour lines at terrace spacings and grades expedites

this work. Some cautions are (1) do not start terrace construction until the terrace system has been designed and satisfactory terrace outlets are established; (2) do not start on too many terraces at one time—build each one sufficiently high to afford protection before starting construction on another; (3) build the top terrace first and work downhill, taking each terrace in succession; and (4) do not give up with the plow method until several replowings of the once-plowed soil have been made—the fact that the plow does not scour is not a sign that it is not moving the soil.

**Sapwood depth and absorption limits in round coast Douglas fir timbers,** J. D. MACLEAN. (U. S. D. A. coop. Univ. Wis.). (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 117–127, figs. 5).—The author tabulates data on average depth of sapwood in coast Douglas fir poles and piling and formulates the calculation of preservative absorption maximum on the basis of the depth of sapwood, density or specific gravity of the wood, moisture content of the treated wood, diameter of the timber, and the length of the timber. Nomograms helpful in the required computations are included.

**The use of preserved wood in home construction,** H. L. REESE (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 263–267).—The author points out that, to meet the recommendations of the U. S. D. A. Bureau of Entomology and Plant Quarantine, about 20 percent of the lumber in an average house should be treated for termite and decay resistance, and states that such lumber could be furnished at about 1 percent increase in the total cost of the building. This would insure against much larger costs, incurred a few years later if termite attack has to be combatted.

**Creosote treatment of white pine piles,** J. F. HARKOM (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 149–150).—From experimental treatments of 2 charges, the first of 7 pieces 6 ft. long and from 10.5 to 14.5 in. in diameter and the second of 11 pieces 8.5 ft. long and from 12 to 16 in. in diameter, the author found that it should be possible to treat white pine piles with 12 lb. of creosote per cubic foot of wood after from 4 to 8 weeks of air-seasoning. Time, temperature, and pressure details of both treatments are stated.

**Preservatives, priorities, and processes,** G. M. HUNT, R. H. BAECHLER, and J. O. BLEW, JR. (U. S. D. A.). (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 62–84).—The authors believe that the quantity of creosote produced in 1942 for wood preservation from domestic sources will considerably exceed the domestic production in 1941, but that we have entered 1942 with such low stocks that the amount of domestic creosote available for use in 1942 may not exceed that of 1941. The preservative salts in common use or potentially applicable are all of more or less limited availability. Zinc chloride seems least likely to be seriously restricted, but not one of them will be available in unlimited quantities and any or all of them may be less available for wood preservation in 1942 than in 1941. The only toxic preservative that seems, at present, likely to be more available in 1942 than in 1941 is pentachlorophenol. Extenders for creosote and solvents for pentachlorophenol, either in the form of ordinary fuel oils or aromatic byproducts of petroleum cracking processes, seem likely to be available in any quantity that may be needed for wood preservation. Among the substitute materials or practices that seem most promising for immediate use if needed for large volume treating requirements are use of higher percentages of petroleum or tar in creosote solutions, raising the limits on the percentage of creosote distillation residue above 355° C. where such limits have been set up, and use of pentachlorophenol in petroleum solutions.

**A study of several products of Disco type low temperature coal tar as wood preservatives,** J. J. REID. (Pa. State Col.). (*Amer. Wood-Preservers'*

*Assoc. Proc.*, 38 (1942), pp. 435-447).—The author reports upon wood preservation experiments with fractions obtained from a coal tar formed at relatively low temperature (450°–500° C.) carbonization of coal. Species of *Fomes*, *Lentinus*, *Lenzites*, and *Porla* were used as test organisms. The preservative designated brown solution is described as an aqueous alkaline solution of certain high-boiling compounds, mostly relatively insoluble tar acids of which little, if any, is found in ordinary high temperature coke-oven or gas-retort tars. With suitable procedures, this brown aqueous solution impregnated into wood acts as a nonbleeding preservative, much of which does not leach out under severe test conditions. The second of these preservatives is Disco creosote, a distillate rather similar to, but not identical with, the creosote from low-temperature carbonization for which the service records have been available for some years. The residue from distillation of Disco-type creosote to 355° contains a considerable amount of tar acids and has been found in the preliminary portion of this study to be more toxic to *Fomes* species than the corresponding residue from distillation of high-temperature creosote.

Test blocks of yellow pine sapwood treated at various retentions with each type of preservative made from Disco tar and others treated at various retentions with recognized good commercial preservatives were air seasoned for several months, subjected to severe leaching, and finally exposed to two standard test organisms. Some retentions of both old and new preservatives were low enough to permit early attack. The order in which the blocks showed attack is recorded, together with the relative condition at the end of 9 months' exposure. The effectiveness of adequate treatment with brown solution when treatment has been followed by seasoning and severe leaching was established. The stabilized type of brown solution did not require as high retention as the purified type. Disco creosote compared favorably with high-temperature creosote in this series of tests, including those in which an unusually high-boiling grade of the oil was employed.

Quantity of wood treated and preservatives used in the United States in 1941, R. K. HELPHENSTINE, JR. (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 498-523, figs. 11).—Statistics compiled by the U. S. D. A. Forest Service, with the cooperation of the American Wood-Preservers' Association, for the year 1941 are presented with interpolated discussion.

A study of fireproofing standards for pressure-treated lumber, L. K. ANDREWS (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 462-481, figs. 9).—Various degrees of fire resistance can be obtained by impregnating wood with various retentions of fire-retarding salts (of which only borax and boric acid are specifically named). Fire resistance increased as the retentions of fire-retardant salts were increased, but no substantial degree of fire resistance was observed for retentions less than 3 lb. per cubic foot of wood. Retentions in excess of about 6 lb. per cubic foot were found apparently not justified, however, the increased fire resistance being very slight. The fire tube, crib, and special crib test methods appeared reliable for determining the effectiveness of fire-retardant treatments, but the timber test was not.

Corrosion studies with certain fire-retardant chemicals, A. VAN KLEECK. (U. S. D. A. coop. Univ. Wis.). (*Amer. Wood-Preservers' Assoc. Proc.*, 38 (1942), pp. 160-171, figs. 3).—Under the specific conditions of these tests, the solutions without sodium dichromate were definitely corrosive to all of the metals except borax with respect to brass, steel, and zinc, and the borax-boric acid mixture with respect to steel. Sodium dichromate inhibited corrosion to a greater or less degree in most instances but actually accelerated corrosion by monoammonium phosphate and diammonium phosphate and the monoammonium

phosphate-boric acid mixture with respect to zinc, and zinc chloride with respect to steel. At the concentrations used the minimum quantity of sodium dichromate necessary for good effectiveness was shown to be in the range of 2.5 percent of the fire-retardant chemical present.

**Gearing farm machinery to the war effort, F. A. WIRT** (*Agr. Engin.*, 23 (1942), No. 9, pp. 285-286, fig. 1).—The author points out that the responsibility of agricultural engineers under present conditions is threefold—(1) to assist in bringing about the best possible use of such new machines as the manufacturers may be permitted to build, (2) to promote efficient use of old machines through proper servicing and stocking of repair parts by implement dealers, and (3) to make known to men in authority their knowledge on all matters pertaining to the application of engineering in agriculture. Comparing the present with two previous wars, the author shows that American production of agricultural machines was increased sharply in 1861-64 and again in 1917-18, and that in England mechanization of agriculture has been greatly increased during the present war. In this country, however, although the farm machinery manufacturers are ready with new designs of more efficient machines with which to do the jobs, for the first time there is a lack of materials out of which to build the machinery needed. He quotes a British agricultural engineering publication to the effect that whereas America has one tractor to every 2 sq. miles, approximately, England now has one to about half that area. He maintains that the only way the food needed by ourselves and our allies can be produced is to have available sufficient farm machines, and that to produce these machines more materials are required than now appear likely to be allocated in 1943. "It should never be forgotten that food, as ammunition for the stomachs of our soldiers, is just as important as ammunition for their guns."

**Farm machinery suitable for southern farms, I. F. REED** (U. S. D. A.). (*Agr. Engin.*, 23 (1942), No. 6, pp. 186-188, figs. 4).—The author holds that the design of equipment suitable for the one-mule unit has been unduly neglected. It is believed to have been the general opinion of engineers, with respect to the operators, very numerous in the South, of one-mule or two-mule units "that the power available to these farmers so limited their operations that there was little that engineers could do to help." As one example of the possibilities of small-unit equipment, it is pointed out that although the one-mule farmer must use a small plow and a small slip scraper he can make a good terrace and do most of the work during slack times. A small, lightweight V drag is also effective and can be made cheaply on almost any farm. Of small plow attachments showing promise for turning green manure crops, a small coulter with one wire and a jointer are described. Other implements discussed included a single-row stalk cutter and a peanut planter equipped with a large shovel which opens the bed ahead of the planting mechanism.

**Methods of handling hay** (*Agr. Engin.*, 23 (1942), No. 6, pp. 193-198, figs. 5).—This is a symposium made up of the following discussions: The Significance of Homemade Sweep Rakes, by W. Vutz (p. 193); Sweep Rakes on Indiana Farms, by R. C. Shipman (pp. 193-194) (Purdue Univ.); Baling Method of Haymaking, by L. G. Samsel (pp. 194-195); The Chopping and Storing of Hay, by F. W. Duffee (pp. 195-196) (Univ. Wis.); The Automotive Buck Rake in Ohio, by C. B. Richey and R. D. Barden (pp. 196-198) (Ohio State Univ.); and Factory-Made and Homemade Sweep Rakes Compared, by F. D. Jones (p. 198).

**The improved single-impulse electric fence, C. F. DALZIEL** (Univ. Calif.). (*Agr. Engin.*, 23 (1942), No. 9, pp. 287-290, figs. 7).—To the fundamental circuit of step-up transformer, two thermionic rectifying tubes, impedances, and con-

denser, the author adds a relay alternatively connected to break either the secondary or the primary transformer circuit and a milliammeter, the relay being of a type opening instantaneously but closing by a delayed action and improving the safety of the fence by accelerating the collapse of the condenser discharge to a voltage harmless to man or animals and incapable of maintaining an arc. A small lightning arrester connected directly across the output terminals protects the condenser from minor static disturbances and from the effects of distant lightning discharges.

The single-impulse electric fence controller is considered to possess two advantages over all other types: (1) Safety—regardless of the time of contact with the fence wire, a human being or an animal receives one and only one single powerful shock; and (2) effectiveness—the fence wire is maintained ready to produce a shock instantly on contact at all times. It is believed that an improved single-impulse electric fence controller with a reasonable leakage current allowance, as here described, should give performance superior to any commercial controller now available.

Electric power serves the dairy farm, G. Q. BATEMAN (*Farm and Home Sci. [Utah Sta.]*, 3 (1942), No. 3, pp. 5, 10, figs. 3).—The author reports concisely upon cost trials of (1) a small hammer mill powered by a 1½-hp. motor used for the grinding of grain for the dairy herd, (2) a three-unit milking machine, (3) a cream separator used to separate skim milk for calves, (4) a 10-gal. water heater, and (5) a utensil sterilizer cabinet. The value on the farm of a small electric motor and the use of electric fly screens for the milk room are also briefly discussed.

Dual motion development in a farm milk refrigerator, J. E. NICHOLAS. (Pa. Expt. Sta.). (*Agr. Engin.*, 23 (1942), No. 7, pp. 219-222, figs. 6).—This paper reports the results of cooling fresh milk (1) when the water bath and the milk can were both in motion at the time of loading and the water:milk ratio was 1:7; (2) when the water bath and the milk were both in motion at the time of loading with a 4:9 water:milk ratio; (3) when the method of cooling was as in (2), except that the motion of the water bath and that of the milk was delayed 15 min.; and (4) when the method of cooling was similar to that of (2) and (3), except that the motion of the water bath and that of the can was delayed ¾ hr.

After a delay in agitation there was a separation of the cream and the formation of a cream layer after the third hour, and its rate of cooling was much slower than that of the remainder of the milk. A longer delay in agitation had approximately the same effect on the cream layer. Delay in cooling milk for several hours after it is drawn may cause a more complete separation of the cream and subsequent slower cooling, and uniform cooling is more difficult to obtain. Under specified conditions, dual motion provided most uniform cooling when milk was placed to cool soon after it was obtained.

A study of egg cooling methods, J. W. WEAVER, JR., R. L. BRYANT, and C. ROGERS. (U. S. D. A., Va. Expt. Sta., et al.). (*Agr. Engin.*, 23 (1942), No. 7, pp. 223-229, figs. 11).—The authors did not observe any significant loss in egg weight, either with or without cooling, during holding periods of from 4 to 6 days. Where eggs are sold from the farm semiweekly through a market which considers quantity only, or quantity and weight, there can be no financial gain by cooling eggs. Where eggs are sold on the basis of U. S. Standards of Quality for Individual Eggs or an adaptation of this system, during hot weather a consistent gain in net income of from 1 to 2 ct. per dozen will be effected when eggs are cooled by a carefully selected method. The value of

cooling eggs increases with the length of the holding period on the farm, and with the distance between producer and market increases at least up to 258 miles requiring 2 days in transit.

Taking into consideration economy as well as effectiveness, the most practical of the various coolers tested was that depending upon a wet burlap curtain through which air was driven by a small electric fan. Such a cooler can be constructed for about \$25, including labor. When eggs are shipped twice each week, this cooler has a weekly capacity of six 30-doz. cases, allowing space for cases to be precooled and trays where eggs are initially stored for quick removal of heat.

**Improvement of fungicidal and insecticidal effectiveness of dusts** (*New York State Sta. Rpt. 1942, p. 29*).—Greatly increased deposition and retention of sulfur dusts, obtained by means of a new dusting machine which provides for vaporizing a small quantity of an oil onto the dust as it leaves the nozzle, are noted.

**Machinery for processing sweet potatoes for livestock feed**, F. A. KUMMER. (Ala. Polytech. Inst.). (*Agr. Engin.*, 23 (1942), No. 7, pp. 215-216, figs. 4).—The author maintains that southern farms are in an unfavorable position with respect to production of carbohydrate feeds, as the yields of corn and other grains are low. The sweetpotato, equal to corn in feeding value, is one crop which is well adapted to the South, fits well into a livestock program, and gives high yields from an acre. In the dried form sweetpotatoes furnish a concentrate comparable to corn, barley, oats, or other grain crops.

As an inexpensive drying surface for sun drying, a soil surface impregnated with asphalt priming oil proved most satisfactory. For shredding, a low-cost machine was made up largely from used automobile parts. A rear axle assembly with wheels and drive shaft was used for the driving mechanism. The torque tube and drive shaft were cut off to a suitable length, and an appropriate length of a separate rear axle, having the tapered and threaded end, was attached to the drive shaft. The drive shaft and torque tube were rotated 90° so as to operate in an upright position. A straight drive shaft roller bearing and race welded into the top of the torque tube provided alignment for the axle part of the drive shaft. Two pieces of 3-in. angle iron were welded to the bottom of the axle housing to support the hopper frame. One axle was cut off 12 in. from the differential and the remaining part of the axle was locked in the housing. The opposite wheel was utilized as the driving pulley. The shredding mechanism was made from a steel disk  $\frac{5}{16}$  in. thick and 20 in. in diameter. A wheel hub flange was turned to fit into a  $1\frac{3}{4}$ -in. center hole in the disk and bolted into place. The disk was attached to the axle part of the drive shaft. The tapered and keyed end of the axle provided a mounting for the disk flange. The shredding knives were beet-type cosette cutters bolted to the disks over three slots which allowed the shredded material to fall below the disk. A 55-gal. oil drum was cut into two parts and both ends were removed. One-half of the drum was mounted on an angle iron frame directly above the cutting disk to serve as a hopper for the sweetpotatoes. The other half was mounted below the disk to prevent scattering of the shredded material. For transportation, a threaded stub shaft was welded into the end of the axle housing opposite the driving wheel which held the wheel in position and allowed it to idle on the hub bearing. A simple angle iron hitch was welded to the lower frame. The machine could be operated at comparatively high speeds. A power unit of at least 5-hp. capacity was needed. A 5-hp. electric motor and also a tractor with belt pulley was used success-

fully. In a test run, using tractor power, 80 bu. of sweetpotatoes were shredded in 15 min.

**A castor bean sheller, M. A. SHARP.** (Univ. Tenn.). (*Agr. Engin.*, 23 (1942), No. 6, p. 188, fig. 1).—This sheller operates on the same principle as the small machine previously described (E. S. R., 87, p. 125). The rubber-faced disks are 12 in. in diameter and rotate at 525 r. p. m. No stop bar or rings as used around the central feed opening in the stationary disk of the small machine are necessary on this one, but V grooves about  $\frac{1}{16}$  in. wide in the rubber disks improved the efficiency slightly on varieties shelled. The 3- by 16-in. suction fan, running at 1,000 r. p. m., removes all hulls, immature beans, and dust. A  $\frac{1}{2}$ -hp. electric motor is used.

**Temperature studies in various types of potato storage houses, T. E. LONG** (*North Dakota Sta. Cir.* 66 (1942), pp. [4], figs. 4).—The author tabulates fall, winter, and spring temperatures in a bin in a farm-type storage, a bin in a medium-size trackside storage, and bins in two deep bin trackside storages, together with mean monthly temperatures and departures from normal from October 1941 to March 1942, inclusive. He notes that the individual operator will find these records a useful guide to the probable temperature in his own particular type of storage.

**Bulk handling of potatoes, H. BERESFORD** (*Idaho Sta. Cir.* 86 (1942), pp. 7, figs. 4).—The author describes a pick-up cart having a 6-ft. 10-in. tread, a 6- by 6- by 2-ft. box, and a differential hoist for dumping, and shows its construction detail. Other features of bulk handling are very briefly noted.

**Plywood for grain bin construction, F. C. FENTON.** (Kans. State Col.). (*Agr. Engin.*, 23 (1942), No. 7, pp. 217-218, 222, figs. 5).—It is claimed that the bin described has some unusual features besides being the first circular all-plywood bin. It is entirely free from vertical framework, thus making full use of the strength qualities of the plywood. It has only three horizontal hoops, made by gluing together four 3-in. strips of plywood. These hoops serve more to give shape to the structure than for needed strength. The bin has walls 8 ft. high, so that one panel applied vertically extends the full height, and is 14 ft. in diameter, a size which permits triangular roof sections to be cut from standard size plywood 4- by 8-ft. panels with almost no waste. The normal strength of plywood (due to the cross banding of the layers of wood used in making plywood) is utilized in the walls as the plywood sheets are glued and bolted together into a one-piece covering which literally is wrapped around three laminated plywood hoops. Design of the bin was drawn specifically to provide a simple granary which could be erected on the farm by the farmer and his helper, or prefabricated by the lumber dealer and hauled to the farm. It can be built by the ordinary handy man, and the design requires no intricate operations.

The specifications are, in part: Capacity, 1,000 bu.; foundation, four 4-in. concrete walls, 12 in. high and about 3 ft. on centers, decking of 2- by 10-in. planks spaced 3 in. apart (a simpler and less expensive foundation would serve); floor,  $\frac{3}{8}$ -in., exterior-type fir plywood over 2- by 2-in. joists spaced 12 in. on centers; framework, three laminated plywood hoops on inside of wall at top, bottom, and midheight (hoops are  $3\frac{1}{2}$  in. wide, formed of four thicknesses of  $\frac{3}{8}$ -in. exterior plywood glued, clamped, and nailed together); wall covering,  $\frac{3}{8}$ -in. exterior-type fir plywood (covering applied in one sheet after 4- by 8-ft. plywood panels have been bolted and glued together into a continuous strip to be wrapped around hoops); roof,  $\frac{3}{8}$ -in. exterior-type fir plywood over 2- by 2-in. rafters spaced about 2 ft. at perimeter and supported at center by a 16-in. ring of sheet steel; and finish, two coats raw linseed oil and

two coats of varnish on walls, two coats oil and two coats aluminum paint on roof.

Results of tests made on  $\frac{1}{4}$ -in. plywood joints using bolted joints, bolted and glued, nailed and glued, each with lapped joints, and butted joints with splice battens are tabulated. Glued and nailed joints seemed to be the most promising method of joining plywood for grain bin construction. Because of the regular thickness, excellent joints can be made by clinching small nails by driving them against a steel plate laid under the joint, a quick and easy method of joining plywood together on the job.

**Refrigerated farm apple storages**, D. COMIN (*Ohio Sta. Bul. 632 (1942), pp. [1]+68, figs. 16*).—This is a somewhat detailed treatment of building requirements and the choice and effective use of mechanical cooling equipment. The location, size, and construction of the building to be refrigerated for apples are discussed. The dry-coil, forced-air, floor-mounted units are held to afford the greatest satisfaction and economy in refrigeration for apples. Ducts for the distribution of the cooled air are considered an unnecessary expense unless two or more rooms are to be cooled by a single unit. Evaporative or shower-type condensers and cooling towers, which save up to 95 percent of the water that otherwise would be needed to condense the refrigerant, are proving very popular. It has proved feasible to reuse the water pumped through waste water condensers (shell-and-tube, shell-and-coil, and shell-and-finned tube types) by exhausting it on the storage roof either through ordinary orchard spray nozzles or directly onto the roof, where it is cooled sufficiently for reuse after collection in a large reservoir tank. Small window-mounted evaporative-type condensers used as one or more units are very economical and have the advantage of operating as strictly air-cooled condensers as winter approaches and the air temperature drops sufficiently to allow dispensing with water entirely. By using them, the need for heating the machine room to keep the water pipes from freezing is eliminated. It is pointed out that in selecting cooling units (evaporators) of the finned-tube, forced-air type, it is of the utmost importance to have sufficient total coil area that the maximum daily cooling load can be handled with no more than from 8° to 10° F. difference between the refrigerant and air temperatures, and that a proper design will automatically maintain an 85-percent relative humidity during the holding period in a reasonably vaportight room. Other topics dealt with are humidification, arrangements for entirely automatic operation of the refrigeration system, holding temperatures for apples in storage, calculation of the peak heating load to be handled by a proposed refrigeration system, and insulation.

The results of storage tests carried on over a period of years with apples emphasized that the seasonal effect was primarily responsible for the appearance of disorders, with the exception of shrivel, which showed no significant difference due to season. The variety was also of great importance in the occurrence of disorders, including shrivel. The effect of storage, container, and time in storage was not so strongly evident. There was more shriveling after 5 mo. in the refrigerated storage with gravity air movement (33.5 percent) than in one where the air was moved by blower fans (21.5 percent), because of the higher relative humidity held in the latter through the maintenance of higher average refrigerant temperature. There was nearly twice as much shriveled fruit in the crates (36 percent) as in the boxes or baskets (21.7 percent), but in the latter containers there were two and two-thirds times as many scalded fruits. Shriveled fruit appeared to a small extent (8 percent) after 75 days in storage and nearly doubled in quantity by the hundredth day (14 percent), after which the increase in number of fruits showing shrivel was moderate until the two-

hundredth day (24 percent). Scald appeared slightly in 100 days (4 percent), nearly doubled in 150 days (7 percent), and nearly doubled again (13 percent) by the two-hundredth day. The relative humidity of the storage air is of the greatest importance, since fruits should be stored in slatted crates to lessen the occurrence of scald. Forced-air cooling equipment maintaining a high refrigerant temperature answers these requirements.

**Investigations in low-cost housing**, D. G. CARTER (*Arkansas Sta. Bul.* 422 (1942), pp. 46, figs. 35).—This study of low-cost housing includes an investigation of costs and construction of nine houses in Arkansas, one example of remodeling, and the installation of six sets of plumbing equipment. The variations in the size, material, cost, and method of construction did not permit basing definite conclusions on totals or averages. The data, however, are held to reveal certain general results and possibilities for cost reduction.

Of the total calculated cost of conventional houses, approximating 10.9 ct. per cubic foot, with approximately 2 ct. per cubic foot added if plumbing and electricity are included, about 75 percent was cash expenditure. The value of the noncash, or home, contribution of materials and labor was approximately 50 percent where a definite effort was made to obtain maximum reduction of cash expenditure. Unskilled labor may be used for almost all of the construction work in low-cost housing if some technical supervision is given and planning aids are provided.

## AGRICULTURAL ECONOMICS

**Current Farm Economics**, [October 1942] (*Oklahoma Sta., Cur. Farm Econ.*, 15 (1942), No. 5, pp. 141-171).—Included are the usual review of the agricultural situation, and articles entitled: The Quality of Cotton Produced in Oklahoma in 1941, by K. C. Davis (pp. 149-153) and Some Characteristics of Oklahoma Farm Owners and Their Farms, by R. T. McMillan (pp. 156-164). The tables of prices, indexes of prices and purchasing power of Oklahoma farm products, and indexes of United States and Oklahoma prices, factory payrolls in the United States, and demand deposits in Oklahoma are brought down through August 1942.

**Wartime farming on the southern Great Plains** (*U. S. Dept. Agr., Misc. Pub.* 496 (1942), [pp. 12], figs. 26).—A popular account, very freely illustrated, of conservation farming in this region.

**Wartime farming on the northern Great Plains** (*U. S. Dept. Agr., Misc. Pub.* 497 (1942), [pp. 20], figs. 50).—This publication, prepared by H. L. Carr, is similar to the above.

**Oklahoma cotton in wartime: A comparison of Oklahoma production and military requirements**, K. C. DAVIS and W. A. WILLIAMS (*Oklahoma Sta. Cir.* 105 (1942), pp. 22, figs. 3).—"There is a so-called surplus of 10 million bales of cotton, but most of this cotton is short staple or low grades, or both, and under present conditions cannot be used in America. Therefore, the United States has a surplus of cotton and at the same time a shortage of usable cotton. From the standpoint of profit and also from the standpoint of patriotism, the Oklahoma farmer must not add to this stock of unusable cotton, but must produce the kind of cotton that can go into domestic consumption, namely, the middle staple lengths with grades as high as possible."

**Seedtime and harvest today**, R. G. HAINSWORTH, O. E. BAKER, and A. P. BRODELL (*U. S. Dept. Agr., Misc. Pub.* 485 (1942), pp. III+97, figs. 109).—This publication is based largely on Circular 183 (*E. S. R.*, 47, p. 295) and a Yearbook article (*E. S. R.*, 39, p. 495). Maps of the United States show by 10-day periods the dates of seeding and harvesting, and in some cases other operations,

for winter wheat, spring wheat, winter oats, spring oats, corn, cotton, tobacco, potatoes, sugar beets (thinning only), and field beans; and of harvesting grain sorghums, timothy and clover, alfalfa, Elberta peaches, Delicious apples, strawberries, cranberries and oranges, green or snap beans, cantaloups and muskmelons, green peas, onions, lettuce, and asparagus grown for sale. Other maps (usually for 1938 or 1939) show the number of tractors on farms; percentage of land broken (plowed, listed, bedded, etc.), disked, and harrowed with tractor-drawn implements; percentage of wheat acreages harvested with combines; percentage of acreage of small grains drilled with tractor-drawn drills, cradled, and harvested with tractor-drawn machines; oat acreage harvested by different methods; corn acreage planted by hand and machine method; percentage of corn cultivated with animal-drawn cultivators; acreage of corn cut by different methods; hay acreage cut by tractor- or animal-drawn mowers; percentage of cotton cultivated with animal-drawn cultivators; and percentage of seed cotton hauled to gin with animal and mechanical power. Graphs show monthly distribution of labor per acre in designated areas for growing, harvesting, and marketing spring and winter wheat; growing and harvesting corn; producing cotton; and growing, harvesting, curing, preparing, and marketing tobacco. Other graphs show the number of family and hired workers in agriculture in the United States 1900-40, the relation (1910-40) of employment in agriculture to size of agricultural enterprise, and the number of tractors and of mules and horses on farms on January 1, 1915 to 1941.

**An economic study of land utilization in Schuyler County, New York.** L. B. DARRAH ([*New York*] *Cornell Sta. Bul.* 781 (1942), pp. 40, figs. 29, map 1).—The county, the land-use problem, the crops, livestock and dairy production, types of farming, etc., are described. The rural lands are divided into five different classes for farming, and analysis is made of the land use by land classes and by tenure, the soils in each land class, the number and value of properties, the tax base in each town, etc. Programs are suggested for the development of roads, rural electrification, and reforestation.

**Significant changes in agriculture of Cumberland County, Tennessee.** C. E. ALBRED, H. J. BONSER, and E. J. LEBRUN (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog.* 139 (1942), pp. [1]+II+38, figs. 26).—Since many of the farms are self-sufficing, with a high degree of part-time farming, a relatively decentralized agricultural marketing system has developed, which operates largely through small markets and to consumers within the area. Beef cattle, sheep, and hogs are the principal types of livestock grown for market. The area in farms has decreased from 177,926 acres in 1860 to 128,874 acres in 1940. This has meant a decrease from 42.4 percent of the total area in farms in 1860 to 29.7 in 1940. Farms have decreased in size from 116.6 acres per farm in 1860 to 62.5 acres in 1940. The number of farms, on the other hand, have increased from 260 in 1860 to 2,063 in 1940. The total number of animal units increased from 5,241 in 1860 to 12,502 in 1940. Horses decreased in number, while mules increased in number. On a per-farm basis, the number of milk cows, beef animals, hogs, sheep, and poultry decreased in number, but due to an increased number of farms there was a greater number of each class of livestock in 1940 as compared to 1860.

**Economic conditions and problems of agriculture in the Yakima Valley, Washington.**—IV, Hop farming, H. F. HOLLANDS, E. B. HURD, and B. H. PUBOLS. (Coop. U. S. D. A.). (*Washington Sta. Bul.* 414 (1942), pp. 33, figs. 4).—Continuing this series of investigations (E. S. R., 87, p. 436), hops were grown successfully throughout parts of the valley, but several thousand acres of land not now producing hops are physically adapted to the crop. Acreage planted

to hops in the valley could be doubled if and when there are profitable market outlets. However, the hop industry will support relatively few farmers in a few favorable locations, and relatively large capital resources are required for hop growing. In 1937, the average cost of producing hops on 27 hop farms was 19.1 ct. per pound. Out-of-pocket expenses of 12 of the 27 hop growers were higher than the average price received for their hops, and total costs of production (out-of-pocket and all other) of 22 of the 27 growers were higher than the average price received, 16.8 ct. About 85 percent of the hop crop is marketed through dealers or handlers who buy directly from the producers or through appointed brokers and sell directly to the consumers and brewers. Many dealers also are producers, and only a small part of the crop is sold directly to consumers by growers who are not dealers.

**Satellite acres:** A study of 1,100 households in rural Rhode Island with income from combinations of non-agricultural employment and agricultural production, W. R. GORDON (*Rhode Island Sta. Bul.* 232 (1942), pp. 80, figs. 34).—Production for a major proportion of the families represented in this study was a spare-time endeavor, and what selling of products occurred was, in the main, by either of two methods, sales to the neighbors or sales to wholesalers, so that even the marketing was of the kind that requires a minimum of time and attention of the producer, or was such as could be done at irregular times. Subsistence and noncommercial production develop into part-time and commercial farming in the poultry and dairy enterprises. The nonagricultural work which these families combined with their agricultural production was subdivided into five major classes as follows: Semi- and unskilled, skilled, service, proprietary, and professional. Skilled workers and proprietors appeared to be more inclined to combine nonagricultural employment with agricultural production than the other three. But the largest proportion of each single class was in the back-yard and small-scale production divisions. The semi- and unskilled produced for home consumption. Skilled workers inclined to production for sale from small farming units. Proprietors inclined to commercial production. The nonagricultural employment was virtually full-time employment for most of the household heads. Two-fifths of all male heads were foreign-born. They came more frequently from farms. The Rhode Island natives were mainly from villages. Those from other States in the United States were mostly from cities. The data suggest the possibility that a combination of farming and nonagricultural employment is an arrangement engaged in by these people in their early middle years, foreign-born entering early and staying in it.

**The place of woodland in the farm organization in Coos County, New Hampshire,** J. M. CHANDLER. (Coop. U. S. D. A.). (*New Hampshire Sta. Bul.* 337 (1942), pp. 34, figs. 4).—Data concerning the present farming resources and organization, hours of man and horse labor used in woodland operations and additional labor available for such operations during a normal year, and the operator's interest in more woods work were obtained from 80 farms in three towns of the county. Information was also obtained as to prices and trucking costs. The woodlands, the markets for forest products, the labor situation, the present status of forest lands—ownership, merchantable timber, growth of timber, and income from timber—forest management, etc., are described and discussed. Illustrations as to how incomes might be increased are included for a medium-sized dairy-potato farm with a substantial acreage of woodland, a large dairy-potato farm with a small acreage of woodland, and a small dairy farm with little woodland.

**Agricultural finance: Principles and practice of farm credit, W. G. MURRAY** (*Ames: Iowa State Col. Press, 1941, pp. X+328, figs. 30*).—The first part of this textbook, principles of farm credit, includes chapters on use of farm credit; classification of farm credit; balance sheet analysis; income analysis; marginal analysis; natural hazards, insurance, and loan policy; price risk and loan policy; security and budgeting for short-term credit; buying a farm on credit; payment terms; interest rates; and credit instruments and foreclosure procedure. The second part, analysis of lending agencies, includes chapters on function and classification of lenders; insurance companies; farm mortgage middlemen; commercial banks; merchants and dealers; Farm Credit Administration and other public agencies; Federal land banks; Land Bank Commissioner loans and the Federal Farm Mortgage Corporation; joint stock land banks; foreclosure problems of F. C. A. agencies; the national farm loan association problem; intermediate credit bank system; production credit corporations and associations; banks for cooperatives, Commodity Credit Corporation, and Rural Electrification Administration; emergency crop and feed loans; Farm Security Administration program of rehabilitation loans and debt adjustment; tenant-purchase loans; and governmental farm credit and tenancy. Each chapter is followed by questions and problems and a list of references.

**Ninth annual report of the Farm Credit Administration, 1941 (U. S. Dept. Agr., Farm Credit Admin., Ann. Rpt., 9 (1941), pp. VI+273, figs. 22)**.—This report is of the same form as that for the previous year (E. S. R., 86, p. 544).

**Farm debt adjustment in Michigan through the Farm Security Administration, H. E. LARZELERE** (Coop. U. S. D. A. et al.). (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 47-65, fig. 1).—This article describes the policies and procedures followed by the Farm Security Administration farm county debt adjustment committees in dealing with individual debt adjustment cases and analyzes the assembled data with respect to the financial conditions of the applicants, the nature and extent of debt scale-downs effected by the committee mediations between creditors and debtors, and of refinancing arranged through the Administration. It is based on data obtained from the Milwaukee regional office of the Administration covering 523 debt adjustments in 65 counties of Michigan handled by the committees between 1937 and 1940.

**Characteristics and cost of short-term farm loans made by Ohio country banks, P. S. ECKERT and J. I. FALCONER** (*Ohio Sta. Bul.* 633 (1942), pp. [1]+22).—Detailed descriptions of 3,049 short-term loans were obtained from 81 country banks in 30 counties. The characteristics of the loans—size, purpose, length, renewals, payments, and security given—contract rate of interest, true per annum cost, etc.—are discussed. Analyses are made of 1,518 of the loans covering the costs of individual loans and of all loans combined, cost with different contract rates of interest, cost of loans of different sizes and lengths, cost according to number of payments, cost where interest was taken at maturity and where loans were discounted, cost with and without chattel mortgages, and cost with and without minimum charges.

Of the total loans studied, 84.7 percent were for less than \$500, the most common size being \$100. Most of the loans became due in 90 days. There was a direct relationship between length of "due periods" and size of loans. About 50 percent of the loans were paid at the first maturity date and about 20 percent before the due date. About two-thirds of all paid loans were paid without being renewed. Most of the remainder were paid with less than six renewals. Nine-tenths of the loans were paid with less than six payments and 55.6 percent with one payment. The median of the costs of 1,518 loans was 6.963 percent. There

was an inverse relationship between cost of loans and their size, the cost ranging from 11 percent for loans of less than \$50 to 6.3 for loans of \$1,000. Costs of loans decreased with length of loan up to 270 days. Discounted loans cost 7 percent, while loans with interest taken at maturity were 6.6 percent. The cost of all minimum-charge loans averaged 8.2 percent as compared with 6.6 for those without a minimum charge. For all loans there was but slight difference in the cost of those involving and not involving chattel mortgages. For loans of less than \$200 with and without chattel mortgages the cost were 8.9 and 7.4 percent, respectively.

**Interest charges payable on farm indebtedness in the United States, 1910-40.** H. T. LINGARD and W. O. BROWN (*U. S. Dept. Agr., Bur. Agr. Econ., 1942, pp. [1]+46, figs. 8*).—A summary of available data, in part previously noted (*E. S. R., 87, p. 488*).

**Agricultural credit in Germany.** W. BAUER (*[U. S. Dept. Agr.], Farm Credit Admin. [Bul. CR-1] (1939), pp. VI+98, figs. 5*).—This is the first bulletin of a series on agricultural credit in foreign countries. Part 1, Economic Aspects of the Agricultural Credit System, includes sections on sources of farm mortgage credit, economic history and background, debt-relief legislation and mortgage debt, agricultural credit under National Socialism, agricultural credit on personal security—short- and medium-term credit, and a statistical survey of total agricultural indebtedness. Part 2, Some Technical Aspects of the Basic Farm Mortgage Credit System, contains sections on organizational structure of lending agencies, methods and principles of raising or allocating funds for making farm mortgage loans, and lending policies. A bibliography is also included.

**Agricultural credit in Denmark.** W. BAUER (*U. S. Dept. Agr., Farm Credit Admin. Bul. CR-2, (1940), pp. [2]+IV+71, figs. 2*).—This is the second of the series noted above. Part 1, Economic Aspects of Agricultural Credit in Denmark, includes sections on the main characteristics of Danish agriculture, farm credit implications of the agricultural situation, and development and structure of agricultural indebtedness. Part 2, Organizational and Technical Aspects of the Agricultural Credit System, contains sections on mutual credit associations (*Kreditforeninger*), mutual mortgage associations (*Hypotekforeninger*), savings banks, other private mortgage creditors, government sources of mortgage credit, government sources of medium- and short-term credit, and private sources of medium- and short-term credit. A bibliography is also included.

**Agricultural credit in Canada.** J. L. WOOSTER and W. BAUER (*U. S. Dept. Agr., Farm Credit Admin. Bul. CR-3 (1941), pp. [2]+IV+63, figs. 2*).—This third bulletin of the series describes the situation of agricultural credit in Canada before World War II in sections on sources of agricultural credit, government-sponsored farm mortgage credit, history of government-sponsored farm credit in the Provinces, extent of indebtedness, and measures for the relief of indebtedness. Appendixes describe the land settlement credit schemes established by the Dominion and the Provinces and the Cooperative People's Banks of Quebec and include a bibliography.

**Land tenure policies at home and abroad.** H. W. SPIEGEL (*Chapel Hill: Univ. N. C. Press, 1941, pp. XII+171*).—Analyses and discussions are included in chapters on foundations of land tenure policy, the legal background of land tenure in the United States, facts and factors in European and American land tenure, farm tenancy policy, English land tenure policy, and land tenure under the Swastika. A bibliography covers the several sections of each chapter.

**An analysis of farm mortgage experience in Kent County, Delaware.** M. M. DAUGHERTY (*Delaware Sta. Bul. 237 (1942), pp. 65, figs. 21*).—The objective

of this investigation was to throw light on the safety of investments in farm mortgages in Kent County from 1912 to 1933, for the purpose of measuring the losses that have accrued, and thereby enabling lenders on the one hand and borrowers on the other to judge the risk involved. It is concluded that the experience in Kent County "does not indicate that the field of investment has been unprofitable, or that the lending or borrowing on farm mortgages is endowed with extraordinary hazards."

An analysis of the land acquisition program under Title III of the Bankhead-Jones Farm Tenant Act, T. E. WILKINS and G. B. MCINTIRE (*U. S. Dept. Agr. Soil Conserv. Serv., 1942, SCS-MP-26, pp. [1]+34, figs. 2*).—"The submarginal land purchase program of the United States Department of Agriculture is conducted by the Soil Conservation Service under authority of Title III of the Bankhead-Jones Farm Tenant Act, approved by Congress July 22, 1937. Under Title III of this act the Secretary of Agriculture is 'authorized and directed to develop a program of land conservation and land utilization, including the retirement of lands which are submarginal and not primarily suitable for cultivation, in order thereby to correct maladjustments in land use. . . .' In order to effectuate this program the Secretary of Agriculture is authorized to 'acquire by purchase, gift or devise, or by transfer from any agency of the United States or from any State, Territory, or political subdivision, submarginal land and land not primarily suitable for cultivation, and interests in and options on such land.' The purpose of this study is to show, in a general way, the procedures and methods employed in acquiring land under Title III of the act; to recommend changes in methods and procedures whereby the process of land acquisition can be improved; to analyze the effects of adjustments in methods and procedures on the progress of land acquisition; and to present information relative to the land and improvements acquired and data relative to the ownership and occupancy of the land previous to its acquisition. The information used in this study was obtained from the records and files of the Land Acquisition Division of the Soil Conservation Service. The period covered is from January 1938 to June 1941."

Special improvement district finance in Arkansas, E. E. SPARLIN (*Arkansas Sta. Bul. 424 (1942), pp. 32, figs. 8*).—"The chief purpose of this study has been to determine the indebtedness, extent of default, assessments levied, delinquency, income, and expenditures of special improvement districts, rural and urban, in relation to the financial operations of these districts. The methods used have included the collection of information from county, city, and district records on indebtedness, assessments charged and delinquent, and financial operations, and the arrangement of such information to reveal the essential facts pertaining to the financial problems of the districts." The legislation authorizing and the organization and administration of improvement districts in the State are briefly described. Tables are included and discussed showing data as to the indebtedness, assessments, delinquencies, etc., of levee and drainage districts, farm-to-market road, suburban road, fence, and paving, curb and gutter, sidewalk, sewer, water, light, and gas districts. The problems of the different types of districts and of the districts in general are discussed.

The indebtedness of the 619 improvement districts with debts outstanding in 1940 was \$34,547,782, of which \$3,436,751 was in default. In 1937 the 658 districts with assessments charged levied \$5,613,232 against the real estate within the districts. Of 8,738,195 acres in the levee and drainage districts, 3,304,390 acres were included in two or more overlapping districts. The percentage of levee and drainage assessments not paid when due, from 1928 to 1933, increased from 24.4 to 72.5 percent, and then decreased each year to 36.1 percent in 1939.

"Districts with annual assessments of less than 20 ct. per acre had 31.3 percent of their assessments delinquent in 1937, while those with \$1.50 and over per acre had 86.7 percent delinquent. . . .

"In the entire improvement district system in the State, whether rural or urban, there is need for a better coordination and administration. In the case of rural districts, present evidence indicates that the State should establish a department of government authorized to coordinate and, to the extent necessary from a State viewpoint, supervise these districts. As most of the rural districts have as their principal objective the control of water in the lowlands, the State agency established to better the improvement district situation should have sufficient powers to coordinate completely the protection and drainage efforts of all areas in the State subject to such problems. These reforms would eliminate the inadequate administrative methods now used, and, if intelligently administered, would greatly improve the usefulness of these districts, especially the drainage districts that often are not adequately performing the function for which they were established. In the case of municipal districts, because of their strictly local nature, major control might well remain with the municipality, with the exception that all such districts should be audited annually by the State. In each city one person should serve as secretary and collector for all districts. This increases the efficiency of handling the accounts, and places all records in a central office, where the municipal officials and citizens can more easily observe the transactions of the district."

**Farm buildings and the land**, J. T. STONE (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 32-40, figs. 9).—The author relates the type of farm buildings to the class of land in 5 counties. Of the 5,589 classifications made of farm homes, 51 percent were considered adequate, one-quarter were poor, 6 percent pioneer ventures, and one-fifth abandoned or unfit for occupancy.

**Haying practices and machinery in Knox County, Tennessee**, C. E. ALLRED and B. H. LUEKE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog.* 140 (1942), pp. IV+34, figs. 10).—The data for this report were obtained from a survey of 115 farms in 4 civil districts of the county made in 1939 by teachers of vocational agriculture in 2 high schools. Findings as to haying machinery and equipment, haying practices, quality of hay, losses of hay, and miscellaneous practices are presented and discussed.

**The prevention of accidents on farms and in homes** (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1942, pp. [3]+49+V).—"This report attempts an analysis of farm- and home-accident data collected from all available sources and representing practically all types and conditions of agriculture in the country. Although incomplete in regard to many sections, where information is not being collected, the data [are] believed sufficient to give basic direction for a generalized approach to the problem of prevention or compensation in the event of accidental injuries." The four sections of the report deal with farm and home accidents, organized programs for agricultural-accident prevention, articles of miscellaneous nature on agricultural accidents, and safety education in accident prevention. The fifth section, "report by States," includes analyses of available agricultural-accident data, together with notes on the application of farm labor to the provisions of workmen's compensation laws by States. Appendixes include tables showing by States the claims and medical expenses of farm labor under workmen's compensation and amount of payroll, policy years 1935 and 1936 combined; workmen's compensation premium rates for farm labor by States; individual accident reports of farm labor from workmen's compensation experience; and a suggested questionnaire form for reporting farm accidents.

**Size and efficiency in farmers' mutual fire insurance companies.** V. N. VALKEN (U. S. Dept. Agr., *Farm Credit Admin., Misc. Rpt. 54* (1937) pp. [2] + 28, figs. 8).—This study is based on data, compiled with the assistance of H. I. Johnston, for 1,804 companies for each of the years from 1935 to 1937, respectively. Analysis is made of the relations between annual costs of insurance and extent of business territory, volume of insurance, and concentration of business. The authors state that "in summary it may be said that, although a given business territory and a given volume of business may be more conducive to low cost than larger or smaller territories and volumes, they are at most minor contributing factors. Concentration of business, or at least a reasonable volume in relation to the territory operated in, is somewhat more significant as a cost factor."

**The marketing of Washington apples in Los Angeles, California.—Part II, Retail distribution.** M. T. BUCHANAN and E. F. DUMMEIER (*Washington Sta. Bul. 415* (1942), pp. 68, figs. 7).—This second bulletin of the series (E. S. R., 86, p. 851) is based on information obtained from representatives of 10 chain store headquarters and from the owners or managers of 220 individual retail outlets, of which 20 were in the high-income areas and 117 and 83, respectively, in areas of medium and low income. Ninety-seven of the records are for supermarkets and the remainder for stores grouped into 3 classes, primarily on the basis of size. The volume data are based on 1 week's sales during January or early February 1941 of oranges, apples, grapefruit, bananas, pears, and grapes. The data are analyzed and discussed in sections on quantities of fresh fruit sold weekly, retail prices and gross margins, waste or spoilage, and miscellaneous factors relating to apple marketing—condition, display, advertising, brands, pack, size, and source of retailer supplies.

The average weekly sales per store were: Oranges 1,002 lb., apples 774, grapefruit 432, bananas 250, pears 71, and grapes 11 lb. The average realized retail prices per pound (retail price adjusted for spoilage) were: Apples 5.3 ct., oranges and grapefruit 2.5, pears 4.7, bananas 5.4, and grapes 6.1 ct. The average gross margin on apples was 34.2 percent of the realized retail price. For the other fruits they were: Grapefruit 54.4, oranges 48.9, pears 34.2, grapes 29.3, and bananas 21.5 percent. Supermarkets made the higher gross margins. The gross margins in high-income areas were significantly higher than in medium- or low-income areas. Realized retail prices for apples, oranges, and grapefruit declined as the volume of sales increased. Average losses from waste or spoilage ranged from 3 percent for grapefruit to 5.6 for apples and bananas, and 5.9 percent for pears. About three-fourths of the supermarkets and one-third of the stores in the high- and medium-income areas and 8 percent of those in the low-income areas advertised apples. More than two-thirds of the retailers stated no brand preference. With the exception of Rome Beauty, medium-sized apples were preferred by all retailers.

**Livestock marketing practices in South Dakota.** W. P. COTTON (*South Dakota Sta. Bul. 362* (1942), pp. 79, figs. 44).—This study was a part of the regional study conducted in cooperation with 13 other State experiment stations in the Corn Belt area and the U. S. Department of Agriculture. The data for South Dakota were obtained from questionnaires mailed to 10 percent of the farmers in each county, 454 additional questionnaires obtained by personal visits, questionnaires obtained from 23 of 50 livestock auction agencies, 70 of the some 900 livestock dealers, truck buyers, and custom truckers, all (9) livestock shipping associations, all (9) packing plants, 1 concentration yard, and 17 retail meat dealers who did their own slaughtering. The State was divided into 7 areas on the basis of type of farming, together with distribution of differ-

ent species of livestock. Producers' practices when selling and when buying livestock, the market information used and the reasons for selecting particular types of markets, the characteristics and practices of the different marketing agencies, the regulation and supervision of marketing, and the livestock marketing problems in the State are discussed. The findings show both for South Dakota and the Corn Belt area for feeder and slaughter cattle, hogs, and sheep and lambs where sales and purchases were made, the size of lots, the relationship between sales of livestock and type of market, the average weight of animals, methods of transportation used, grades of animals, proportion of the animals handled through cooperative marketing associations, sources and disposition of livestock handled by different types of markets, trade of areas of different types of markets, etc.

Market classes and grades of dressed veal and calf carcasses, W. C. DAVIS and C. M. HARRIS (*U. S. Dept. Agr. Cir. 103, rev. (1942), pp. 32, pls. 18, fig. 1*).—A slightly revised edition (E. S. R., 63, p. 263).

Use of the level production plan in milk marketing, L. F. HERRMANN and W. C. WELDEN (*U. S. Dept. Agr., Farm Credit Admin., Misc. Rpt. 57 (1942), pp. [2]+23, fig. 1*).—The Chicago base plan of purchasing milk for the Chicago market was discontinued in 1939, and the level production, or quota, plan adopted in the Janesville market in 1940 was developed to encourage seasonal uniformity of production. "The present study compares the effect of both plans on producers' incomes and analyzes producers' own appraisals of the new plan. Personal visits to the farms of more than 50 of the producers supplying the Janesville, Wis., market afforded a broad cross section of producers' attitudes. Complete data on 5 years' milk deliveries of the 72 producers on that market in June 1941 were obtained from association records. The brief experience of the Janesville market is supplemented with conclusions drawn from 10 and 5 years' use of similar plans in the Chattanooga, Tenn., and Hartford, Conn., markets."

Cooperative creameries in South Dakota, W. P. COTTON, G. LUNDY, and L. M. BROWN (*South Dakota Sta. Bul. 363 (1942), pp. 31, figs. 9*).—Information regarding the organization, membership, patronage, trade territory, method of financing, buying and sales policies, and financial statements was obtained for 33 cooperative creameries in the State. Operation statements and balance sheets were obtained covering the business in 1938 and 1941. The characteristics of the dairy industry in the State and the organizational and characteristics of cooperative creameries are described. The financing of the cooperative creameries, the volume of business, methods of assembling butterfat, and butterfat buying policies are discussed. Analysis is made of the effects on net returns of volume of business, investment, cost of procurement, manufacturing and administrative expenses, percentage overrun, marketing operations, byproducts sales, and side line enterprises.

Honey marketing as the grocer sees it, G. N. MORRIS. (*Mich. Expt. Sta.*). (*Gleanings Bee Cult.*, 69 (1941), No. 8, pp. 492-493; *abs. in Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, p. 73).—This article briefly summarizes and discusses data obtained from a questionnaire returned by 230 independent retail grocers in 29 Michigan cities regarding kinds of honey sold, sources of supplies, advertising and displays, size of containers used, and suggestions for improvement of honey marketing.

Better income for truck growers as markets improve, M. GUIN (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, p. 7).—A brief statement is made regarding the average receipts, expenses, labor income, yields, prices for products, etc., for 80 Copiah County truck farmers in 1941.

**World wheat survey and outlook, September 1942, J. S. DAVIS** (*Wheat Studies, Food Res. Inst. [Stanford Univ.], 19 (1942), No. 1, pp. [2]+24, figs. 4*).—World net exports in 1941–42 were in the neighborhood of 400 million bushels, the smallest since 1896–97. Canada supplied some 55 percent of the total, Argentina about 20. Aggregate wheat supplies in the world ex-Russia are this year huge beyond all precedent, yet blockades and shipping stringency continue to limit drafts on burdensome overseas surpluses to 'relieve bread-grain shortages where they exist. Soviet Russia, whose food position has been seriously impaired by the Axis gains of recent months, needs more import wheat than is likely to reach her. Phenomenal crops in North America include bumper wheat harvests in the United States and Canada from record yields on the lowest acreage sown in many years. With enormous stocks of old-crop grain, North American wheat supplies for 1942–43 are over 50 percent larger than in the depression years of superabundance. Acute storage crises have been or are being successfully met, but at heavy cost. The 1943 carryover in North America may exceed 1,500 million bushels, which is more than the two countries ever produced in any year prior to 1942.

**Price comparisons for Arkansas rice, O. J. HALL** (*Arkansas Sta. Bul. 423 (1942), pp. 48, figs. 8*).—"The purpose of this study is to show the price paid Arkansas farmers for rough rice for the period 1931–32 to 1940–41. Factors that affect prices paid farmers for rice are considered, including price by varieties, grades, months, and mills. Relationship of rice prices to long-time planning for production is also treated." The data were obtained from purchase slips for from three to eight Arkansas mills. A table is also included and discussed showing the acreage, production, yield per acre, price per bushel, and purchasing power of rice in Arkansas, 1905–41.

The prices of rough rice, 1905 to 1940, varied from 35 ct. per bushel in 1932 to \$1.97 in 1919. During the period 1931–32 to 1940–41 the average annual prices varied from 38.8 to 85.3 ct., averaging 67.3. The average for Blue Rose was 73.7 ct. and for Early Prolific 59.7. From 1931–32 to 1937–38 the price of grade 1 rice averaged 4.4 ct. per bushel more than that for grades inferior to grade 1. "Analysis of differences between the lowest prices paid for grade 1 and the highest paid for grades inferior to 1 shows that, typically, the prices for the best lots of grades inferior to 1 are higher than the lowest prices paid for grade 1 for the same variety sold to a mill during the same day, week, or month. Additional grades or subgrades of rice appear highly desirable." Mills purchased from 45 to 50 percent of the annual purchases during October and November, the monthly averages being 25.6 and 21.2 percent, respectively. From 1905 to 1941 "the time between the high points on acreage deviations from secular trend was from 6 to 8 yr., except in the last period studied. Analysis of the data shows that deviations from the trend are greatly affected by the relative level of the purchasing power of rice for the year previous to the one for which planting operation and production occurred."

**Recent developments in sampling for agricultural statistics, G. W. SNEDECOR and A. J. KING.** (Iowa State Col. and U. S. D. A.). (*Jour. Amer. Statist. Assoc.*, 37 (1942), No. 217, pp. 95–102).—A paper presented before the American Statistical Association at New York City, December 28, 1941.

## RURAL SOCIOLOGY

**The farmer and the war** (U. S. Dept. Agr., *The Farmer and the War*, Nos. 1 (1942), pp. 7, figs. 3; [2], pp. 8, figs. 8; 3, pp. 10).—In this series of leaflets No. 1 deals with land values and No. 2 with farm parity prices. No. 3, Farmers

and a Stable Economy, discusses the seven-point program outlined by President Roosevelt in his radio talk on price control, April 28, 1942.

**Migratory beet workers in Michigan**, J. F. THADEN (*Michigan Sta. Spec. Bul.* 319 (1942), pp. 47, figs. 8).—This is a study of certain social aspects of Mexican labor employed in the sugar beet industry of Michigan. Approximately 12,000 farmers produced sugar beets, four-fifths of whom hired workers. About 85,000 acres are worked by hired labor, requiring from 70 to 75 hr. per acre. Out of some 12,400 sugar beet laborers in the State in 1939, about 7,000 were Mexican migrants from Texas, and many of the 4,800 resident beet workers were Mexicans who had migrated from Texas or Mexico during the past two or three decades. In 1941, approximately 6,000 Mexican laborers were recruited in Texas. Another 1,000 migrated from Texas without registering at the employment center or passing through the health center. Their ages ranged from 14 to 78 yr., the average being 28.6 yr. while the median age was 23.8. Seventeen-year-old workers were the most numerous, followed by those 19, 18, and 16 yr., respectively. Less than one-fifth of the farmers provided housing facilities. The average worker cared for 7 acres apiece. Because of conditional government benefit payments, the Agricultural Adjustment Administration specified the minimum wage for sugar beet workers. For 1939, 1940, and 1941 the payment for blocking, thinning, and hoeing was \$11 per acre, and for harvesting a certain rate per acre was paid depending upon yield per acre. For a yield of 9.4 net tons per acre this rate was \$8.67 per acre. In 1941, 1,800 Mexican beet workers came to Michigan and Ohio by train at special rates, while others came in automobiles or trucks—the majority in their own conveyances. Child labor provisions of the Sugar Act of 1937 would not allow employment of children under 14. Eight-week summer schools were operated in 22 centers in the State in 1942. Conditions under which migratory beet workers are employed have shown steady improvement in recent years.

**Migratory sugar beet workers**, H. TITUS (*Michigan Sta. Quart. Bul.*, 25 (1942), No. 1, pp. 1-8).—A condensation of the above.

**Culture of a contemporary rural community**, Landaff, New Hampshire, K. MACLEISH and K. YOUNG (*U. S. Dept. Agr. Bur. Agr. Econ., Rural Life Studies No. 3* (1942), pp. [4]+117, figs. 10).—This is the third in a series of six reports on rural communities studied contemporaneously during the year 1940 (E. S. R., 86, p. 697).

**Culture of a contemporary rural community: The Old Order Amish of Lancaster County, Pennsylvania**, W. M. KOLIMORGEN (*U. S. Dept. Agr., Bur. Agr. Econ., Rural Life Studies No. 4* (1942), pp. [4]+105, figs. 13).—The fourth in these studies of six communities presents sections on the identification and characterization of what is termed a socio-religious, strictly rural community, history and background of the settlement, making a living, community organization and values, the farmers' expanding world, and integration and disintegration in community and individual life.

## AGRICULTURAL AND HOME ECONOMICS EDUCATION

**Permanent agriculture: A textbook of general agriculture**, W. SCOTT and J. B. PAUL (*New York: John Wiley & Sons; London: Chapman & Hall, 1941*, pp. XVI+614, figs. 210).—"The subject matter presented in this textbook is . . . more inclusive than what is usually found in books on the subject of general agriculture. It presents not only problems of how to grow crops and breed animals but also other problems, such as cooperation, taxation, credit, conservation, and education."

**Farm management livestock manual (including poultry and bees)** R. L. ADAMS (*Berkeley: Univ. Calif., 1941, pp. [2]+IV+157*).—"This Farm Management Livestock Manual contains various data useful when planning, testing, analyzing, and appraising livestock and related enterprises. The data pertain to beef cattle, dairying, hogs, sheep, turkeys, poultry, rabbits, goats, and bees."

**Mathematics in agriculture**, R. V. McGEE (*New York: Prentice-Hall, 1942, pp. IX+189, figs. 87*).—"A practical book on mathematics designed especially to fit the needs of persons interested in agriculture." The several chapters cover mathematical operations; percentage; equations; lengths, areas, and volumes; ratio and proportion; the right triangle and trigonometry; averages; graphs; special applications of practical measurements; and exponents, logarithms, and the slide rule. Tables "contain information which possesses practical value for anyone engaged in agriculture."

### FOODS—HUMAN NUTRITION

[Foods and nutrition studies by the New York State Station] (*New York State Sta. Rpt. 1942, pp. 25-27*).—This is a brief progress report (E. S. R., 86, p. 550) concerning studies on the freezing preservation of meats and poultry and fruits and vegetables; the preparation of maraschino cherries and glacéed fruit; the vitamin content of vegetables, fruits, and fruit juices; the nutritive value and palatability of dehydrated vegetables; the chemistry of pectin and pectic enzymes; and quality studies with vegetable canning crops.

What the kitchen owes to science, M. S. PITTMAN. (Kans. State Col.). (*Kans. State Bd. Agr. Bien. Rpt., 32 (1939-40), pp. 91-110, figs. 3*).—This popular review concerns the contributions of applied research to problems in food preparation, specifically in meat cookery; use of eggs; use of milk and milk products; use of fats and oils; preparation of breads, batters, and doughs; sugar cookery; cooking of fruits and vegetables; and jelly making.

The home preparation and preservation of food, M. C. FRUND. (Cornell Univ.). (*Jour. Chem. Ed., 19 (1942), No. 3, pp. 138-143*).—This is a discussion of the chemistry involved in many everyday cooking procedures.

Frozen foods and our civilian food supply, H. CARLTON. (Univ. Tenn.). (*Ice and Refrig., 103 (1942), No. 4, pp. 235-239*).—This report reviews the critical food situation, particularly as it applies in Tennessee, and points out how little of nonrecurring critical material would be required for additional freezing facilities in comparison with the critical materials used for cans alone in preserving the necessary protective foods by canning for even one season.

Freeze fruits and vegetables for variety, D. KNOWLES. (N. Dak. Expt. Sta.). (*N. Dak. Agr. Col. Ext. Spec. Cir. A-22 (1942), pp. [4], figs. 2*).—This leaflet summarizes procedures to be used in freezing different kinds of fruits and vegetables.

Influence of freezing on tenderness in "aged" beef, R. W. BRAY, G. E. VAIL, and D. L. MACKINTOSH. (Kans. Expt. Sta.). (*Kans. Acad. Sci. Trans., 44 (1941), pp. 327-331, figs. 3*).—The beef for this study was obtained from four Hereford steers weighing about 700 lb. The carcasses from the two animals grading U. S. Good were aged for 32 days, while those from the other two animals, grading U. S. Medium, were aged for 42 days. Steaks  $1\frac{1}{2}$  in. thick were cut from the short loin cut, eight steaks, beginning at the anterior end, being cut from each loin, four of which represented the anterior portion and four the posterior portion. Alternate steaks from paired right and left loins were wrapped in a moisture-, vapor-proof paper and frozen at from  $-10^{\circ}$  to  $-15^{\circ}$  F. Within 24 hr. after slaughter, control steaks were cooked, by a method effecting uniform cooking, and tested for tenderness by the Warner-Bratzler

tenderness shear test applied to lateral, central, and medial cores cut from the steaks. Frozen steaks, thawed at 34°–38°, were similarly cooked and tested. The tenderness data, analyzed statistically, indicated that there was little or no change in tenderness of aged beef due to freezing, but that this might vary with the animal. Considerable variation was found in the tenderness between animals and among the cores taken from the steaks (longissimus dorsi muscle). The greatest variation occurred in the lateral core. The posterior section of the short loin was found to be more tender than the anterior section, and the right side significantly more tender than the left side.

The effect of the rate of freezing and temperature of storage on the quality of frozen poultry, C. W. DuBois, D. K. TRESSLER, and F. FENTON. (N. Y. State Expt. Sta.). (*Refrig. Engin.*, 44 (1942), No. 2, pp. 93–99, figs. 13).—Drawn roasting chickens, packaged by wrapping in moistureproof Cellophane and inserting in a stockinet, were frozen with and without air blast at +10°, 0°, –8°, and –25° F.; some were also frozen in a Birdseye multiplate freezer. The drop in temperature during freezing, as measured by thermocouple and plotted as freezing curves, showed that the time required for freezing at any given temperature was reduced by approximately one-half when the fan was used, and that the birds frozen in the Birdseye multiplate freezer were frozen in a much shorter time than those in an air blast at this temperature. Frozen sections of the muscle tissues were prepared for microscopic examination. The photomicrographs showed that as the rate at which the chickens were frozen increased the less was the break-down of the muscle fibers; those that were frozen more slowly showed more disruption. In palatability studies of the chickens after thawing and roasting it was found that, with one exception, the birds frozen rapidly rated higher than those frozen more slowly. All of the roasted chickens were of good quality, however, and there was scarcely any difference in flavor, aroma, and texture between the two extremes of the series.

Other chickens were drawn, packaged in four different materials, rapidly frozen, and then stored at +15°, +10°, 0°, and –8°. Flavor changes were noted sooner in chickens packaged in the waxed paper, which had a high moisture-vapor transmission rate, than in those packaged in more moisture-vapor-proof materials. Likewise, moisture losses of chickens packaged in the waxed paper and stored at 0° amounted to 4.7 and 6.4 percent in 12 and 20 mo., respectively, as compared with very slight losses by chickens packaged in moisture-vapor-proof viscose sheets or in rubber latex. The internal fat, as judged by peroxide values and organoleptic tests, turned rancid more quickly than did the external fat. In the former rancidity was noted after 5, 10, and 18 mo. of storage at 15° and 10°, 0°, and –8°, respectively.

Meat in nutrition.—XXI, Distribution and partition of fats in certain tissues of rats fed a diet containing dried autoclaved pork muscle, E. B. WILCOX. (Iowa State Col.). (*Iowa State Col. Jour. Sci.*, 17 (1942), No. 1, pp. 158–160).—A supposedly adequate diet containing dried autoclaved pork muscle had been shown to produce a pregnancy disorder at parturition in about one-third of the animals maintained on the ration (E. S. R., 85, p. 268). Pregnant and virgin rats on this experimental diet were observed in the present study in comparison with corresponding normal animals on the stock diet as a control. Pregnancy per se in the normal animal brought about an increase in liver weight. This increase was also observed in the pregnant animals on the experimental ration. These rats showed in addition a dehydration of the liver tissue and an increase in its fat content greater than that occurring in the virgin or in the normal pregnant rat; this condition was not changed in the pregnant rats

exhibiting toxemia. The livers of pork-fed pregnant rats showed, in comparison with livers of normal gravid animals, an increase in neutral fat and cholesterol esters accompanied by a reduction in free cholesterol; toxemia did not change this picture. Total fatty acids, phospholipides, and total cholesterol in the plasma of pregnant controls were each about twice as high as these fractions in the plasma of pregnant experimental animals. An investigation of the liver lipides of a group of toxicemic females fed the basal pork diet showed, however, that about half of these animals had livers normal with respect to fat. These various findings are interpreted as indicating that fat metabolism is altered in the pregnant rat following the feeding of a diet containing dried autoclaved pork muscle, but that the development of a fatty liver is not a basic cause of the pregnancy disease that so frequently occurs in rats maintained on this ration.

**Digestion characteristics of various types of milk compared with human milk,** F. J. DOAN and J. L. DIZIKE. (Pa. Expt. Sta.). (*Milk Plant Mo.*, 31 (1942), No. 9, pp. 24-28, 44, fig. 1).—An abstract of the study noted previously (E. S. R., 88, p. 127).

**Making fruit and vegetable juices in small lots** (*Farm Res.* [New York State Sta.], 8 (1942), No. 4, pp. 6-7, figs. 3).—Essentially noted from another source (E. S. R., 88, p. 129).

**Vegetable juices present special problems,** H. G. BEATTIE and C. S. PEDERSON (*Farm Res.* [New York State Sta.], 8 (1942), No. 4, pp. 10-11, fig. 1).—Essentially noted from another source (E. S. R., 88, p. 129).

**Experiments on concentrated food bars,** W. V. CRUESS, H. F. FRIMM, and C. SUMNER. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 12, pp. 359-360, 379, 380).—The authors point out a need for two types of concentrated food bars of the customary 5-ct. candy bar size and appearance but better balanced nutritionally, one being a bar high in protein, mineral elements, and calories, the second a bar in which dried fruits predominate, it, too, being of high caloric value and basic ash minerals as well as rich in sugars. Such bars are needed as military and other emergency rations, and the authors believe, also, that they may be made sufficiently attractive in flavor and appearance to have general salability. Recipes for nine such mixtures are given and procedure for the preparation of the bars is discussed, together with the general requirements with respect to the components and the mixture as a whole.

**Fruit bar for Army K ration,** W. V. CRUESS and J. LA MOGLIA. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 22 (1942), No. 1, p. 13).—General specifications and several formulas are noted for the preparation of fruit bars for possible inclusion in Army emergency field rations. Fondant, chocolate, nuts, etc., are omitted. Honey, invert sugar sirup, or glycerine are added to prevent hardening or drying out in the field. Moisture content is kept between 14 and 20 percent in order for the bars to remain edible in texture at 0° or 130° F. Pasteurization when packed and fumigation in storage are recommended for insect control.

**Fruit bars for Yanks,** W. V. CRUESS and J. LA MOGLIA. (Univ. Calif.). (*Canner*, 95 (1942), No. 14, p. 13).—Noted above.

**Natural foods in the American dietary,** C. A. ELVEHJEM. (Univ. Wis.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 5, pp. 279-284).—This paper, presented as the first Mary Swartz Rose Memorial Lecture before the Greater New York Dietetic Association February 3, 1942, stresses two points—"first, the necessity of more accurate information regarding the distribution of essential nutrients in all foods; and, second, a more careful consideration of the type of educational

and promotional methods used to induce the entire public to believe that improved nutrition pays dividends."

**A short method for dietary analysis**, E. G. DONELSON and J. M. LEICHSEN-  
RING. (Minn. Expt. Sta.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 7, pp. 429-434).—The proposed short method is based on the use of representative mean values for the composition of food groups. The means, derived from the values for foods most commonly occurring in a series of dietaries used in the North Central region of the United States, were weighted in accordance with the frequency with which certain foods occurred in the dietaries. It is suggested that some modification may be required to adapt the method to regions in which the typical diet differs appreciably from that in the locality studied. Results obtained by this short method compared favorably with those computed by the usual long method. Statistical analysis showed the differences between results by the two methods to be statistically insignificant whether computations were based on food records for a week or for only a day, although the degree of concurrence was higher when weekly records were available. The results by the short method agreed most closely with those by the long method when a varied diet was used and when only foods of known composition were included. A food composition table showing the calories, protein, minerals, and vitamins per serving (or measure) for each group or subgroup of foods is presented for use in the short method.

**An experience with low-cost diets**, J. WHITACRE. (Tex. Expt. Sta.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 5, pp. 285-294).—Low-cost menus for three meals daily for a weekly period are presented according to six different diet plans, each of which was directed toward attaining nutritional adequacy. Schedules are presented showing costs and amounts of the various foods and the nutritional values attained. The meals as planned cost from about 12.5 to 18.5 ct. per day and, as actually served to regular members of diet groups, illustrated that really good low-cost diets may be achieved in a way that is teachable.

**The caloric intakes of twenty-seven college women**, M. S. PITTMAN, H. MCKAY, B. L. KUNERTH, M. B. PATTON, N. EDELBUTE, and G. COX. (Kans. and Ohio Expt. Stas. and Kans. State Col.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 7, pp. 449-453).—This report, presented as paper No. 9 of the regional project of the North Central States relating to the nutritional status of college women, presents data on the caloric intakes of the same 27 subjects (12 Kansas and 15 Ohio) whose mineral intakes were previously discussed (E. S. R., 87, p. 452). The subjects, on diets freely chosen as to calories, were studied over periods ranging from 7 to 67 days, their caloric intakes being determined by analysis of aliquots of the food eaten. The mean caloric intakes of the different subjects were found to vary greatly, ranging from 27.6 to 56.4 calories per kilogram per day for Kansas subjects, a difference of 104 percent, and from 19.9 to 50.0 calories per kilogram for Ohio subjects, a difference of 151 percent. These differences between subjects were significantly greater than differences between periods for the same subject. The mean intake for all subjects from Kansas for all periods was 39.3 calories per kilogram per day and 32.8 for all Ohio subjects, or 35.7 for the two States combined. The mean caloric intake for the subjects from both States, individually and collectively, was well below the commonly used standard for moderately active women (about 43 calories per kilogram as estimated on the basis of 2,400 calories daily for the average woman of 56 kg.) and still lower than the standard (2,500 calories daily) proposed for the average woman by the Committee on Food and Nutrition of the National Research Council.

**Good nutrition important for older school children**, L. DICKINS (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 9, p. 1).—In a study conducted in

five schools in one Mississippi county, it was found that relatively more of the children over 13 yr. of age were underweight for their height and age and more frequently showed defects of posture, hearing, and vision than in the case of the younger children. These findings suggested that more attention than was customary should be given to the food consumption of adolescents and that they should be guided in food selection for adequate nourishment.

**Preliminary findings of the Virginia nutrition study: First seasonal survey, W. H. RONEY, M. S. EHEART, and G. PARKER (*Virginia Sta., Rural Sociol. Rpt. 20 (1941), pp. [2]+15, fig. 1*).**—This study (Nutrition Report 1) was initiated to obtain more exact information concerning food habits and nutrition conditions of Virginia people, with the ultimate aim of providing, through the findings, a more practical basis for State action agencies and programs concerned with the improvement of nutrition and health on a specific local basis, as well as on a general State-wide basis. The study is sponsored by the Virginia State Nutrition Committee in cooperation with the following agencies: State Department of Education, Virginia Polytechnic Institute, Virginia Home Demonstration Service, Virginia State Planning Board, National Youth Administration for Virginia, Work Projects Administration, and the station.

The study comprises three seasonal surveys of the diets of school children from the fifth to the tenth grades. The first survey, taken in April and May, 1941 and embracing about 5,700 white and Negro children of both county and city schools, is described and summarized in the present report. This considers particularly the general picture of the total diet in protective foods in the State, in individual regions, and in individual school communities, and the diet adequacy in specific protective foods. In general, it appears that the total rural and urban children of both races (white and Negro) were getting an average of only approximately two-thirds of the amount of all protective foods (excluding butter and cream) recommended by nutrition standards. Contrasting rural and urban children, it appears that for both racial groups the urban children were the better nourished. For all regions and races combined, the diet adequacy of children in families producing their own milk was approximately 10 percent higher than in the case of families purchasing the milk. Similarly, children whose families reported the use of greater varieties of home-grown vegetables showed higher adequacy ratings for vegetables.

**The Virginia nutrition study: A progress report, W. H. RONEY, M. S. EHEART, and G. PARKER (*Virginia Sta., Rural Sociol. Rpt. 22 (1942), pp. [2]+7*).**—This report (Nutrition Report 2) comprises a brief summary of the April and May survey, noted above, and the October and November 1941 survey, involving about 4,700 children from the sixth to the eleventh grades in rural and city schools. The nutritional ratings as to adequacy in all major protective food classes (vegetables, fruits, and tomatoes; meats; milk and milk products) showed relatively little improvement in the fall, in spite of the greater supply of vegetables and fruits as compared to the supply in early spring, except for slight improvement in the rural Negro children in the eastern southside region. The improvement in this group was probably due to larger wage incomes. As revealed in the fall survey, the influence of the economic level of families on the diet adequacy was highly significant in the rural group. The nonfarm group as a whole showed slightly higher adequacy than the farm group, doubtless because of the higher cash incomes of the nonfarm people. Farm owners were somewhat higher in their diet adequacy rating than tenants and laborers combined. The professional and business groups ranked highest, while unskilled labor and domestic service groups ranked lowest. In the urban group the professional and business groups also ranked highest, followed by the skilled and the semiskilled groups.

Although the urban professional group was at the top of the economic ladder, the children of this group received less than three-fourths of the recommended nutritional standard. For both races of children in both rural and urban groups in all regions, the major food classes ranked as follows in order of decreasing percentage of adequacy: (1) Meat, (2) fruit, (3) milk and milk products, (4) vegetables, and (5) whole-grain cereals.

**Food for health in Hawaii**, C. D. MILLER and H. Y. LIND (*Hawaii Sta. Bul.* 88 (1942), pp. 84, figs. 23).—This publication, written in popular style, presents notes on choosing foods and planning meals for nutritional adequacy, with recipes and menus.

**Relation of multiple dietary deficiencies to hypochromic anemia**. (Univ. Nebr.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 3, pp. 160-161).—This editorial, essentially an abstract of an address by R. M. Leverton, is based on studies noted previously (*E. S. R.*, 86, p. 419).

**The contribution of amino-acids to normal nutrition**, H. H. MITCHELL. (Univ. Ill.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 3, pp. 137-140).—An address.

**Effect of apples, tomatoes, and dates on urinary acidity and blood alkali reserve**, K. G. SHEA and C. R. FELLERS. (Mass. Expt. Sta.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 7, pp. 454-457).—Of the nine young men who served as subjects in these tests, four received a basal diet which was approximately neutral and five a diet that was slightly acid-forming. During the test periods in which they received Baldwin and McIntosh apples ingested in 800- and 1,000-gm. amounts, all subjects behaved similarly. Both varieties of apples slightly lowered the pH of the urine, but did not significantly affect the blood alkali reserve. About 90 percent of the organic acids of the apples was completely oxidized or otherwise transformed in either the acid-forming or the neutral diets. The two basal diets gave similar results insofar as acid and ammonia excretion in urine and blood alkali reserve were concerned. Tomatoes (800- and 1,000-gm. amounts) and dates (400-gm. portions) had practically no effect on the composition of the urine or on the blood alkali reserve. Again the neutral and acid-forming diets gave closely similar results. In spite of the high alkalinity of the ash of dates, the pH of the urine was not increased and the organic acids were not decreased. Data are reported on the proximate chemical composition of the McIntosh and Baldwin apples, tomatoes, and dates.

**The effect of lemon juice on calcium retention**, M. G. MALLON and D. J. LORD. (Univ. Calif.). (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 5, pp. 303-305).—Ten litter-mate female rats were placed at 28 days on a basal diet composed of 1 part powdered whole milk and 5 parts whole-wheat flour (and containing 0.166 percent Ca.). Half of the animals also received 5 cc. of lemon juice daily. At 60 days the Ca retention of these animals, determined by carcass analysis and with due allowance for the Ca content at 28 days, compared very favorably with the Ca retention of the litter-mate controls on only the basal diet. The lemon juice had not, apparently, affected the calcium retention.

**Effect of manganese on calcification in the growing rat**, C. CHORNOCK, N. B. GUERRANT, and R. A. DUTCHER. (Pa. State Col.). (*Jour. Nutr.*, 23 (1942), No. 5, pp. 445-458, figs. 2).—In the high-manganese diets used manganese carbonate molecularly supplemented or replaced the calcium carbonate of the basal rachitogenic diet, the resulting diets varying in Mn content from 0.312 to 1.73 percent. In the low-Mn diets the basal diet was supplemented with 0.006 and 0.01 percent Mn added as the carbonate, or the supplementation was effected by subcutaneous injection of manganese lactate in amounts equivalent to those consumed in the rations. On the high-Mn intakes the growth of the

rats was retarded in proportion to the amount of Mn in the diet, and the excretion of P was increased in all cases and that of Ca was increased at the highest Mn levels. In some cases this fecal excretion of Ca and P was sufficient to deplete the body supply of these elements. The effect was less marked when the Ca in the diet was replaced than when it was supplemented by Mn except with complete replacement of Ca, in which case results were fatal because of the severe loss of Ca and P from the body. A more favorable Ca:P ratio in the diet, produced by increasing the P content, tended to improve the retention of Ca and P even in the presence of Mn. Rats fed large amounts of Mn developed severe rickets, as evidenced by the low serum P level and by the condition of the bones. With the levels of Mn that produced negative P balances, the Ca and P were drained from both bones and other tissues and the rickets was apparently complicated with osteoporosis. Administration of vitamin D resulted in an improved condition. The addition of potassium citrate to the diet also produced a striking improvement in Ca and P retention and subsequently in bone calcification. Mn was stored chiefly in the liver. Injected Mn was largely excreted in the feces, but some was stored in the liver and the bones. Low-Mn intakes did not retard growth and showed little or no effect on bone calcification either in conjunction with normal or with rachitogenic diets.

**Studies on manganese deficiency in the rat,** P. D. BOYER, J. H. SHAW, and P. H. PHILLIPS. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 143 (1942), No. 2, pp. 177-125, figs. 2).—Pronounced Mn deficiency was produced in rats weaned without access to Mn by placing the pregnant female on a low-Mn ration during the last few days of gestation and during the suckling period. Of the two Mn rations used, the mineralized milk (1 mg. of Fe and 0.1 mg. of Cu per 100 cc. of milk) containing about 0.03 p. p. m. of Mn produced a greater retardation of growth than did the solid ration containing about 2 p. p. m. Mn supplementation, bringing the Mn in the milk to a concentration of 10 p. p. m. and in the dry ration to 50 p. p. m., effected a definite growth response in both the male and the female rats. "In the Mn-deficient female rat oestrous cycles were irregular or absent, and there was a marked delay in the opening of the vaginal orifice. A Mn deficiency in the male rat caused testicular degeneration and complete sterility due to lack of spermatozoa production. Both male and female Mn-deficient rats were unable to reproduce. No histological abnormalities were detected in the adrenal, kidney, pituitary, and thyroid of the Mn-deficient rat." The Mn deficiency did not result in reduced ascorbic acid content of tissues, since kidney, liver, adrenal, and testis of the deficient animals showed essentially the same ascorbic acid content as corresponding tissues from normal animals. Ascorbic acid, equivalent to 10 mg. per rat per day, administered to Mn-deficient animals for a period of 30 weeks did not stimulate the growth of these animals. In vitro synthesis of ascorbic acid from mannose could not be obtained by rat liver, kidney, intestine, or spleen with or without the addition of Mn. These results are interpreted to indicate that there is no relation between Mn and ascorbic acid synthesis. A reduced arginase concentration in the liver of the Mn-deficient rat was found, but there were no essential differences in the activity of the intestinal dipeptidases studied.

**Hematologic standards for healthy newborn infants: Erythrocyte count, hemoglobin content, cell volume, color index, volume index, and saturation index,** E. G. CHUINARD, E. E. OSGOOD, and D. M. ELLIS (*Amer. Jour. Diseases Children*, 62 (1941), No. 6, pp. 1188-1196, figs. 2).—This article, one of a series giving hematologic standards for normal persons from birth throughout adult life, reports the results of determinations on oxalated fontanel blood of 195

infants, about 10 of each sex being studied on each of the first 10 days of life. No significant differences with age or sex were noted during this age period. "The average erythrocyte count was 4,600,000 cells per cubic millimeter, with an extreme range from 2,600,000 to 6,300,000. . . . The average hemoglobin concentration was 16.3 gm. per 100 cc., with an extreme range from 10.3 to 22.6 gm. . . . The average packed red cell volume 43.4 cc. per 100 cc. of blood, with an extreme range from 25.5 to 61.0 cc. . . . The average hemoglobin coefficient was 17.8, with an extreme range from 1.25 to 23.5. . . . These results correspond to an average color index of 1.00, with a range from 0.78 to 1.23. The average volume coefficient was 47.6, with an extreme range from 34 to 61. . . . The average saturation index was 1.00, with an extreme range from 0.77 to 1.46; 95 percent of the values fell in the range from 0.85 to 1.15. The cells of newborn infants are larger and contain more hemoglobin than those of older persons, but the corpuscular hemoglobin concentration is similar to that of adult men. Hemoglobin content should be reported in terms of grams per 100 cc. of blood; for the calculation of color, volume, and saturation indexes, standards for healthy persons of the patient's sex and age group must be used."

**The absorption and excretion of 'minor' elements by man.**—H. COBALT, nickel, tin, and manganese, N. L. KENT and R. A. McCANCE (*Biochem. Jour.*, 35 (1941), No. 8-9, pp. 877-883).—This study, carried out in the same manner as the work noted in part 1 (E. S. R., 87, p. 748), involved metabolism experiments on men and women combined with intravenous injection of Co, Ni, Sn, and Mn salts. One man during a 7-day test period excreted about 20 percent of his food Co in the urine; in the following week in which a total of 13 mg. of Co was injected intravenously, only 2.89 mg. was excreted, 74 percent by the kidneys. From 60 to 70 percent of food Ni ingested by two men in the test period was excreted in the urine; injected Ni (9 or 20 mg. in a week) was, like the cobalt, excreted slowly and rather incompletely, mainly by the kidneys. Two men excreted from 50 to 80 percent of their food Sn in the urine; in subsequent periods when Sn was injected, from 60 to 70 percent of the amount administered was recovered, most of this Sn being excreted by the kidney. Only a very small part of the Mn in the food was excreted in the urine, and there was no increase even after intravenous injections of Mn salts. Two persons retained the whole of the injected Mn, while a third excreted about 50 percent by the bowel.

**Choline metabolism, VII, VIII** (*Jour. Nutr.*, 21 (1941), No. 6, pp. 633-646, fig. 1; 23 (1942), No. 1, pp. 91-100, figs. 4).—A continuation of the series, some papers of which have been noted (E. S. R., 86, p. 859).

**VII. Some dietary factors affecting the incidence and severity of hemorrhagic degeneration in young rats.** W. H. Griffith and D. J. Mulford.—It has been shown that hemorrhagic degeneration produced in young rats by diets low in choline and in labile methyl food mixture is accompanied by loss in weight and spectacular rise in nonprotein nitrogen of the blood at the critical stage of the hemorrhagic state, followed by gains during the period of spontaneous recovery, if this occurs. Restriction of food intake results in protection against the renal lesions developing on the same diet fed ad libitum. Dietary supplements of cholesterol produce injurious effects within from 30 to 40 days even on diets containing more than the amount of choline required for complete protection during the critical 8-day period. Supplements of thiamin, riboflavin, pyridoxin, calcium pantothenate, ascorbic acid, vitamin K, and "vitamin P" do not affect the severity of the results of labile methyl deficiency, but nicotinic acid exerts a moderate choline-opposing action.

**VIII. The relation of cystine and of methionine to the requirement of choline in young rats.** D. J. Mulford and W. H. Griffith.—Experiments are reported which

are interpreted as demonstrating that the 18-percent casein diet is a suboptimal source of cystine for the young rat, inasmuch as growth and efficiency of food utilization are improved by supplementary cystine (0.1-0.2 percent). Such additions, however, increase the deposition of liver fat and the incidence of renal hemorrhagic degeneration if the diet is low in choline and necessitate the addition of choline. In the absence of dietary choline 30 percent of casein is required to supply sufficient methionine and cystine to prevent signs of choline and cystine deficiency. It is considered that the needed methionine is not utilisable as a source of cystine sulfur.

The significance of the ratio of lactic to pyruvic acid in the blood after exercise, T. E. FRIEDMAN and C. J. BABORKA (*Jour. Biol. Chem.*, 141 (1941), No. 3, pp. 993-994, fig. 1).—Attention is called to observations of previous workers that the concentration of pyruvic acid in the blood increases greatly after muscular exercise and then decreases as the lactic acid returns to normal. Experiments by the authors are presented showing that the pyruvic acid rises and falls logarithmically, or nearly so, with time, and following severe muscular exertion the early extremely high ratio of lactic acid to pyruvic acid falls rapidly during the first few minutes and then decreases slowly, with the point of inflection of the curve occurring at from 4 to 10 min., depending upon the severity of the exercise. It is considered of special interest that it is at this time that the pulse, respiration, oxygen intake, and oxygen content of the blood are rapidly returning to normal. The belief is expressed that the ratio of lactic to pyruvic acid is an indication of returning normal oxidative conditions.

Removal of pyruvic acid from human blood in vitro, E. BUEBING and R. GOODHART (*Jour. Biol. Chem.*, 141 (1941), No. 3, pp. 931-944).—In continuation of studies of pyruvic acid in the blood (E. S. R., 85, p. 852), evidence is presented that defibrinated, heparinized, citrated, and oxalated human bloods are capable of removing added pyruvate in vitro. The removal is shown to begin immediately upon withdrawal of the blood and to continue at an increasing rate for the first 30 min. The removal from whole blood is increased by incubation with 0.075 M phosphate, with optimum pH at 7.4, and is not affected by the addition of thiamin, cocarboxylase, and glucose or by the oxygen tension of the blood. In the presence of 2 percent of fluoride, from 83 to 95 percent of the pyruvic acid removed can be recovered as lactic acid. Experiments with whole blood, plasma, and washed blood cells showed that the enzyme system responsible for the removal of pyruvate by blood is heat labile and is located within the blood cells. The plasma contains a heat-stable activator of the enzymatic reaction which appears to be a phosphorylated intermediary of carbohydrate catabolism, probably triose phosphate. The evidence is thought to indicate an analogy between the mechanism for the anaerobic removal of pyruvate in blood and in muscle.

The effect of pyridoxine on the urinary excretion of a new fluorescent substance, S. A. SINGAL and V. P. SYDENSTRICKER. (Univ. Ga.). (*Science*, 94 (1941), No. 2449, p. 545).—A four- to tenfold increase in the bluish-purple fluorescence of urines of normal persons or pellagrous patients was noted following ingestion of 100 mg. of pyridoxin hydrochloride as compared with the preceding control period. The urinary substance responsible for this fluorescence resembled the  $F_1$  described by Najjar and Wood (E. S. R., 85, p. 702) in its adsorption on permutite, elution with 25 percent KCl, and extraction from the eluate with isobutanol, but differed from  $F_1$  in that it was extracted from only the untreated eluate. The presence of the unknown substance could not be demonstrated in in vitro tests with pyridoxin either alone or incubated with

urine. These results indicated that it might be a new entity and perhaps of significance in the intermediary metabolism of pyridoxin.

**Chemistry and physiology of the vitamins**, H. R. ROSENBERG (*New York: Interscience Pubs., Inc., 1942, pp. XIX+674, figs. 25*).—This monograph, presenting a comprehensive up-to-date treatment of the chemistry and physiology of the vitamins, represents the work of a decade in a very thorough compilation of the literature covering all topics of vitamin research. The book begins with a definition of the vitamins which distinguishes this group of compounds sharply from the hormones and from other essential and nonessential food constituents, and continues with a new classification for compounds which act as vitamins and at the same time serve as structural building units or suppliers of energy. Each vitamin is then discussed separately, with a review of the nomenclature, a tabulation of the historical development, a paragraph on the occurrence, and the main discussion dealing with the chemistry and physiology of the vitamins. Under chemistry, consideration is given to the following topics: Procedures used for the isolation of the vitamin; proof of its constitution; its synthesis; industrial methods of preparation; biogenesis; specificity of action; methods of determination, including physical, chemical, and biological methods; and vitamin standards. "The physiology of plants and micro-organisms is separated from the animal physiology, which is subdivided into the metabolism of the vitamin, the physiological action, and the mechanism of the vitamin action. The relation of each vitamin to other vitamins, to hormones, and to inorganics is presented in special paragraphs. This is followed by a short review of the present-day knowledge of the pathological aspects, the hypovitaminoses, avitaminoses, hypervitaminoses, and paravitaminoses, with a special section on clinical test methods. Finally, the vitamin requirements are briefly stated. The book ends with a list and abstracts of vitamin patents which have issued in the United States of America, Great Britain, Germany, and France."

**Ueber den Vitamingehalt fertiger Speisen [The vitamin content of prepared foods]**, H. WILLSTAEDT (*Ztschr. Vitaminforsch., 11 (1941), No. 4, pp. 340-361; Fr., Eng. abs. pp. 360-361*).—About 100 foods, as prepared in the home or for restaurant service (Uppsala, Sweden) were analyzed, by methods noted, for one or more of the following constituents: Vitamin A, total carotenoids,  $\alpha$ - and  $\beta$ -carotene, thiamin, riboflavin, nicotinic acid, and ascorbic acid. Soups; hors d'oeuvres; egg, fish, meat, and vegetable dishes; desserts; and beverages were included among the foods analyzed.

**Meat and human health**, C. A. ELVEHJEM. (Univ. Wis.). (*Jour. Amer. Dietet. Assoc., 18 (1942), No. 3, pp. 145-148*).—This address gives attention to the importance of meat as a source of vitamins, particularly those of the B complex.

**Vitamin A value of fresh and dehydrated carrots**, R. H. WILSON, J. O. THOMAS, and F. DEEDS. (U. S. D. A. et al.). (*Fruit Prod. Jour. and Amer. Vinegar Indus., 22 (1942), No. 1, pp. 15-17, 27, figs. 3*).—Carrots of the Chantanay variety were used in this study. The dehydrated product was prepared from the fresh carrots, scraped, cubed, and blanched in steam for 2 min., by drying for 7 hr., the initial temperature being 161° F. dry bulb and 85° wet bulb, and the final temperature 140° dry bulb and 83° wet bulb. Combined  $\alpha$ - and  $\beta$ -carotene was determined on both the fresh and the dehydrated carrots by a modification of the chromatographic adsorption method of Moore (E. S. R., 85, p. 583). These determinations were paralleled by bio-assays of vitamin A, using the same representative samples of the fresh and dehydrated carrots throughout the whole bio-assay period. The samples were stored under nitrogen throughout the test period, the fresh carrots in addition being kept at 5° C.

in small lots, each sufficient for a week's feeding. The assay procedure, described fully, involved determination of the response, as evaluated by growth and improvement in eye condition, of vitamin A-deficient rats fed supplements of the fresh or dehydrated carrots in comparison with the response of rats fed supplements, at two levels, of a pure carotene preparation. The fresh carrots were found to contain 87.7 percent of water and by chemical analysis 101 $\gamma$  of total carotene per gram (820 $\gamma$  per gram, dry basis); by the animal assay procedure they were found to contain the biological equivalent of  $123 \pm 10\gamma$  per gram. The dehydrated carrots, with a moisture content of 6.6 percent, contained 722 $\gamma$  of carotene per gram (773 $\gamma$  per gram, dry basis) according to the chemical analysis and the biological equivalent of  $702 \pm 64\gamma$  per gram. These results indicate close agreement between the chemically determined value for carotene and the bio-assay value of provitamin A as obtained by the procedure described. The results also show that carrots dehydrated under the particular conditions employed lost but little of their provitamin A content during dehydration.

**Vitamin A and ascorbic acid in pulmonary tuberculosis: Determination in plasma by the photoelectric colorimeter, II.** R. GETZ and T. A. KOERNER (*Amer. Jour. Med. Sci.*, 202 (1941), No. 6, pp. 831-847, figs. 8).—Among the comparisons noted in this study of the plasma vitamin A and ascorbic acid values in presumably normal individuals (staff members) and nontuberculous and tuberculous patients (some immediately following diagnosis and others who had been receiving treatment) in a Philadelphia chest clinic serving both Negro and white populations, with many of both races on public assistance, are the following:

The plasma vitamin A levels in tuberculous patients decreased in proportion to the extent of tuberculous involvement. This was also true of the ascorbic acid which approached prescorbutic levels with advanced tuberculosis. Non-tuberculous, as well as tuberculous, patients were malnourished in both vitamins A and C. The patients under treatment had higher levels of both vitamins than those just diagnosed. Females of both races had lower A and higher C values than males, and there was no age difference in the A values. Negroes in general had lower values of both A and C than the white subjects.

**The comparative value of the blood plasma vitamin A concentration and the dark adaptation as a criterion of vitamin A deficiency,** O. BODANSKY, J. M. LEWIS, and C. HAIG (*Science*, 94 (1941), No. 2442, pp. 370-371).—A series of comparisons of blood plasma levels of vitamin A and dark adaptation tests on varied intakes of the vitamin is reported, with the conclusion that the plasma vitamin A concentration is a considerably more sensitive indicator of vitamin A deficiency than is the dark adaptation test.

The mean plasma vitamin A value for 46 infants from 3 weeks to 6 mo. of age receiving from 1,200 to 1,500 International Units of vitamin A was 74 I. U. per 100 cc. and for 47 infants of the same age receiving 17,000 I. U. daily was 93 I. U. per 100 cc. In no case did the value fall below 45 I. U. No differences between the two groups were found in dark adaptation readings. In a group of infants kept for from 2 to 4 mo. on diets furnishing only about 335 I. U. of vitamin A daily, the plasma values fell by from 4 to 23 units with no increase in dark adaptation. In another group of 12 infants who were kept for periods of from 2 weeks to 4½ mo. on a diet devoid of vitamin A the plasma values of 7 fell below 45 units, and the subjects showed abnormal dark adaptation. When 5 were given 150 I. U. of vitamin A daily for 1 mo., the dark adaptation became normal in every case, though the plasma concentration remained low.

The mean value for 19 normal children from 6 to 12 yr. of age was 117 I. U. per 100 cc., with a range of from 70 to 197, and all of the subjects had normal

dark adaptation. In a group of 118 children of the same age hospitalized for various conditions, including malnutrition, the mean plasma vitamin A value was 89 and the range from 25 to 198 I. U., with values below the designated normal of 67 I. U. for children of that age in 22 cases. Only one of the entire group showed abnormal dark adaptation.

**Dark adaptation and vitamin A: Further studies with the biophotometer,** P. C. JEANS, E. L. BLANCHARD, and F. E. SATTERTHWAITE (*Jour. Ped.*, 18 (1941), No. 2, pp. 170-194, figs. 11).—Further observations with the biophotometer as an instrument for determining dark adaptation as a measure of vitamin A deficiency (E. S. R., 77, p. 886) are reported, with a critical discussion of the inconsistent results reported by some investigators.

"Evidence is presented that the results obtained with this instrument are consistent from test to test of the same subjects and correspond with the vitamin A status of those subjects, when the technic employed is satisfactory and when certain interpretations are applied. By mathematical analysis of the results, the technic described in 1937 has been shown to be satisfactory. Reports of inconsistent results by other observers have been reinterpreted in the light of our own experience, with the conclusion that the apparent inconsistencies have a logical explanation in variability of the status of the subject rather than in fallibility of the test. Normal subjects with ample vitamin A intake, while remaining in good health, have normal test results at all times. The subjects of our observation group who had poor dark adaptation and who submitted to therapy attained normal adaptation in all instances while receiving vitamin A. Three subjects receiving an experimental diet of low vitamin A content showed changes in dark adaptation ability paralleling the depletion of this material and later repletion."

In the authors' experience dietary deficiency alone appeared to be the cause of impaired dark adaptation in only a few instances. The most common cause was thought to be a deficiency in utilization of vitamin A resulting from illness, especially infections. Seasonal differences in incidence are thought to be related more closely to seasonal variations in infection than in diet.

**A comparison of two methods of measuring dark adaptation,** R. E. ECKHARDT and L. V. JOHNSON (*Jour. Ped.*, 18 (1941), No. 2, pp. 195-199, figs. 2).—From results of repeated dark-adaptation tests on the same subject with the biophotometer and the Hecht adaptometer, the authors conclude that as usually conducted the light used for bleaching in the biophotometer test is not bright enough, with the result that cone adaptation is absent. When the intensity of the bleaching light is sufficiently increased, the cone adaptation can be measured with the biophotometer. The first reading obtained after the bleaching period with the biophotometer is thought to represent the final cone threshold obtained with the adaptometer. Within the limits of error, rod adaptation was found to be identical with both instruments. Continued use of the biophotometer in the study of vitamin A deficiency is thought to be valid, and it is suggested that measurements of dark adaptation be continued for 15 or 20 min. following the bleaching period.

**Cure of egg-white injury in rats by the "toxic" fraction (avidin) of egg white given parenterally,** P. GYÖRGY and C. S. ROSE (*Science*, 94 (1941), No. 2437, pp. 261-262).—In the experiments reported here avidin concentrates mixed with the food proved toxic, but parenterally they were nontoxic and even permitted improvement in the manifestations of egg-white injury when cooked egg white was substituted for commercial egg white in the diet. The explanation offered for this paradox is that the avidin concentrates contained not only free avidin but also bound biotin. This compound of biotin was stable under conditions prevailing in the intestine so that the biotin remained

effectively inactivated, whereas a split occurred in the parenteral medium liberating the concealed biotin, which then acted therapeutically.

On the porphyrin nature of the fluorescent "blood caked" whiskers of pantothenic acid deficient rats, L. W. McELROY, K. SALOMON, F. H. J. FIGGE, and G. R. COWGILL (*Science*, 94 (1941), No. 2446, p. 467).—The reddish material observed around the nose and on the whiskers of rats on a pantothenic acid-deficient diet, a condition described by Daft and Sebrell (*E. S. R.*, 83, p. 139) as nosebleed and by Unna (*E. S. R.*, 86, p. 423) as blood-caked whiskers, has been found to contain a large proportion of coproporphyrin shown to be derived from the Harderian gland. Attention is called to the report of Chick, Macrae, and Worden (*E. S. R.*, 85, p. 856) in which the material was designated as a protoporphyrin.

Dietary requirements for fertility and lactation.—V, The lactation-promoting properties of cystine when added to casein diets. VI, Quantitative requirements of various components of the vitamin B complex for lactation. VII, The existence of a new dietary factor essential for lactation, B. SURE (*Arkansas Sta. Bul.* 425 (1942), pp. 34).—In continuation of the series of bulletins on the general subject of dietary requirements for fertility and lactation (*E. S. R.*, 69, p. 760), the present publication submits recent findings on three phases of the investigation. Parts V and VII have been essentially reported (but with less detail) in another source (*E. S. R.*, 87, p. 592). The quantitative requirements discussed in part VI were determined following the depletion of reserves of the vitamin B complex of female rats with litters transferred from an optimal stock diet to a highly purified experimental diet. For rearing of the young to proceed normally, it was found necessary to furnish the mother with the following daily vitamin supplements: "120  $\mu$ g. B<sub>1</sub> (thiamin), 120  $\mu$ g. riboflavin, 50  $\mu$ g. B<sub>6</sub>, 15 mg. choline chloride, 1 cc. of a solution of 'W' factor equivalent to 1 gm. of liver extracts, and 6 mg. niacin. It was not determined whether the niacin is essential for the lactating rat. By such procedure of transfer experiments it is, of course, possible that there was still storage of unidentified components of the vitamin B complex essential for lactation from the previous stock diet. Choline was found to be an indispensable component of the vitamin B complex for growth and lactation of the albino rat."

The vitamin C content of New York State vegetables, D. K. TRESSLER (*New York State Sta. Cir.* 196 (1942), pp. 16, fig. 1).—This circular, based chiefly on previously published work of the station as noted in the bibliography, brings together data on the ascorbic acid content of various vegetables, and discusses the factors, such as variety, freshness, maturity, cooking, fermentation, and dehydration, that affect the ascorbic acid content.

A comparison between interlitter and intralitter variation in rats with respect to the healing of rachitic bones by vitamin D, K. H. COWARD and E. W. KASSNER (*Biochem. Jour.*, 35 (1941), No. 8-9, pp. 979-982).—"It has been shown, by carefully planning an experiment designed primarily for other purposes and analyzing the variance according to the method proposed by Fisher, that the variation between litters of rats in response to vitamin D is much greater than the variation between rats of the same litter as judged by their weights when they were first given the rachitogenic diet. The results emphasize strongly the importance of using 'litter-mate' comparisons in biological assays of vitamin D."

## TEXTILES AND CLOTHING

Directory of commercial testing and college research laboratories, A. E. RAPUZZI (*U. S. Dept. Com., Bur. Standards Misc. Pub.* 171 (1942), pp. III+63).—

This directory lists 244 commercial testing laboratories with 71 branch laboratories or offices, together with indications of the types of commodities which they are willing to test for commodity acceptance purposes. Laboratories of 199 colleges which are used not only for purposes of instruction but also to a considerable extent for research work are also listed. The laboratories are listed alphabetically and again according to geographical distribution. An outline is given of the certification plan in accordance with which manufacturers have expressed their willingness to certify to purchasers that material supplied on orders based on the indicated Federal specifications and commercial standards complies with the requirements and tests of these specifications. The types of commodities investigated are classified as follows: Animals and animal products (except wool and hair); vegetable food products, oil seeds, expressed oils, and beverages; vegetable products (except food, fibers, and wood); textiles; wood and paper; nonmetallic minerals; ores, metals, and manufactures (except machinery and vehicles); machinery and vehicles; chemicals and allied products; and commodities not elsewhere classified.

**Determination of resilience of textiles by compression testing, K. R. Fox and E. R. SCHWARZ** (*Textile Res.*, 12 (1942), No. 10, pp. 2-7, figs. 3).—This paper discusses the proper interpretation of the load-deformation curves obtained in testing the behavior of fabrics or bulk fiber during compression and the recovery therefrom. It is pointed out that the time factor is of importance and must be considered for an intelligent interpretation of compression-test diagrams. Further statistical methods for planning the tests and analyzing the data are suggested.

**New fibre, made from cow's milk, used in textile manufacturing** (*Jour. Milk Technol.*, 4 (1941), No. 6, pp. 343-346, figs. 4).—It is noted that this fiber, known as Aralac, is now being made on a commercial scale, after 4 yr. of experimentation, at Taftville, Conn., by a special manufacturing division of the National Dairy Products Corporation. Casein, which constitutes about 3 percent of skim milk, is extracted, dried and ground, treated with chemicals, and heated for conversion into a viscous honeylike form. This is forced through spinnerets, and the emulsion emerges as thousands of strands of fiber called "wet tow." After many other treatments, the wet tow becomes the soft fiber Aralac, which can be cut into any length. The felt hat industry was the first to use Aralac, and today most fur-felt and wool-felt hats in the United States, Canada, and South America are made in part from it. Textile mills, experimenting with the fiber, found that several processing changes were necessary before desirable blending qualities with other fibers were achieved. Aralac, as processed for textiles, was found to supply drape and substance which previously could be obtained only through the use of fur and wool in some fabrics.

**What is "Aralac"?** H. R. MAUERSBERGER (*Rayon Textile Mo.*, 23 (1942), No. 3, pp. 54-55, figs. 3).—In this article, which consists of excerpts from a speech by F. C. Atwood, it is pointed out that Aralac, although made from casein, is not, correctly speaking, a casein fiber but a protein base or modified protein man-made fiber, since the coagulated filaments formed by extruding the thick, sirupy casein dispersion through spinnerets do not constitute the Aralac fiber, and is only after the extruded filament has been subjected to various chemical treatments to harden it and modify both its physical and chemical nature that Aralac results. The properties of the Aralac fiber can be regulated by the type of chemical reaction to which the filaments are subjected, and in practice the chemical treatments to be applied are governed by the properties required in the than for the textile manufacturer. It is pointed out that further research can textile fiber. For example, a different fiber is made for the hat manufacturer

improve this protein-base fiber, and that even the present-day Aralac need not possess the weaknesses of the protein fiber as first made by the Italians.

**The present situation in ramie fiber,** A. C. WHITFORD (*Rayon Textile Mo.*, 23 (1942), No. 8, pp. 49-51, figs. 3).—This review of the ramie situation points to the successful development in America of a machine for decorticating ramie and of a process for degumming the fibers to overcome their brittleness. It is noted further that experiments have shown that ramie can be successfully and economically grown in the South, and that the 'domestic material can be decorticated with less loss to give a finer, more easily worked fiber than the imported Chinese ramie. In discussion of the chemical and physical properties of ramie, it is pointed out that it has greater tensile strength and a greater water absorptive power than cotton, and that the tensile strength of ramie fiber is from 30 to 60 percent greater when wet than when dry. In blends with wool or rayon or cotton it gives added strength and wearing quality, and prevents shrinkage upon soaking in water or laundering. The ramie blend, in the case of rayon, also prevents stretching and loss of strength upon wetting; and, in the case of cotton, results in a cloth with greater luster and eye appeal. Because of these desirable qualities and its promise as a new staple crop, it is predicted that ramie, either alone or in blends, will find increased war and post-war use.

**The effect of sodium thiosulfate and sodium hydrogen sulfite on some silks,** R. L. JOHNSON, M. E. LICHTER, and R. EDGAR. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 16 (1942), No. 4, pp. 411-419).—"Quantitative comparison has been made of the effect of 50-volume baths of water and of N sodium thiosulfate in 10 hr. at 40° C. on the residual weight, ash nitrogen, and wet strength of plain-woven wild-silk fibroin, silk fibroin, and iron-weighted, lead-weighted, tin-weighted, tin-lead-weighted, and zinc-weighted silks. Similar data have been presented for the effect of 50-volume baths of 1.9232 N sodium hydrogen sulfite in 10 hr. at 40°, and for this treatment followed by 1 hour's steaming at 123.9°. But slight changes occurred in the total nitrogen or wet strength of the silks during these treatments. The effect of sodium thiosulfate on the weight and ash of the weighted silks appears anomalous. Sodium hydrogen sulfite, in 50-volume baths, 0.0500 to 2.0000 N, has been shown to have no effect in 1 hr. at 100° on the wet strength of either silk fibroin or wild-silk fibroin."

**A new culture medium for the growth of *Chaetomium globosum*,** W. G. CHACE and G. S. URLAUB (*Amer. Dyestuff Rptr.*, 31 (1942), No. 14, pp. 331-333, figs. 3).—This investigation was directed toward developing a medium better suited to the growth of *C. globosum* than the Czapek agar in general use, in order that a large quantity of the spores might be available for the accepted testing of mildew-proofed fabrics. The medium finally developed used finely divided cellulose (mechanically disintegrated) as a source of carbon and  $\text{KH}_2\text{PO}_4$  as a buffer. It is claimed for the proposed medium that (1) the time of sporing is cut to 4 or 5 days, (2) the quantity of spores produced is many times that obtainable on Czapek agar, (3) growth of common air-borne contaminants is greatly reduced if not entirely eliminated, and (4) the work of preparation of the medium is not much greater than with other culture media.

**Stain removal from fabrics: Home methods,** M. S. FURRY (*U. S. Dept. Agr., Farmers' Bul.* 1474, [rev.] (1942), pp. [21+30, figs. 8]).—This revision of an earlier edition (E. S. R., 55, p. 898) presents the general principles of stain removal, and tells how to remove many kinds of stains from present-day fabrics.

## HOME MANAGEMENT AND EQUIPMENT

**Performance of domestic frozen food cabinets, J. E. NICHOLAS.** (Pa. Expt. Sta.). (*Agr. Engin.*, 23 (1942), No. 7, p. 232, fig. 1).—This report concerning three domestic-type frozen-food cabinets assigned to use by four families indicates satisfactory performance of the units in the freezing and frozen storage of various fruits and vegetables and meats prepared according to standard practices as the home supplies warranted packaging throughout the season. In the opinion of housewives, all of the food frozen was highly satisfactory. All of the foods were usable over the study period of 10 mo., and there were no losses. Frozen cauliflower was considered preferable to fresh cauliflower. The cost of operation for the 3-, 6-, and 15-cu. ft. cabinets was found to be 56, 65, and 123 kw.-hr. per month, respectively. A few tests on the rate of freezing of meat in different shapes, cuts, and weights, placed in the freezer with one flat surface in contact with the plate and the rest exposed to the air, showed that the entire piece did not freeze simultaneously. A 2.8-lb. steak required about a 2-hr. period to pass through the zone of crystal formation and was nearly uniformly frozen at the end of 6 hr.; these two periods, respectively, amounted to about 6 hr. and from 15 to 16 hr. with a 5-lb. roast. The latter, removed from the freezer and placed in a domestic refrigerator in a compartment at about 38° F., required nearly 10 hr. to reach the average temperature of 28°. After 30 additional hours, parts of the meat attained a temperature of 31.5°, with the largest portion below 30°.

**Pressure gasoline and pressure kerosene stoves, A. E. BARAGAR** (*Nebraska Sta. Cir.* 70 [1942], pp. 12, figs. 13).—This publication summarizes in nontechnical terms the factors of safety, construction, and performance from the detailed report noted previously (E. S. R., 87, p. 897).

## MISCELLANEOUS

**Proceedings of the Eighth American Scientific Congress.—V, Agriculture and conservation** (8. *Amer. Sci. Cong.*, Washington, 1940, *Proc.*, vol. 5, pp. 348, pls. 9, figs. 7).—This volume contains about 40 papers presented before the section of agriculture and conservation of this Congress (E. S. R., 83, p. 1).

**Experiment station research on war problems in the home, S. L. SMITH and G. ADAMS** (*U. S. Dept. Agr., Misc. Pub.* 503 (1942), pp. [2]+36).—This publication, dealing with the work of the State agricultural experiment stations throughout the fiscal year 1940-41 on problems affecting the home, brings together findings of investigations in the following fields: Mineral utilization and requirements; vitamin functions and requirements; vitamins in foods; food selection, preparation, and utilization; food preservation; food consumption and nutritional status; textiles and clothing; the house—construction, care, and equipment; family economics; and family relationships.

**Sixty-first Annual Report of the New York State Agricultural Experiment Station, [1942], P. J. PARROTT** (*New York State Sta. Rpt.* 1942, pp. 96).—The experimental work not previously referred to is for the most part noted elsewhere in this issue.

**Farm Research, [October 1, 1942]** (*Farm Res.* [New York State Sta.], 8 (1942), No. 4, pp. 12, figs. 8).—In addition to articles noted elsewhere in this issue, this number contains the following: Filtering Milk on the Farm, by A. C. Dahlberg (pp. 1, 2); Looking Ahead, by A. J. Heinicke (p. 4); and Dehydrating Fruits and Vegetables (p. 7) (E. S. R., 87, p. 450).

## NOTES

---

**Georgia University and Coastal Plain Station.**—Silas H. Starr, director of the Coastal Plain Station since 1919, died November 6, 1942, at the age of 54 years. A native of Georgia and a graduate of the College of Agriculture in 1910, he served as instructor there from 1914 to 1919. He was widely known in the State for his work in developing its tobacco, peanut, hog, and cattle-raising industries and for his studies with shade tobacco near Bainbridge.

**Massachusetts Station.**—Dr. Arthur D. Holmes of the E. L. Patch Company has been appointed research professor of chemistry vice Dr. E. B. Holland, recently retired, and will devote himself very largely to the study of foods and problems of nutrition. Dr. Julia Holmes (nee Outhouse), formerly professor and chief in nutrition in the Illinois University and Station, has been appointed research professor in home economics.

Dr. William B. Esselen, Jr., assistant professor of horticultural manufactures, is devoting about half of his time to consultation service in the U. S. D. A. Office of Agricultural War Relations along food processing and packaging lines. Military leave has been given to Drs. Monroe E. Freeman and Dale H. Sieling, research professors of chemistry; Dr. Carl Olson, Jr., research professor of veterinary science; Ralph L. France, assistant research professor of bacteriology; Dr. Arthur S. Levine, assistant research professor of horticultural manufactures; Peter M. Bembien, laboratory assistant; Edward B. Donnelly, technical assistant in floriculture; and Dr. H. Robert DeRose, assistant chemist.

**Minnesota University and Station.**—The outstanding career of Dr. Ross A. Gortner, associated with the institution since 1914 and for nearly 25 years chief of its division of agricultural biochemistry, was brought to a sudden close by his death on September 30, 1942, at the age of 57 years. While at the station, he had made important contributions in many fields including the black animal pigments, or melanins; proteins, especially the cereal proteins and their relation to the properties of flour and dough; and colloids, especially their physico-chemical properties and the role of water in living processes. His contributions to scientific journals numbered over 300. He was also author of *Outlines of Biochemistry*, *Selected Topics in Colloid Chemistry*, and *J. Arthur Harris, Botanist and Biometrician*. He was a recipient of the Osborne medal in cereal chemistry and at the time of his death was president of Sigma Xi.

**Oklahoma Station.**—The utilization of native bluestem pasture is being tested on an extensive scale on 1,450 acres of a land utilization area of 3,000 acres, which has been made available to the station by the U. S. D. A. Soil Conservation Service. The present tests involve use of different supplements and comparison of all grazing v. use of part of the area for hay.

Raymond Marshall and K. C. Davis, cooperative agents in cotton marketing of the U. S. D. A. Agricultural Marketing Service, have been succeeded by William B. Hudson and John D. Campbell.

**Puerto Rico Federal Station.**—Dr. Kenneth A. Bartlett, acting director since November 1941, has been appointed director.

## RECENT WORK IN AGRICULTURAL SCIENCE

---

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY

**Alkaloids in certain species and interspecific hybrids of *Nicotiana***, H. H. and C. R. SMITH. (U. S. D. A.) (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 7, pp. 347-359, fig. 1).—Of wild species of *Nicotiana*, 29 which comprised a representative sample of the genus as regards phylogenetic grouping, chromosome number, and geographic distribution were found to contain one or more alkaloids. *N. alata*, *N. bigelovi*, *N. gossei*, and *N. wigandoides* apparently contained only nicotine. *N. glutinosa*, *N. maritima*, *N. otophora*, *N. tomentosa*, and *N. trigonophylla* apparently contained only nornicotine. *N. glauca* and *N. debneyi* contained largely anabasine with some nicotine. The remaining 18 species analyzed contained mixtures of nicotine with nornicotine, and in 13 of these nornicotine was the predominant alkaloid. In crosses between *N. tabacum*, which contains mostly nicotine, and species whose alkaloidal complex was made up largely or entirely of nornicotine, the hybrids contained mainly nornicotine, together with small amounts of nicotine. The  $F_1$  and amphidiploid *N. tabacum*  $\times$  *N. glauca* (anabasine) contained mostly anabasine with some nicotine. In one sample of this  $F_1$  a trace of nornicotine was detected. It was concluded that the genetic factors for nornicotine and anabasine formation are partly dominant in the  $F_1$  over those controlling nicotine formation. Although the species considered as the probable wild progenitors of the cultivated *N. tabacum* and *N. rustica* have a low alkaloidal content which is predominantly nornicotine, the two cultivated species themselves have a high alkaloidal content that is mostly nicotine. A suggested explanation of this relation is that the manner of origin, selection, and culture of the cultivated species produced a high alkaloidal content, which in turn favored the formation of nicotine.

**The distribution of phytic acid in wheat and a preliminary study of some of the calcium salts of this acid**, J. G. HAY (*Cereal Chem.*, 19 (1942), No. 3, pp. 326-333, fig. 1).—Analyses, by methods outlined, of various commercial (English) mill products of wheat showed that the phytic acid phosphorus was proportional to the fiber content. In certain constituents of these products, notably germ and parenchymatous cellular tissue of the endosperm, the phytic acid phosphorus was in a higher ratio to the fiber than in the pericarp tissue. The calcium salts of phytic acid produced at different pH values and dried at different temperatures were characterized as to their composition and solubility. With the phytic acid extracted from bran, the calcium salt obtained at pH values likely to exist in the digestive system was a hexacalcium salt.

**Kinetics as a function of temperature of lipase, trypsin, and invertase activity from  $-70$  to  $50^\circ$  C. ( $-94$  to  $122^\circ$  F.)**, I. W. SIZER and E. S.

JOSEPHSON (*Food Res.*, 7 (1942), No. 3, pp. 201-209, figs. 3).—It was found that the rate of hydrolysis effected by all three enzymes at temperatures both above and below 0° C. increases exponentially with temperature in accordance with the Arrhenius equation. Heat inactivation of these enzymes occurred above 40°. A sharp break in the relationship of rate to temperature appeared at from 0° to -2°, a low activation energy characterizing the system above this temperature. The activation energies observed were as follows: Lipase 7,600 and 37,000 calories, trypsin 15,400 and 65,000, and invertase 11,100 and 60,000 calories. In all the enzyme systems studied (except in that of lipase with glycerol present in the digest, of which the freezing point was -18.5°) the shift in activation energy from a low to a high value occurred at about the temperature at which the digest changed from liquid to solid. It is therefore impossible to predict enzyme action below 0° from experiments made above this temperature. It was found that although enzyme action is markedly retarded in the solid state, low temperatures do not inactivate enzymes. The storage of lipase, trypsin, and invertase for 27 days at -70° did not affect their hydrolytic activity subsequently measured at 30°. The application of these results to the problem of low-temperature storage of foods is pointed out.

**Micro-Kjeldahl nitrogen determination without use of titration procedure,** W. H. TAYLOR and G. F. SMITH. (Univ. Ill.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, pp. 437-439, figs. 2).—Two modifications avoid the troublesome use of methyl red as indicator. The first method consists in a potentiometric titration to the pH represented by the boric acid absorption solution after dilution to a definite volume and estimation of the ammonia content by reference to a calibration curve. The second consists in reading the ammonia content from a calibration curve of pH values plotted against milliliters of 0.01 N ammonia, pH having been determined by means of a direct-reading meter.

**An improved Soxhlet extractor,** M. H. NEUSTADT. (U. S. D. A.) (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, p. 431, fig. 1).—The freedom of flow of the solvent through the thimble was increased by placing in the extractor a piece of glass rod of such a length as to rest at an angle and to support the thimble about 3.25 cm. above the bottom of the extractor. In the extraction of fat from samples of soybean flour the rate of removal of the soluble material was markedly increased.

**Stable sodium thiosulfate and starch solutions,** J. EHRLICH (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, p. 406).—A 0.1 N thiosulfate solution was effectively stabilized by adding 0.05 percent sodium hydroxide and 0.1 percent sodium benzoate. A starch solution of essentially the A. O. A. C. formula was stabilized by 0.1 percent of the benzoate and 0.1 percent of sodium hydroxide.

**Amperometric titrations: Amperometric determination of phosphate with uranyl acetate,** I. M. KOLTHOFF and G. CONN. (Univ. Minn.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, pp. 412-418, figs. 8).—A procedure for the amperometric titration of phosphate with uranyl acetate at room temperature is given. The accuracy was shown to be 1 percent or better with from 0.01 to 0.0003 M concentrations of o-phosphate. In 0.0001 M phosphate the accuracy was of the order of 4 percent. When the phosphate concentration is greater than 0.004 M the galvanometer can be used simply as a null-point instrument. Uranyl acetate is added with exclusion of air until the deflection of the galvanometer suddenly increases. Alkaline earth phosphates can be titrated by the standard procedure. Calcium in large amounts, iron, and organic anions interfere. Methods for eliminating the interference are described.

**Quantitative determination of cellulose in raw cotton fiber: A simple and rapid semimicro method,** J. H. KETTERING and C. M. CONRAD. (U. S. D. A.).

(*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 5, pp. 432-434, fig. 1).—A new semimicromethod for the quantitative determination of cellulose in raw cotton, simpler and more rapid than any heretofore available, accomplishes the maximum removal of the accompanying organic noncellulose materials with a minimum of equipment, sample, and damage to the fiber itself. The method consists of a 4-hr. Soxhlet extraction with hot ethyl alcohol, followed by drying and a 2-hr. extraction with boiling 1 percent sodium hydroxide. The cellulose is determined by dichromate oxidation of the whole sample and titration of the residual dichromate with ferrous ammonium sulfate. The proposed method is recommended particularly for the determination of the cellulose content of raw cotton and may be used in analyses of desized fabrics but not for cellulosic materials which contain lignin.

A special feature of the procedure is the titration of potassium dichromate solutions with ferrous ammonium sulfate using *o*-phenanthroline indicator over a ground-glass plate beneath which is an electric light. This is much more rapid and convenient than the usual titration with an outside indicator and spot plate.

**Phosphorus analysis of plant material**, B. R. BERTRAMSON. (Oreg. Expt. Sta.) (*Plant Physiol.*, 17 (1942), No. 3, pp. 447-454).—The author describes a method based upon the extraction of the finely ground plant material with 1 percent sulfuric acid, a reagent which he found to effect a separation of the inorganic phosphate content from the organically combined phosphorus such that the latter could be determined as the difference between total phosphate content and the phosphate extracted by the dilute acid and colorimetrically determined.

**Spice contamination and its control**, J. YESAIR and O. B. WILLIAMS (*Food Res.*, 7 (1942), No. 2, pp. 118-126).—In general, spices as received by importers showed heavy contamination with bacteria. There may be an appreciable reduction in the bacterial content during their processing at the manufacturing plants through mechanical removal by screening methods.

Several lots of black pepper were subjected to heat, ranging from a treatment of 5 lb. of steam pressure for 5 min. to 15 lb. of pressure for 15 min. Results indicated that the spice contamination varied in its resistance, but that a relatively mild treatment is effective in most instances. Cooking tests indicated a loss in potency of about 10 percent following a heat treatment of 15 min. at 15 lb. of pressure. Practical sterility of spices was obtained by the use of ethylene oxide. The effectiveness of this agent appeared to be due to a true germicidal property and not to a bacteriostatic action. Ethylene glycol was much less effective than ethylene oxide. Only moderate destruction of vegetative forms or spores was effected by ethyl formate. Formaldehyde was effective, especially against spores, although destruction may have been due to the combined effect of residual formaldehyde and the heat treatment used to destroy vegetative cells. Upon vegetative cells there may be a combined effect of destruction and bacteriostasis. Ultraviolet light and ethyl ether were ineffective in the tests which were made.

**Action of Visking sausage-casing material on bacterial growth**, I. C. HALL (*Food. Res.*, 7 (1942), No. 2, pp. 104-110, figs. 2).—Pieces of a sausage-casing material resembling cellophane were cut 5 by 4.5 cm., laid upon the surface of poured plates of 2-percent agar peptone medium in Petri dishes, and their effects upon the growth of various organisms compared with those of glass cover-slips of the same size. The behavior of the following organisms was observed: Obligate anaerobes—*Bacillus botulinus* (types A and B), *B. perfringens* (type A), *B. bifementans*, *B. sporogenes*, and *B. paraputrificus*; facultative aerobes—*B. carnis*, *B. tertius*, *B. polymyxa*, and *B. histolyticus*; facultative ana-

erobes—*Bacterium coli*, *B. aerogenes*, *B. proteus*, *B. mucosum*, and *B. paratyphosum alpha*; obligate aerobes (group 1—intermediate)—*Bacillus anthracis*, *B. subtilis* (Ford), *Micrococcus aureus*, and *B. subtilis* (Cohn); and obligate aerobes (groups 2—strict)—*B. subtilis* (Marburg), *B. atterimus*, *Bacterium pyocyaneum*, *B. aertryke*, *B. cloacae*, and *B. fluorescens*.

The only spore-bearing bacteria which grew under Visking covers were the facultative aerobes and members of the first or intermediate group of obligate aerobes. None of these is likely to cause spoilage, none has been known to cause food poisoning, and all are greatly inhibited by the reduced supply of oxygen under Visking covers. Of the obligate anaerobes and strictly obligate aerobes, none will grow in agar plates under Visking and, therefore, almost surely not in sausages. The Visking casings used on cervelat summer sausages not only inhibit the growth of the obligate anaerobes by allowing the passage of oxygen, but they also inhibit the growth of the obligate aerobes and to some extent that of many facultative aerobes by restricting the passage of oxygen.

**Detection of *Bacillus thermoacidurans* (Berry) in tomato juice, and successful cultivation of the organism in the laboratory,** R. M. STEEN, C. P. HEGARTY, and O. B. WILLIAMS (*Food Res.*, 7 (1942), No. 3, pp. 186-191).—The organism named fails to grow in many artificial culture media, and when such growth is obtained the organism shows a tendency to attenuation or loss of its ability to grow in, and to cause the characteristic "flat-sour" spoilage of, tomato juice. A culture of *B. thermoacidurans* in an artificial medium was acclimatized, however, by repeated transplanting from tomato juice to tomato juice until spoilage would always develop upon its inoculation into normal juice. A combination containing proteose peptone, yeast extract, glucose, and  $K_2HPO_4$  at pH 5 proved to be a satisfactory medium for the cultivation of the organism. Abundant crops of vegetative cells and of spores were obtained in this medium. Continued transfer of *B. thermoacidurans* on nutrient agar produced cultures that were unable to grow in and spoil normal tomato juice. On the other hand, continued transfer of the organisms on proteose peptone acid agar had no apparent influence on the ability of the organism to spoil tomato juice. After 4 months' storage in the ice box sealed cultures on proteose peptone acid agar of *B. thermoacidurans* were still viable and were still able to cause spoilage in tomato juice.

For the detection of *B. thermoacidurans* in tomato juice a plating technic employing proteose peptone acid agar was found to be most satisfactory because the results obtained give both a qualitative and quantitative picture of a spoilage case. Tomato juice was observed to have an inhibiting effect on the growth of *B. thermoacidurans*. Only 1 cc. of juice, therefore, was plated out in 20 cc. of medium.

**The preparation and absorption spectra of five pure carotenoid pigments,** F. P. ZSCHEILE, J. W. WHITE, JR., B. W. BEADLE, and J. R. ROACH. (Ind. Expt. Sta. and U. S. D. A.). (*Plant Physiol.*, 17 (1942), No. 3, pp. 331-346, figs. 4).— $\alpha$ -Carotene,  $\beta$ -carotene, cryptoxanthol, luteol, and zeaxanthol were isolated and purified by chromatographic and crystallization methods accompanied by spectroscopic control. The absorption spectrum of each was determined from 3,800 to 5,200 a. u. by a photoelectric spectrophotometric method. Absorption coefficients were found to be relatively insensitive to changes in slit width, except in regions where absorption values change rapidly with wavelength. Experiments with mercury arc radiation and filters also indicate that scattered radiation is negligible. The absorption values given are considered a suitable spectroscopic basis of analysis for individual carotenoids. Differences due to solvent are discussed.

**Vitamin-B<sub>1</sub>: Estimation in yeast and bread and stability during bread**

**making**, E. R. DAWSON and G. W. MARTIN (*Jour. Soc. Chem. Indus., Trans.*, 60 (1941), No. 9, pp. 241-245).—Different methods for extraction and estimation of thiamin in yeast and bread are reviewed. Of these, it is indicated that the modification of the thiochrome method described by Pyke (E. S. R., 85, p. 701) and the further modification suggested by Wang and Harris (E. S. R., 83, p. 851) are the most satisfactory. For extracting thiamin from yeast, it is recommended that a suspension of the sample in 0.04 N acetic acid be heated to boiling, cooled, and incubated with takadiastase for 4 hr., a portion of the diluted centrifuged solution then being used for the thiochrome estimation. For extraction from bread, the procedure outlined by Pyke or the shorter boiling method gives satisfactory results, although care must be exercised in the latter method to prevent charring of the semisolid suspension. Because of this difficulty, it is found desirable to soften the dried sample by heating the 0.04 N acetic acid suspension for 15 min. by immersion in boiling water and to liquefy the starch by incubating the cooled suspension with takadiastase for 1 hr. preliminary to the boiling and the subsequent treatment with takadiastase. Analyses by the recommended methods of a series of thiamin-rich yeasts and of breads made with these yeasts, over a 6-mo. period in large-scale commercial production of 2-lb. loaves, showed that 92 percent of the thiamin added to the dough as thiamin-rich yeast is retained in the bread.

**Determination of vitamin B<sub>1</sub> by yeast fermentation method: Improvements related to use of sulfite cleavage and a new fermentometer**, A. S. SCHULTZ, L. ATKIN, and C. N. FREY (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 1, pp. 35-39, figs. 5).—The method, described in detail, is a modification of the original method (E. S. R., 79, p. 11) and depends on the chemical inactivation of thiamin by sulfite and the determination of the interfering substances exerting fermentation activity in the residue. Approximately 99 percent of the fermentation activity of thiamin is destroyed by sulfite at pH 5.0-6.0 at 100° C. for 30 min. Similar treatment of natural materials seldom results in such complete inactivation of the fermentation-stimulating property, but in the majority of cases 90 percent or more of the activity is removed by sulfite, leaving a sulfite blank of 10 percent or less. The known interfering substances are not affected by this treatment. In the assay, therefore, the fermentation activity is measured before and after sulfite treatment, and the difference, expressed in terms of pure thiamin chloride, is taken as a measure of the thiamin content of the unknown. A small, compact, fermentometer, occupying about 2 sq. ft. of table space and requiring only one-half the quantities employed in the original method, has been designed to make the yeast fermentation method available for routine use. This apparatus is described and illustrated. Data obtained in the application of the technic to a variety of materials are presented.

**The accuracy of the spectrophotometric determination of vitamin B<sub>1</sub>**, K. H. COWARD (*Quart. Jour. Pharm. and Pharmacol.*, 14 (1941), No. 4, pp. 329-336).—This paper presents an analysis of the results of spectrophotometric determinations of four different solutions of thiamin in five different laboratories. The tabulated results of the determinations indicate that rather wide variations were obtained. The two possible sources of error, (1) differences in the purity of the samples and (2) differences in instruments (and the operators), are discussed. An appendix on the analysis of variance of the results, by J. O. Irwin, is given.

**A new colorimetric method for determining small quantities of nicotinic acid**, R. P. DAROGA (*Jour. Soc. Chem. Indus., Trans.*, 60 (1941), No. 10, pp. 263-266, figs. 3).—In the simple rapid method, described in detail with regard to reagents and procedure, the nicotinic acid is precipitated with phosphomolybdic acid, and the precipitate, after washing with dilute acetic acid, is dissolved in

**0.1 N NaOH.** The nicotinic acid-phosphomolybdate complex is reduced by treating the alkaline solution with stannous chloride, and the molybdenum-blue color is matched in the tintometer against the color developed by similar treatment of a nicotinic acid standard. The nicotinic acid is extracted from foodstuffs by treatment of a water suspension of the material with sodium chloride and calcium oxide and steam distilling. The distillate, collected in 20 percent HCl, is concentrated by evaporation. For application of the method to urine, the diluted urine is steam-distilled for 20 min. to remove the interfering compounds trigonelline and methylpyridinium hydroxide, which are also precipitated by the reagent. The residual mixture of urine and water is cooled and treated with lime and sodium chloride and carried through the procedure adopted for foodstuffs. Determinations by this procedure gave quantitative recoveries of nicotinic acid added to food or urine samples, showed in normal urine a mean nicotinic acid and amide content of 1.5 mg. per 100 cc., and gave values for foodstuffs agreeing with those obtained by other workers. Mean values, in milligrams per 100 gm., are reported for a few materials as follows: Liver extract 110, dried bakers' yeast 30, yeast tablets 45, dried beef extract 64, dried milk powder 2.3, and rice 1.0.

**Further notes on the determination of ascorbic acid and sulphur dioxide in fruit juices,** H. F. W. KIRKPATRICK (*Jour. Soc. Chem. Indus., Trans.*, 60 (1941), No. 11, pp. 298-299).—In continuance of earlier work (E. S. R., 87, p. 481), a study was made of the effect of SO<sub>2</sub> with varying sugar concentrations on the direct titration of citrus fruit juices with dichlorophenolindophenol. It was found that SO<sub>2</sub> in citrus juices did not affect the titration until the sugar concentration of the juice fell below 20 percent. With 15 percent of sugars, the critical amount of SO<sub>2</sub> was about 1,000 p. p. m. and with 10 percent about 500 p. p. m. Equilibrium between the sugar and SO<sub>2</sub> was reached in 1 hr. The titration procedure, similar to that noted in the previous study, is described, together with a modified procedure for separation of the SO<sub>2</sub>. The latter permitted an accurate and rapid determination of the SO<sub>2</sub> in the same operation as the determination of the ascorbic acid by titration with the dye solution. The direct titration method was not affected by SO<sub>2</sub> in the titrated solution in amounts up to 30 p. p. m. The possible application to materials containing little or no hexose solution is suggested.

**Multiplication of bacteria in water and its significance in food spoilage,** C. H. CASTELL and L. A. McDERMOTT (*Food Res.*, 7 (1942), No. 3, pp. 244-253, figs. 3).—Water from several hundred deep and shallow wells having an initially low bacterial content contained organisms which underwent extensive multiplication when the water was enclosed in a container. The type of container and its size (up to 80 gal.) appeared to have relatively little effect on the numbers of bacteria which developed. Inoculations of sterile tap water with pure cultures of known organisms appeared to confirm the observation that growth in water of low organic content was restricted to certain groups of gram-negative bacteria. Known species of *Pseudomonas* were particularly active in water. Results of water examinations made directly after samples were taken from the well and again after the samples had been sent through the mail to the laboratory were widely discrepant, as were those of examinations of samples taken at various points in the same water supply, great increases in dead-end or unused pipes being especially noted.

The types of bacteria that develop were observed to include mainly nonsaccharolytic, gram-negative organisms having the general characteristics of the genera *Alcaligenes*, *Pseudomonas*, and *Achromobacter*. A large proportion of these were lipolytic, proteolytic, and oxidase-positive. Many were active at temperatures not far above freezing. That such organisms are injurious to

stored meats, fish, butter, and other nonacid, protein, or fatty foods is considered self-evident.

Preliminary experiments indicated that initial concentrations of 1 p. p. m. or more of chlorine markedly reduced the number of organisms, and there was no evidence of aftergrowth after a period of 120 hr. Lower initial concentrations of chlorine (from 0.12 to 0.37 p. p. m.) effected a temporary decrease or lag in growth, followed by a rate of increase which was greater than that in the control (unchlorinated) water.

**Abstracts of papers presented at Technical School for Pickle and Kraut Packers, Michigan State College, East Lansing, Michigan, February 17, 18, and 19, 1942, F. W. FABIAN.** (Mich. State Col.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 7, pp. 206-212).—Abstracts of papers from State colleges and experiment stations collected under this title are as follows: The Death-Rate of Microorganisms During the Pasteurization of Cucumber Pickle (p. 207), and Pasteurization of Pickle Products—A Review (pp. 210-211), both by J. E. Etchells and I. D. Jones (U. S. D. A. and N. C. Expt. Sta.); Producing Sauerkraut Acceptable for Government Purchase (p. 207), Important Bacteria That May Be Harmful or Beneficial to Kraut Fermentation (p. 208), and When, How, and Why Should Kraut Factories be Heated? (p. 211), all by C. S. Pederson (N. Y. State Sta.); and Factors Influencing the Spicing of Pickles, by F. W. Fabian and M. C. van Wormer (p. 207). Vitamins, What They Are and What They Do, by C. F. Huffman (pp. 208-209), Vitamin A and C Content of Pickles From Different Parts of the United States and Canada, by L. J. Camillo, C. A. Hoppert, and F. W. Fabian (p. 209), and Production Shorts—A Symposium on Cucumber Production Problems, by J. H. Muncie, C. B. Dibble, and J. Tyson (p. 210) (all Mich. State Col.).

**Cooperative pickling investigations of the United States Department of Agriculture, H. E. GORESLINE.** (U. S. D. A.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 8, pp. 232-233).—This is a brief general account of the Department of Agriculture work on pickling begun under a separate appropriation in 1935 and now carried on in cooperation with the North Carolina Experiment Station and one of the large pickling companies. The intention to cooperate with the pickling industry as a whole and some problems of wartime packaging are topics given special emphasis.

**Olive experiments of 1940-41 season, W. V. CRUESS, J. R. GILLILAND, J. OSBOURNE, and J. SUGIHARA** (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1941), No. 4, pp. 113-115).—The authors report briefly upon some results of mixed pack experiments, further experiments on buffer processing, role of enzymes in darkening, further data on use of calcium salts in ripe processing, calcium chloride in processing Greek-style olives, experiments on use of calcium chloride on green ripe olives, tests on use of calcium chloride with Spanish green olives, green olive experiments, and frozen pack.

**Freezing vs. canning, S. BULL.** (Univ. Ill.). (*Quick Frozen Foods*, 4 (1942), No. 12, p. 21).—This is a brief discussion of the relative merits of frozen and canned foods with respect to palatability, safety, economy, nutritive value, and use of critical war materials.

**Dehydrated food specialties, W. V. CRUESS, H. F. FRIAR, and J. SUGIHARA.** [Univ. Calif.] (*Canner*, 95 (1942), No. 11, pp. 20, 22).—Very general notes are given concerning the preparation, use, and quality of the following dehydrated products: Dried vegetable powders, tomatoes, soup mixtures, salad mixtures, dehydrated citrus fruits for marmalade, precooked dry rice, precooked dehydrated beans, precooked dehydrated split peas for soup, and dehydrated meats.

**Vegetable tests, W. V. CRUESS.** (Univ. Calif.). (*West. Canner and Packer*, 34 (1942), No. 10, pp. 39, 41-42, fig. 1).—This paper gives a brief review of

investigations conducted by the University Fruit Products Laboratory on dehydrated vegetables, with recommendations to producers.

**Experiments on drying unsulfured apricots and peaches**, W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 5, pp. 135, 157).—These experiments show that peaches and apricots are not prevented from darkening by dipping in brine, or pineapple juice, or in thiourea solution. They also show that dried peaches and dried apricots of fairly good color and of exceptionally good cooking quality can be secured by steaming the fruit until cooked through, or by heating it in a cane sugar sirup or in a glucose corn sirup solution before the fruit is dehydrated or dried in the sun. Dehydration of fruit so treated is more practicable than sun drying as there is less darkening and no danger of spoilage by molding or fermentation during dehydration. The author believes that both steaming and the heating in sirup before drying have commercial possibilities and suggests them for small commercial trial by operators of dehydrators. Samples 3 yr. old stored at 48° F. were still of good color, flavor, and cooking quality.

**A note on the Japanese quince**, A. S. LEVINE. (Mass. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 6, p. 177).—The pleasing fruity aroma of the fruit is lost after heat treatment, the jelly prepared from this quince alone having little flavor. The Japanese quince improves the flavor and character of such products as apple jelly or European quince jelly, however, when used at the rate of about 20 percent of the fruit, and has additional possibilities in improving the flavor of apple products, including low-acid ciders and cherry, plum, and prune preserves. In addition to its high acid content this quince is a good source of pectin. Its low starch content permits the concentrated juice to be used directly as a source of acid and pectin.

**Some factors affecting taste and flavor of beverages**, M. LEVINE. (Iowa State Col.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1941), No. 3, pp. 82-85, 91-93, figs. 2).—Precipitation of flavors may be affected by either over- or undersweetness or sugar inversion. Copper, iron, or chlorine in the water may cause off-flavors, especially in the presence of air or under exposure to sunlight. Micro-organisms may cause flavor changes. Vitamin B produced very objectionable taste, particularly in true fruit and cola products, whereas vitamin C tended to preserve the true fruit flavors.

**Survey of apple juice packed in 1940**, H. H. MOTTERN, T. NOLD, and J. J. WILLAMAN. (U. S. D. A. et al.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1941), No. 3, pp. 68-71).—Recommendations presented by the authors are in part as follows:

The apples used may be small but must be of good quality, sound, and ripe. A blend is always better than a single variety. The juice may be clarified or not, at will. Enzyme clarification probably leaves better color and flavor in the juice than does the gelatin-tannin process, but it costs more. Centrifuging for the production of a cloudy juice is very satisfactory. Deaeration should probably be employed if plain tin containers are used. Glass containers are satisfactory beyond question, since glass cannot affect the juice, but breakage and weight have to be considered. Enameled tin is less likely to affect the juice than plain tin. The juice should be flush pasteurized at from 180° to 190° F. for a few seconds and placed in the cans within this temperature range. The cans should be inverted for 2 or 3 min. and then cooled quickly.

**Cider preserved by new method** (*Ohio Sta. Bul.* 617 (1940), p. 36).—This report notes improvement of cider flavor by bubbling carbon dioxide through the cider to remove oxygen before pasteurizing.

**Honey wine: This article reports on experiments on honey mead (honey wine) and honey brandy**, F. FILIPPELO and G. L. MARSH. (Univ. Calif.).

(*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1941), No. 3, pp. 78-79, 90).—Certain nutrient salts providing potassium, nitrogen, and phosphate aided fermentation of mead. Variety of honey and variety of yeast were found to affect the rate of fermentation and the quality of the product.

A very satisfactory honey brandy was obtained. A brandy flavored with from 5 to 10 percent of honey added after distillation was also very satisfactory.

**Experiments with antioxidants for preventing flavor deterioration in canned orange juice**, A. J. NOLTE, G. N. PULLEY, and H. W. VON LOESECKE. (U. S. D. A.). (*Food Res.*, 7 (1942), No. 3, pp. 236-243, figs. 3).—Nine antioxidants (*d*-isoascorbic acid, asparagine, lecithin, resorcinol, hypophosphorus acid, chloesterol, "methyl glucamine,"  $\alpha$ -naphthol, and methyl-*p*-aminophenol (Elon)) in different concentrations were added to Florida Valencia orange juice in an attempt to prevent off-flavor development in the canned product. Although some of the antioxidants prolonged the induction period as measured by the peroxide value of the petroleum ether-soluble matter of the canned juice, no correlation could be found between the peroxide value and taste of the juice. Such correlation was made difficult by peel oil in the experimental packs. As measured by the peroxide number of the petroleum ether-soluble material of canned orange juice, there were three induction periods. This is believed to be due to the successive oxidation of terpenes, fats, and resins in the canned juice, probably in the order named. None of the antioxidants in the amounts used prevented the destruction of sulfhydryl compounds or the formation of higher ketones in the juice.

There was no correlation between vacuum in the cans and peroxide value of the petroleum ether extract of the canned juice. Juice packed in enamel cans was found to have a better taste than that packed in plain tin cans, but it is questioned whether the difference could be detected by the average consumer.

**An improved orange juice concentrate**, A. SEDKY, C. R. FELLERS, and W. B. ESSELEN, JR. (Mass. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 5, pp. 136-138, figs. 3).—The authors describe an apparatus designed to concentrate sweetened or unsweetened orange juice with a minimum loss of flavor and vitamin C. A method of juice extraction from navel oranges which was successful in eliminating most of the bitter principle usually present in the juice is also described. It was further shown that the addition of sugar to orange juice before concentration gives a pleasing effect to the concentrate and does not affect the vitamin C content, and that, if carefully prepared, a concentrate from a sweetened juice can be used successfully as a beverage base. A beverage containing juice reduced to 30 percent of the original volume was found to have good flavor and a vitamin C content comparable to that of fresh orange juice.

**The effect of ethylene treatment upon the recovery of citrus pectin**, J. L. HEDD (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1941), No. 4, pp. 100-103, 125, figs. 2).—After ethylene treatment the method of extraction should be modified to obtain maximum jelly-unit yields of pectin. When identical methods of extraction were applied, a lower jelly-unit yield of pectin was recovered from ethylene-treated fruit than from fruit stored for the same time and at the same temperature without ethylene treatment, and fruit thus stored yielded less jelly units than did fruit extracted prior to storage.

**Experiments with asparagus butts: Preliminary report**, G. L. MARSH and W. V. CRUESS (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 11, pp. 333-336, 344, figs. 2).—The authors discuss probable available tonnages, composition of the stalks, possible fertilizing value, value as feed for livestock, drying for feed, drying ratio and time, extraction and utilization of the juice, frozen pack juice, canned juice, use in replacing brine in canning of asparagus,

concentrates, lactic soured juice for canning, and drying the juice. Canning the edible portion of the asparagus in juice from the butts instead of using brine for this purpose yielded a product of greatly superior flavor. The juice acidified by *Lactobacillus plantarum* gave the canned produce a noticeable flavor resembling that of sauerkraut, however.

## AGRICULTURAL METEOROLOGY

**Climatology in the service of agriculture**, C. W. THORNTON (U. S. Dept. Agr., Soil Conserv. Serv., 1942, SCS-MP-25, pp. [1]+9).—A paper delivered before the Second Inter-American Conference on Agriculture, Mexico City, July 6-16, 1942.

**Astronomy, maps, and weather**, C. C. WYLLIE (New York and London: Harper & Bros., [1942], pp. X+449, [pl. 1], figs. [210]).—The book contains chapters on the seasons and the calendar, the weather, and weather forecasting, as well as incidental meteorological data elsewhere.

**Insects and weather as they influence growth of cactus on the central Great Plains**, C. W. COOK. (Utah State Agr. Col.). (*Ecology*, 23 (1942), No. 2, pp. 209-214, figs. 6).—The recent drought period (1930-40) brought a very noticeable increase of cacti in grazing lands of the central Great Plains, and this led to a study (1937-40) of the causes of this increase during dry years and the reverse during moderately wet years. Insects were found to play an important role in cactus control, and rodents, especially rabbits, were important in seed dispersal. Of the insects studied, *Chelinidea vittiger* (Uhl.), *Melittara dentata* (Grote), and *Dactylopius* sp., only the last two are considered highly important. The last, a mealy bug, reproduces very prolifically, and cactus plants often become entirely covered and soon die. The larval stage of the most important insect, *M. dentata*, a moth, eats the center of the fleshy stems, causing death of the plant. Moist warm weather was found conducive to population increase of these insects. It is concluded that drought is the primary factor controlling the balance between cactus and insects, but that proper grazing of the native forage greatly aids in producing a favorable habitat for the insects, thus inducing an increase in their numbers and a decrease in cactus.

**The effect of unfavorable weather at harvest upon the quality of North Dakota wheat**, R. H. HARRIS (North Dakota Sta. Bimo. Bul., 5 (1942), No. 1, pp. 23-28, figs. 4).—Since extremely unfavorable weather during the current season has caused heavy financial losses to North Dakota wheat growers and extensive blight, "black point" (*Alternaria* and *Helminthosporium sativum*) sprouting, and other damage to quality of the grain is anticipated, a summary of recent investigations by the station is presented to elucidate the relationships between these degrading factors and wheat quality. Briefly, if heavy damage to durum wheat by blight and black point is present, extreme diligence should be exercised to keep the quantity allowed to go to the mill below 5 percent, and when light and heavy damage are both present the effect on quality will be additive, so that greater attention must be paid to the maximum amount of heavily affected wheat allowed in the mix. Sprouting in durum wheat caused lowering of the grade, the test weight per bushel, and the semolina yield and macaroni color. Where length of the sprouts was less than half that of the kernel and they were not present in more than 10 percent by weight of the total, the effect on milling characteristics was not great but test weight and grade were still reduced, and especially the latter.

**Use of water by native vegetation**, A. A. YOUNG and H. F. BLANEY. (U. S. D. A.). (Calif. Dept. Pub. Works, Div. Water Resources Bul. 50 (1942), pp. XIII+160, figs. 35).—The purpose of this monograph was to bring together the

results of studies of consumptive use of water by a number of species of native vegetation as determined by the Soil Conservation Service for various western climatic conditions in the United States, as well as some of the results of similar investigations by other agencies (seven pages of references), such studies having been carried on for many years. The four general methods used in such investigations are tank studies, soil-moisture investigations, stream-flow studies, and water-table fluctuations. Detailed data are presented for saltgrass, wire rush, willows, tules and cattails, brush and weeds on outwash slopes in arid and semi-arid regions, weeds along ditch banks or in irrigated fields, and riparian growth along streams. Daily water-table fluctuations in areas of high ground water are usually the result of consumptive use by the overlying vegetation. Fluctuations respond to those factors of weather which cause greater or less transpiration.

**Monthly Weather Review [July–August 1942]** (*Mo. Weather Rev. [U. S.]*, 70 (1942), Nos. 7, pp. 153–180, pls. 11, figs. 8; 8, pp. 181–201, pls. 10, figs. 4).—In addition to meteorological, climatological, solar radiation, and sunspot data, No. 7 contains a contribution on Hourly Distribution and Intensity of Precipitation at Kansas City, Mo., by H. H. Martin (pp. 153–159), and No. 8 an article noted below.

**[Meteorological data at the Georgia Coastal Plain Station]** (*Georgia Coastal Plain Sta. Bul.* 32 (1941), pp. 13–14).—Tabulated data are given on rainfall in inches by months and years, 1923–31 and 1932–40; dates on which first and last killing frosts (32° F.) occurred and the number of growing days at Tifton, 1923–40; and temperature by months, 1940.

**Weather (Rhode Island Sta. Rpt. [1941], pp. 59–60).**—A brief report on Rhode Island temperatures, snowfall, rainfall, and early and late killing temperatures for 1941.

**Stream lines of New England, V. CONRAD** (*Mo. Weather Rev. [U. S.]*, 70 (1942), No. 8, pp. 181–185, figs. 4).—A rather strong correlation exists between the frequency of winds from a given direction and their average velocity; the more frequent the direction, the greater the average velocity—the strongest winds come mostly from the most frequent direction. The assumption can be made that the average velocity of the winds from a particular direction is approximately in linear proportion to the frequency of the direction. Streamlines for January, April, July, and October are shown on maps of the region.

**Daily river stages at river gage stations on the principal rivers of the United States, M. BERNARD** (*U. S. Dept. Com., Weather Bur., Daily River Stages*, 37 (1939), pp. III+169, pl. 1).—This is the usual annual volumes (E. S. R., 86, p. 295), issued in 1942 and continuing the record through 1939.

**Experience with irrigation-water forecasting in Upper Columbia drainage basin during 1940, J. C. MARR.** (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 143–144).—The author finds that dry watershed conditions during the preceding fall usually, though not always, reduce the run-off from snow cover. More than 4 years' snow survey record may be required to determine the relationship between water content of snow cover and run-off accurately. Adjacent drainage areas may not respond alike in run-off even though they are subject to the same storm effects; diversity in elevation, depth of area, and regulating influences make it unsafe to assume such parallel performance.

**Correlation of stream-flow and snow-cover in Colorado, R. L. PARSHALL.** (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 153–159, figs. 6).—That reliable forecasting of run-off for Colorado streams, as based on snow surveys, will be attained cannot be definitely stated at this time because of the limited period of records available for correlation. The author points out that in some of the forecast diagrams presented here a fair agreement is to be noted, while in others rather wide variations appear. In some instances the

record of surveys on snow courses located in an adjacent drainage indicates as good correlation as for the course on the stream itself, if not better.

The photographic method of forecasting appears to have promise, as shown by the April 1 relations for 1938, 1939, and 1940. The record is too limited in time to support conclusions as to the final success of this method of forecasting.

**Nevada cooperative snow surveys**, C. ELGES, J. E. CHURCH, H. P. BOARDMAN, ET AL. (Nev. Expt. Sta., U. S. D. A., et al.). (*Nev. Coop. Snow Surveys*, 1941, pt. 1, pp. [4]; pt. 2, Mar. 1, pp. [8]; pt. 2, Apr. 1, pp. [29]; 1942, pt. 1, pp. [4]; pt. 2, Mar. 1, pp. 14; pt. 2, Apr. 1, pp. 28).

**Nevada cooperative snow surveys—eastern slope, central Sierra Nevada: Comparison of forecast and actual results, 1940**, H. P. BOARDMAN, G. G. DEVORE, and L. SANFORD (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 141–142).—The authors conclude that whenever a winter brings considerable rain during the usual months of snowfall, it will be worth while to supplement the snow survey analysis with an examination of available U. S. Weather Bureau winter precipitation records, and if there is a notable excess of precipitation in percent of normal over the snow survey, to make a quantitative estimate of the excess, also taking into account the winter run-off and its relation to normal.

**The Humboldt Basin, Nevada: Two unusual years, 1940–41 and 1941–42**, J. E. CHURCH. (Nev. Expt. Sta.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 156–159).—In the 1940–41 season relatively light snowfall occurred (71.4 percent of normal in March) but precipitation rose to double the normal in April and remained high through the period April–June. In 1941–42 an accumulation of low-level snow, suddenly melted by high temperature, combined with the preceding year's saturation to result in a flood. These unusual phenomena are considered in relation to run-off forecasting.

**Test of snow-sampling tubes of large and small diameter**, B. C. GOODELL and K. L. ROBERTS. (U. S. D. A. et al.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 151–152).—Under the conditions encountered in a test by the Northeastern Forest Experiment Station at New Haven, Conn., the small Mount Rose type of equipment proved to be more practical than the large tube and scales and just as accurate. There is no indication that the larger tube would show any significant advantage to outweigh its disadvantages. Tubular scales with a capacity of about 30 in. (inclusive of the tube weight) and reading to quarter-ounces to improve the accuracy of moisture content determinations in snow of moderate depth may prove useful.

**A new design for a canvas case to carry snow-survey tubes and accessories**, P. S. COWGILL and C. ELGES. (Nev. Expt. Sta. et al.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 148–150, figs. 3).—The authors note that the making of the aluminum tubes in short sections has helped materially, but a convenient carrying case has yet to be supplied. The case shown can be carried on the back by itself or fastened across a knapsack. The entire outfit, including balance, tape, cleaning hook, etc., is contained in one case. Since there is often no need of more than 10 ft. of tube, the case is made in two units, each holding four sections.

## SOILS—FERTILIZERS

**[Soil and fertilizer work in Mississippi]** (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 10, p. 3).—Brief statements of work at the substations on soil fertility and maintenance, sources and rates of nitrogen, and the value of legumes for maintaining soil fertility are presented by C. Dorman.

**[Soil investigations by the Ohio Station]** (*Ohio Sta. Bul.* 617 (1940), pp. 10, 12–13, 18, 69, 70–71, fig. 1).—This report notes a new method to measure

soil moisture, standardization of soil colors by whirling disk method, a new device to indicate when irrigation is needed, unprofitableness of tile drainage on some soils, need of Paulding County soils for organic matter, and superiority of timothy meadows on fertile soil.

**[Soil investigations by the Rhode Island Station]** (*Rhode Island Sta. Rpt.* [1941], pp. 36-38, 40-41).—Progress is reported on the development of a laboratory method for determining available magnesium. Partial sterilization of the soil with chloropicrin, which has a marked effect on microbiological activity, did not entirely overcome the effect of the preceding crops. When various permittite and demineralite [aniline black] complexes were added to sand in glazed pots, treated with various concentrations of essential ions in a common culture solution and planted with red kidney beans and soybeans, the growth produced was proportional to the amount of ions present.

**A microscopic method of studying soil structure**, C. L. W. SWANSON. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 16 (1942), No. 3, pp. 379-389, figs. 10).—An apparatus is described in detail which was made to provide for a quick and easy tracing of projected microscopic images of soil in the natural state as observed in thin sections. The images provided for the comparison of pore spaces on the basis of shape, size distribution, and volume. Tracings of projected images are given for Marshall and Shelby silt loam profiles. The porosity of the Marshall was much greater throughout the whole profile than that of the Shelby. In a comparison of cultivated and virgin land the virgin soil was found to have twice the volume of pores and a higher percentage of large pores than the cultivated soil.

**Studies of clay particles with the electron microscope.—II, The fractionation of beidellite, nontronite, magnesium bentonite, and attapulgite**, C. E. MARSHALL, R. P. HUMBERT, B. T. SHAW, and O. G. CALDWELL. (Mo. and Ohio Expt. Stas.). (*Soil Sci.*, 54 (1942), No. 2, pp. 149-158, figs. 12).—In the second paper of this series (E. S. R., 87, p. 24) the authors show that the use of the electron microscope throws considerable light on the meaning of mechanical analysis within the clay fraction (below  $2\mu$ ). In some cases, notably Putnam clay (a beidellite), fractionation down to very small sizes appears to have real meaning. The larger particles do not appear to be orientated aggregates of small particles, and their compact character suggests that considerable shearing force would have to be employed within the suspension in order to break them down. The nontronite and magnesium bentonite contained a predominance of aggregates in the coarser fractions, and if complete dispersion had been effected most of the material would have fallen in the finer fractions. In these cases, therefore, slight variation in the method of dispersion might cause notable changes in the mechanical analysis figures. Attapulgite represents an extreme example of this tendency, since the finer particles result entirely from cleavage of larger units. Other details of micromorphology beyond the resulting power of microscopes utilizing either the visible or the ultraviolet wave lengths are shown in electron micrographs, and their significance is discussed.

**The composition of soil colloidal clay**, D. I. SIDERT and A. N. LIAMINA (*Soil Sci.*, 54 (1942), No. 2, pp. 83-100, figs. 2).—A method for the fractionation of colloidal clay is described, on the basis of which suspensions of clays belonging to the Quaternary depositions of the Russian plain have been studied by X-ray, chemical, and thermal methods.

The chief component of these clays was found to be a mineral, of the formula  $3\text{SiO}_2 \cdot \text{Al}_2\text{O}_3 \cdot 0.5 (\text{KII}) \text{O} \cdot \text{H}_2\text{O} + \text{bound H}_2\text{O}$ , resembling the sericitelike mineral par-montmorillonite. In its properties this mineral occupies an intermediate place between the minerals kaolinite, sericite, and a mineral of the same composition as montmorillonite. It differs from the last-named mineral in some important

characteristics, however. The sericitelike mineral described here is considered a mixture of  $\sim 33$  percent sericite+63 percent paramontmorillonite+4 percent kaolinite. The sericitelike mineral of Grim<sup>1</sup> may be regarded, in turn, as a mixture of 38 percent paramontmorillonite+62 percent sericite with little or no kaolinite. The character of the mixture, as well as the kind of the mineral designated as paramontmorillonite, may be established only after further study of clays that have been prepared carefully for analysis.

**Some physical properties of the B horizons of Piedmont soils, T. S. COLLE** (*Soil Sci.*, 54 (1942), No. 2, pp. 101-103, fig. 1).—From three soils the author obtained undisturbed samples of B horizons in the field by the use of a sampling cylinder (E. S. R., 76, p. 158) having a diameter of 5 in. and a depth of 2 in. The field samples were allowed to soak in water for 2 weeks, after which the excess soil was removed and measured as the volume percentage of swelling. The volume-weight, shrinkage on drying, percentage of clay (particles less than  $2\mu$  in diameter), and the moisture equivalent minus the xylene equivalent were also determined.

**Influence of low recessional moraines on soil type pattern of the Mankato drift plain in Iowa, C. S. GWYNNE and R. W. SIMONSON.** (Iowa Expt. Sta.). (*Soil Sci.*, 53 (1942), No. 6, pp. 461-466, figs. 3).—The authors show that the distribution of soil types in many parts of the Mankato lobe in Iowa shows a banded pattern of annual recessional moraines. Clarion soils, members of the Prairie group, occupy the low but well-drained swells, whereas Webster soils (Wiesenboden) have been formed in the intervening swales where natural drainage was restricted. The low recessional moraines, which could be identified readily from the study of aerial mosaics, range up to 600 ft. in length, with long axes tending to parallel the outer edges of the lobe. The similarity in pattern of moraines and soil types is shown to be evident from a comparison of aerial mosaics and recent soil maps for counties in north-central Iowa.

It is pointed out that the relation between soils and low moraines in north-central Iowa may exist in other glaciated regions in an early stage of the erosion cycle. Recognition of the pattern of moraines should be helpful in the mapping of soils, and conversely, the soil maps may be helpful in the study of surface geology.

**[Soil Survey Reports, 1935 and 1936 Series]** (*U. S. Dept. Agr., Bur. Plant Indus. [Soil Survey Rpts.], Ser. 1935, No. 22, pp. 68, pls. 3, figs. 2, map 1; 1936, Nos. 14, pp. 68, pls. 6, figs. 3, map 1; 15, pp. 125, pls. 5, figs. 4, map 1; 17, pp. 93, pls. 3, figs. 2, map 1; 19, pp. 60, pls. 4, fig. 1, map 1*).—These surveys were made in cooperation with the State experiment station as respectively noted: 1935, No. 22, Tulsa County, Okla., E. W. Knobel et al. (Okla. Expt. Sta.); 1936, No. 14, Seneca County, N. Y., C. S. Pearson et al. ([N. Y.] Cornell Sta.); No. 15, Roane County, Tenn., M. E. Swann et al. (Tenn. Sta. et al.); No. 17, the Wasco area, Calif., A. C. Anderson et al. (Calif. Sta.); and No. 19, Madison County, N. C., E. F. Goldston et al. (N. C. Sta. et al.).

**Water-permeable jacketed thermal radiators as indicators of field capacity and permanent wilting percentage in soils, C. N. JOHNSTON.** (Univ. Calif.). (*Soil Sci.*, 54 (1942), No. 2, pp. 123-126, figs. 2).—Work with Bouyoucos' plaster electrical conductors (E. S. R., 83, p. 307) suggested that if the heater element in the soil were given a covering of porous material that would have its own moisture-holding characteristics, this jacket would absorb the heat emanating from the heater coil, making the resulting readings a function of the moisture content of the jacket and eliminating the contact difficulties between soil and elements that arise when nonjacketed heaters are used. Plaster of paris was cast as a concentric jacket  $\frac{1}{8}$  in. thick about the 15-mm. glass tubes

<sup>1</sup> Jour. Amer. Ceramic Soc., 19 (1936), No. 11, pp. 307-315.

upon which the heater wires had been wrapped. A winding of No. 40 enameled copper wire, noninductively arranged as in resistance box coils, was used, and resistance changes were followed by means of a Wheatstone bridge. The heater elements were tested in Yolo fine sandy loam and in Holland fine sand. Despite the very different soil moisture percentages for the limits of field capacity and permanent wilting percentage in the two soils, comparable readings resulted, indicating that the plaster-jacketed heater may be applied to other soils with some prospect of obtaining readings similar to those here recorded for permanent wilting percentage and field capacity moisture contents. The plaster of paris jacket appears to be able to adjust itself to comparatively rapidly changing moisture content in the soil in the pots and should, therefore, be suitable for use in the field.

**An automatic self-recording infiltrometer,** D. D. PITTMAN and H. KOHNKE. (Ind. Expt. Sta. coop. U. S. D. A.). (*Soil. Sci.*, 53 (1942), No. 6, pp. 429-434, figs. 4).—Water is applied to the ground from a tank which rests on the balance of a recording rain gage. The water passes through a rubber hose to a plat which is enclosed by a steel frame 3 in. high, of which one-half is driven into the ground to check surface runoff. The decrease in weight of the tank, representing the infiltration that has occurred, is recorded on the chart of the revolving clock drum. The area to which water is applied from the tank is a square 7.09 in. on the side, the same as that of the 8.00-in.-diameter rain gage catchment, so that gage readings are direct in inches of infiltration.

A continuous record of infiltration, showing any change of rate when it occurs, is obtained automatically and is not subject to errors of the operator. The infiltration run can be extended over several hours, or until 6 in. of water have been applied. Many experiments can be performed in a relatively short time, allowing study simultaneously of the infiltration rate of two similar sites that differ essentially only in one plant or soil factor. The operation is simple. The expenses for procurement and operation are low in comparison with those for the sprinkler-type infiltrometers. For the transportation of two outfits and the necessary water a half-ton pick-up truck suffices.

The authors note the following limitations: (1) The area of the infiltration plat is small; therefore, sideward movement of water and air in the soil may tend to increase infiltration rates. This effect is partly compensated by buffer plats. (2) No attempt is made to simulate natural rainfall.

**The thermal conductivity of dry soil,** W. O. SMITH. (U. S. D. A.). (*Soil Sci.*, 53 (1942), No. 6, pp. 435-459, figs. 6).—Methods for cutting large monolith samples are given, and measurements of thermal conductivity on monolith samples cut by these methods from Miami silt loam (Indiana), Miami silty clay loam (Michigan), and Chester loam (Maryland) are reported. These show wide variation, depending on the structure present. Data for these samples when reduced to the finely fragmented state are also given. The thermal conductivities, except for granular structures, are considerably decreased when the soils are thus comminuted. Approximate expressions for the calculation of the thermal conductivity of a dry soil were developed. These require for their use in natural soils specific data regarding the porosity (determined usually from field volume weights and textural density), the soil structure, and the respective thermal conductivities of the soil solids and fluids. The influence of structure on thermal resistance is discussed and an index  $\alpha$  (thermal structure factor) established for measuring its effect. This index depends on the type, class, and grade of structure.

Granular structured horizons were found to have about the same conductivity in both the natural and the finely divided states. Mechanical reduction as usually done in the laboratory has little effect on ordinary granular structures. The

thermal conductivity of most other structure patterns differs greatly from that observed in the finely fragmented condition, and in some cases it may be twice that observed in the comminuted state. Thermal resistance was found dependent on the architecture of the pore space and, in particular, on the component of the pore space included within the thermal paths through the soil solids. It appeared to depend both upon the textural and the secondary pore spaces. So far as the secondary pore space is concerned, the dependence is on the structural, if the soil is natural and structured; if it is in the mechanically fragmented state, the dependence is on that between the fragments. The component of the secondary pore space included within the thermal paths through the soil solids differs significantly in each type of secondary pore space, hence the thermal resistance and, therefore, the conductivity, are generally different in each of these states.

**Some factors of the hydrology of the Sierra Nevada foothills, P. B. ROWE.** (U. S. D. A. and Univ. Calif.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 90-100, figs. 17).—The size of the area, the character, intensity, and duration of the precipitation, and the moisture content of the soil were found, because of their influence on infiltration, surface runoff, erosion, and water yield, to be important factors in the hydrology of the Sierra Nevada foothills. The undisturbed vegetation cover of the woodland chaparral type, by protecting and maintaining soil conditions favorable to the development of high infiltration capacities, is effective in the control of surface runoff, erosion, and floods. A natural cover of woodland chaparral vegetation, by decreasing surface runoff and erosion and by serving to regulate and prolong stream flow from the area, at little or no reduction in the quantity of water yield, is highly beneficial in the production of usable water.

**A 100-year record of Truckee River runoff estimated from changes in levels and volumes of Pyramid and Winnemucca Lakes, G. HARDMAN and C. VENSTROM.** (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 71-90, figs. 5).—Pyramid and Winnemucca Lakes receive and evaporate the waters of Truckee River, hence fluctuations in the levels and volumes of the lakes afford a means of measuring variations in the volume of water discharged into the lakes by this river. The history of the fluctuations in the lake levels and volumes from the discovery of Pyramid Lake in 1844 by J. C. Fremont to 1939 is traced. A considerable part of the runoff of Truckee River has been used for irrigation within the basin or diverted to points outside it. These deductions from the quantities of water which would have reached Pyramid Lake under natural conditions were calculated and added to the volumetric changes in the lakes. A record of runoff of Truckee River for the period of study was prepared by distributing the volumes of water in the lakes into annual seasonal discharges.

**Drainage in the San Joaquin Valley as it may be affected by the Central Valley project, W. W. WEIR.** (Calif. Expt. Sta.). (*Amer. Geophys. Union Trans.*, [22] (1941), pt. 1, pp. 45-49).—As a result of a proposed new source of gravity irrigation water the author expects an entirely new drainage problem to arise in a California area (Contra Costa County) in which there has been no previous irrigation. Elsewhere old drainage situations, now partially alleviated by extensive pumping, will be aggravated to the point where they will again become serious. New lands, or lands heretofore dependent solely on pumped water, will be safe under any normal procedure. The whole drainage problem, however, could be solved by everywhere withholding late-season gravity water to an extent such that 25 or 30 percent of the annual requirement would continue to be pumped from deep wells.

**Effects of wind erosion on the composition and fertility of some Alberta soils, R. L. ERDMAN** (*Sci. Agr.*, 22 (1942), No. 9, pp. 533-545, figs. 5).—As a

comparison of conditions for wind erosion, records are presented of winds in southern and southeastern Alberta where they were found to be about 20 percent higher than at two points in the Dust Bowl of the United States. Pot experiments with wheat comparing eroded and noneroded soils revealed that fine sand soil had been seriously damaged in productivity by erosion. Silt loam soil showed smaller injury, while loam and clay soils studied indicated no decrease in productivity. Chemical analyses indicated marked losses in fertility in coarse-textured soils, these amounting to losses of from one-third to one-half of the nitrogen and the organic matter. In medium-textured soils losses were about 15 percent in nitrogen and organic matter as a result of wind erosion. The fine-textured soils showed a percentage loss similar to that found in the medium-textured soils. Analyses of the dust samples indicated that they were about twice as high in nitrogen and organic matter as cultivated surface soils from adjacent areas.

**A medium for the rapid cultivation of soil actinomycetes,** E. J. BOTCHER and H. J. CONN. (N. Y. State. Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 1, p. 137).—Because of the importance of soil actinomycetes in the production of antibiotic substances, attention has been directed toward the finding of a substitute for agar which would be a more satisfactory medium for the growth of the organisms. Materials investigated included sand, glass beads, gypsum blocks, and cotton. Of the above materials, cotton proved to be the most satisfactory. The advantage of cotton is that it can be saturated with a culture fluid, and although it does not form a gel, it gives the organisms a point of attachment and allows good aeration.

**Are there obligate cellulose-decomposing bacteria?** R. Y. STANIER (*Soil Sci.*, 53 (1942), No. 6, pp. 4:9-480).—By substituting a sterilization by filtering for the heat sterilization previously used, the author was able to provide experimental conditions such that the three species *Sporocytophaga myxococcoides*, *Cytophaga hutchinsoni*, and *C. rubra* all grew excellently in a mineral medium with filtered dextrose as the sole carbon source in quantities ranging from 0.1 to 0.5 percent. The filtered dextrose did not exert a toxic effect on growth in the presence of cellulose, although with the higher concentrations of dextrose the attack on the cellulose was diminished, apparently because of a preferential utilization of the monosaccharide evidenced by abundant growth in the liquid. The similarity in the rates of cellulose, cellobiose, and dextrose oxidation by *C. hutchinsoni* indicates that cellulose is decomposed by an initial break-down to, and subsequent oxidation of, the constituent monosaccharide.

**Nitrogen fixation by *Azotobacter* in association with other bacteria,** C. J. LIND and P. W. WILSON. (Univ. Wis.). (*Soil Sci.*, 54 (1942), No. 2, pp. 105-111).—In the use of a medium in which the readily available iron was not optimum because of an unsatisfactory preparation of iron humate, an aerobic spore-former isolated as a contaminant from a culture of *A. vinelandii* markedly stimulated nitrogen fixation by this organism. Under these conditions fixation by the *Azotobacter*, although good and decidedly higher than most values found in the literature, was not maximum. The two species could be continuously grown together without the contaminant dominating the population and consequently reducing the nitrogen fixed. The same results were obtained by mixing pure cultures of the contaminant with strains of *Azotobacter* at the beginning of an experiment. Attempts to replace this contaminant by other aerobic spore-formers, by rhizobia, and by other nonsporeformers were unsuccessful. Stimulation of nitrogen fixation was also obtained with a mixed culture of *A. vinelandii* and *Clostridium pasteurianum* under conditions in which appreciable nitrogen fixation by the latter would not be expected. When a new preparation of humate

was used or additional iron was supplied the old preparation, the stimulation was no longer evident.

**Influence of potassium chloride on nitrification in Bedford silt loam,** B. E. HAHN, F. R. OLSON, and J. L. ROBERTS. (Ind. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 2, pp. 113-121).—The critical concentration of potassium chloride for measurable inhibition of nitrification in Bedford silt loam at 66 percent of water-holding capacity was found, in laboratory experiments, to occur between 190 and 380 p. p. m. Nitrite formation, but not nitrate formation, was inhibited by potassium chloride. The chloride ion was found to be responsible for the inhibition.

**The neutralization of acid-forming nitrogenous fertilizers in relation to nitrogen availability and soil bases: A report of Windsor lysimeter series D,** M. F. MORGAN, H. G. M. JACOBSON, and O. E. STREET. (Conn. [New Haven] Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 2, pp. 127-148).—Comparisons of the effects of ammonium sulfate, urea, and cottonseed meal, both with and without neutralization of theoretical acid production, and of sodium nitrate, applied to two soils differing in their initial base status, were made in lysimeter tanks without crop. Annual treatments of 200 lb. of nitrogen per acre in these materials were applied in combination with other materials supplying equal amounts of other constituents, except as required to adjust the acidity.

The nitrates supplied as sodium nitrate were almost entirely leached from the surface soils used in the tanks within from 6 weeks to 4 mo., depending upon the conditions of summer rainfall occurring during the 5 yr. of these trials. The rate of nitrification of the other materials was accelerated by the neutralizing treatments, as evidenced by the early leaching of larger proportions of the total annual nitrate production. The lime-adjusted urea treatment showed particularly high acceleration of nitrification on the less acid soil. The transformation of ammonia to nitrates under the fully acid ammonium sulfate treatment was definitely retarded, particularly on the more acid soil. Neutralizing one-half of the potential acidity of this treatment considerably favored nitrification. Cottonseed meal was more slowly nitrified than urea, both with and without neutralization, on both soils. The total measurements of nitrates and ammonia nitrogen in the drainage water indicated a greater capacity for nitrate production on the more acid soil in most comparisons. Nitrate production from ammonium sulfate was definitely increased by partial neutralization. On the other hand, when this material was fully neutralized in applications to the less acid soil, the considerably decreased nitrogen recovery suggested that some losses of ammonia to the atmosphere may have been engendered at a soil reaction approaching the neutral point. Measurements of nitrogen in the soil at the end of the experiment supported this view. The neutralized urea treatment showed a similar tendency. Ammonia nitrogen was leached in considerable amounts from sandy surface soils used in this experiment in years when heavy rains occurred early in the season. Such ammonia losses were chiefly from the ammonium sulfate and urea treatments. They were smaller when these materials were neutralized. The less acid soil, although slightly more sandy, did not leach as much ammonia for corresponding treatments. Since both soils liberated a considerable amount of nitrogen without additions of this element in the treatment, the total leachings of nitrogen produced net losses from the soil during the 5-yr. period in most instances. From lysimeter data, cottonseed meal treatments should have produced small net gains of soil nitrogen in all comparisons. The soil analyses indicated some nitrogen losses, even under this treatment, but these were of smaller magnitude than with the other nitrogen fertilizers.

Considerable amounts of the calcium added in the neutralizing treatments

were not represented in the leaching. Most of this apparent residue was not accounted for in measurements of the exchangeable calcium of the soils at the conclusion of the experiment. On the other hand, net losses of calcium under the acid treatments were similarly evidenced by both leaching and soils data. This was also true of magnesium. Except under the sodium nitrate treatments, potassium losses by leaching were of much smaller magnitude than the decreases in exchangeable potassium. Other leachings were closely in line with the amounts supplied in the treatments, except for phosphorus, which did not leach. Acid nitrogen fertilizers caused considerable leaching of aluminum and manganese, particularly when applied to the more acid soil. After the first 2 yr. the fully acid ammonium sulfate treatment produced similar leachings of these constituents on both soils. The less acid soil had been previously treated with dolomitic lime. Hence, this soil leached more magnesium and less potassium for corresponding treatments, particularly in the earlier years of the experiment. Calcium leachings from both soils were of similar magnitude, although one was much more acid than the other.

Lysimeter data, pH measurements, and base-exchange studies all show the acid effects of ammonium sulfate, urea, and cottonseed meal upon both soils, except when fully neutralized with lime. The acid effects were more pronounced on the initially less acid soil, particularly from the fully acid ammonium sulfate treatment. The neutralization of approximately one-half of the potential acidity of this fertilizer gave similar results to those obtained from urea. Increases in acidity due to strongly acid nitrogen fertilizers were measured by net base depletion, by leaching, by decreases in exchangeable bases, and by increases in exchangeable hydrogen. These represented much smaller calcium carbonate equivalents than could be evaluated from the potential acidity of the treatment. After the soil becomes strongly acid, further applications of an acid-reacting fertilizer produce but slight effects upon the base status of the soil. On the other hand, lime applied in quantities equivalent to the acidity of the fertilizer serves to maintain the net base status of the soil at a fairly constant level, except when applied in connection with a less fully available nitrogen material, such as cottonseed meal. The use of a liming material in neutralizing acid nitrogen fertilizer produces a change in the distribution of the various exchangeable bases. Thus, in this experiment, an acid soil treated with "neutral" fertilizers for 5 yr. was made much more productive for alfalfa, a result believed to be associated with the changed proportions of the various bases.

**Plant symptoms of boron deficiency and the effects of borax on the yield and chemical composition of several crops, G. R. MUIR.** (Mich. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 1, pp. 55-65, figs. 5).—Sugar beets, canning beets, mangels, radishes, chicory, rutabagas, turnips, barley, wheat, corn, and dandelions were grown either on a boron-deficient soil or on boron-deficient quartz sand, and on similar substrates to which borax had been added, to determine boron-deficiency symptoms and to provide normal and boron-deficient plant tissue for chemical analysis.

An insufficient supply of boron for root crops was evidenced by the distortion and premature death of the central leaves, by the formation of numerous small leaves, and by a break-down of the root tissue cells. The formation of corky tissue, sloughed-out areas (cankers), and water-soaked areas (brown heart) accompanied or followed the break-down of the root tissue cells. Barley, wheat, and corn matured later and failed to develop seeds normally when boron was lacking. Dandelions with an insufficient supply of boron failed to bloom. The tissue of plants inadequately supplied with boron contained, in most cases, higher percentages of calcium, nitrogen, magnesium, and iron than the tissue

of plants grown in the presence of sufficient boron. The greatest differences in composition occurred in the contents of nitrogen and iron. The potassium content was not greatly altered by the plants' response to boron. Borax applied to the soil in all cases increased the boron content of the plants. Plants with characteristic boron-deficiency symptoms were relatively low in boron content.

**Occurrence of soluble selenium in soils and its availability to plants.** O. E. OLSON, E. I. WHITEHEAD, and A. L. MOXON. (S. Dak. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 1, pp. 47-53, fig. 1).—Soils and plants from 32 locations within a small seleniferous area (in sec. 2, T. 107 N., R. 78 W., South Dakota) were analyzed for total selenium. Some of the soils were analyzed also for soluble selenium. The results indicate that in the region specified the second and possibly the third foot of soil are the important source of selenium available to plants, and that the top foot of soil is, in general, relatively unimportant. Most of the soluble selenium was found to occur as selenates, but selenites appeared also to be present in the soils. The data obtained indicate that highly seleniferous soils may be formed by the removal of soluble selenium from seleniferous rock and its redeposition in materials of relatively low selenium content.

**Response of cos or romaine lettuce to chloropierin soil treatment, phosphate, and lime.** J. B. SMITH and F. L. HOWARD. (R. I. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 49 (1942), pp. 552-556, fig. 1).—Soil treatment with chloropierin, used at the rate of 5 cc. per cubic foot of soil prior to cropping, was compared with soil acidity, phosphate levels, manure, boron, and magnesium to determine the effect of soil fertility on crop yield. The authors point out that soil may be producing below its capacity because the effects of injurious and competitive micro-organisms have not been given due consideration. The chloropierin treatment is reported as having removed the major factors inhibiting vegetable growth. Large applications of phosphate with the chloropierin treatment gave the greatest response. The effect of difference in acidity (pH 5.3-5.5 compared with pH 6.1-6.3) on vegetative growth is decreased as greater amounts of phosphate are added, or the greater the phosphate level in the soil the less acidity acts as a limiting factor of growth. Chloropierin soil treatment gave at least a doubling of the yield and brought a proportionally greater growth response at the lower phosphate levels than at the higher.

**Agronomic value of kitchen waste.** M. M. MCCOOL. (*Contrib. Boyce Thompson Inst.*, 12 (1942), No. 5, pp. 345-358, figs. 2).—Results of greenhouse and field experiments are given on the soil-improving value of air-dried and ground samples of kitchen waste. In greenhouse tests the waste was found to be less effective for the first crop than tankage and to be superior to cow manure and shredded stockyard manure, when compared on the basis of the addition of equal amounts of nitrogen to the soil cultures. Residual effects were greater than were those from tankage and the manures employed. The addition of small amounts of sodium nitrate was effective in reducing the time required for response after planting. In a field test with sweet corn, waste comprised of a mixture from different sources was superior to stockyard manure. Availability of the waste was not increased by incubating with material from active composts. Incubation, however, was considered by the author to be practicable when one considers changes in color, structure, loss of obnoxious volatile materials, and the large decrease in water content during decomposition.

## AGRICULTURAL BOTANY

**Plant material introduced by the Division of Plant Exploration and Introduction, Bureau of Plant Industry, April 1 to June 30, 1937** (U. S. Dept. Agr., *Inventory 131* (1942), pp. 55).—This number lists 1,284 lots of plant material with descriptive notes in many cases.

**A modern classification of the plant kingdom**, O. TIPPO. (Univ. Ill.) (*Chron. Bot.*, 7 (1942), No. 5, pp. 203-206, fig. 1).—Knowing of no general modern classification reflecting the newest sound developments in all branches of plant phylogeny and in which the various groups are named in such a way as to indicate rank or degree of affinity and in which the various group names are brought into conformity with the system used by zoologists, the author has assembled and here presents a classification which he has found useful and which he believes may be of interest to other botanists, especially teachers of botany.

**Plant life: A textbook of botany**, D. B. SWINGLE (New York: D. Van Nostrand Co., [1942], 2. ed., pp. XVI+457, [pl. 1], figs. 295).—Without sacrificing the technical material and in response to student interest, this edition introduces a little more "natural history" than was found in the first (E. S. R., 73, p. 593).

**Tabular keys for identification of the woody plants**, F. B. ROBINSON (Champaign, Ill.: Garrard Press, [1941], pp. [4]+156). This set of keys has been evolved for use of students and others interested in studying and identifying the more used woody plants of the Northern States and Canada in the field and includes 500 trees, shrubs, and vines. Separate keys are provided for trees, shrubs, vines, conifers, and broad-leaved evergreens in leaf and in winter.

**Medicinal plants: Native and naturalized plants of Virginia which have been officially used in the preparation of drugs**, A. B. MASSEY (Va. Polytech. Inst. Bul., 35 (1942), No. 13, pp. 52, figs. 15).—Based on a general survey of the State and data already in hand, this contribution was prepared in answer to the many requests as to what native plants are of value, and how to market them, among the approximately 140 species found in Virginia which have been officially used in medicine. For each plant its occurrence in Virginia, data on collecting and preparing the crude drug, and a brief description are presented.

**The uptake of ions by bacteria**, T. M. McCALLA and V. D. FOLTZ. (Kans. Expt. Sta.) (*Kans. Acad. Sci. Trans.*, 44 (1941), pp. 46-47).

**Dissimilation of phosphoglyceric acid by Escherichia coli**, M. F. UTER and C. H. WERKMAN. (Iowa State Col.). (*Biochem. Jour.*, 36 (1942), No. 5-6, pp. 485-493, figs. 3).

**Dissimilation of pyruvic acid by cell-free preparations of Clostridium butylicum**, H. J. KOEPEL and M. J. JOHNSON. (Wis. Expt. Sta.) (*Jour. Biol. Chem.*, 145 (1942), No. 2, pp. 379-386, figs. 3).—The authors describe the preparation of a vacuum-dried cell-free water extract from frozen cells of *C. butylicum* which catalyzes the fermentation of pyruvic acid to acetic acid, CO<sub>2</sub>, and H<sub>2</sub>, the reaction being most active at pH 6.5. There are 19 references.

**The bacterial oxidation of rubber**, C. E. ZOBELL and C. W. GRANT. (Univ. Calif.). (*Science*, 96 (1942), No. 2495, pp. 379-380).—Besides demonstrating that neither synthetic nor pure India rubber is biologically inert and proving that rubber-oxidizing micro-organisms occur fairly abundantly in nature, the studies reported suggest that such forms may play an important role in the deterioration of rubber products, especially those exposed to moisture. Not only species of *Actinomyces* and *Proactinomyces*, but also of *Mycobacterium* and *Pseudomonas*, were found capable of oxidizing rubber, and the aerial mycelium of an unidentified mold virtually enveloped the moist rubber on which it was growing and its substrate mycelium seemed to penetrate the rubber.

**Flagella staining of anaerobic bacilli**, E. O'TOOLE (*Stain Technol.*, 17 (1942), No. 1, pp. 33-40, figs. 14).—The technic described involves use of the flagella stain of H. D. Bailey<sup>2</sup> and careful attention to several details, the most important of which are listed.

<sup>2</sup> Soc. Expt. Biol. and Med. Proc., 27 (1929), No. 2, pp. 111-112.

**A flagella staining technic for soil bacteria**, P. J. FISHER and J. E. CONN. (N. Y. State Expt. Sta.). (*Stain Technol.*, 17 (1942), No. 3, pp. 117-121, figs. 5).—The flagella of many soil bacteria are so fine that they are difficult to stain by most methods, but the technic developed by the authors, combining the best points of the Hofer-Wilson method (E. S. R., 79, p. 456) with that of Bailey as developed by O'Toole (noted above), is reported to have given satisfactory preparations of bacteria of the genera *Pseudomonas*, *Phytomonas*, *Alcaligenes*, *Escherichia*, *Azotobacter*, and *Bacillus*. The method is recommended as a rapid and constant technic for routine staining of all motile aerobes.

**The occurrence of actinomycetes of the genus *Micromonospora* in inland lakes**, W. W. UMBREIT and E. MCCOY (In *A Symposium on Hydrobiology*. Madison: Univ. Wis. Press, [1941], pp. 106-114, fig. 1).

**The carotenoid pigments of cryptogams**, D. L. FOX. (Univ. Calif.). (*Chron. Bot.*, 7 (1942), No. 5, pp. 196-198).—A review of studies of these pigments in bacteria, fungi, and algae.

**The occurrence and significance of marine cellulose-destroying fungi**, E. S. BARGHOORN, JR. (*Science*, 96 (1942), No. 2494, pp. 358-359).—In this preliminary note the author reports the isolation of a series of marine fungi readily attacking wood and other cellulosic materials under marine conditions and shows them to be of very common occurrence along the North Atlantic coast.

**The role of the aquatic fungi in hydrobiology**, W. H. WESTON (In *A Symposium on Hydrobiology*. Madison: Univ. Wis. Press, [1941], pp. 129-151).—This is a general, critical review (59 references), presenting evidence that these fungi play a significant role in the complexly interwoven pattern of life in inland waters, and that they deserve more attention from limnologists.

**A sporulation stock medium for yeasts and other fungi**, E. M. MRAK, H. J. PHAFF, and H. C. DOUGLAS. (Univ. Calif.). (*Science*, 96 (1942), No. 2497, p. 432).—An agar medium made from aqueous extract of carrots, beets, cucumbers, and potatoes induced sporulation and served as an excellent stock culture medium. Its preparation is described.

**Nuclear behavior in the Mucorales.—I, The Mucor pattern**, V. M. CUTTER, JR. (Cornell Univ.). (*Bul. Torrey Bot. Club*, 69 (1942), No. 7, pp. 480-508, figs. 66).—Employing several techniques not known to have been used on the group previously, the nuclear behavior in nine species of the Mucorales is traced through all the life history stages. There are 31 references.

**Spore dispersal in the Mucorales**, C. G. DOBBS (*Nature [London]*, 149 (1942), No. 3786, p. 583).—A brief note.

**Plant resources of Honduras**, W. POEYNOE (*Chron. Bot.*, 7 (1942), No. 5, pp. 217-219).

**Chaves para a determinação de gêneros brasileiros e exóticos das dicotiledoneas mais cultivadas no Brasil [Keys for determining the indigenous and introduced dicotyledons commonly cultivated in Brazil]**, L. J. BARROSO (*Bol. Soc. Brasil. Agron.*, 5 (1942), No. 2, pp. 173-182, pls. 3).—Genera of the Araliaceae, Urticaceae, Loranthaceae, and Proteaceae are included here.

**Eucalyptus: Contribución al conocimiento del eucalipto y de sus esencias, en la Provincia del Tungurahua [Eucalyptus: Contribution to the knowledge of eucalyptus species and their volatile oils in Tunguragua Province, Ecuador]**, A. CASTILLO V (*Bol. Inst. Bot., Univ. Cent. Ecuador*, 1 (1942), No. 1, pp. 125-159).

**Indiana plant distribution records, II—1941**, C. C. DEAM ET AL. (*Ind. Acad. Sci. Proc.*, 51 (1941), pp. 120-129).—This second in the series of distribution records<sup>1</sup> is intended to keep Deam's "Flora of Indiana" up to date.

<sup>1</sup> *Ind. Acad. Sci. Proc.*, 50 (1940), pp. 72-78.

**Additions to the revised catalogue of Ohio vascular plants, X, C. H. JONES.** (Ohio State Univ.). (*Ohio Jour. Sci.*, 42 (1942), No. 5, pp. 201-210).—This annotated list represents a majority of the new county and State records added to the State herbarium during the preceding year.

***Panicum bennettense*, a new species from North Carolina, W. V. BROWN** (*Bul. Torrey Bot. Club*, 69 (1942), No. 7, pp. 539-540, fig. 1).—This new grass was found in dry thickets in a savanna near Durham.

**Revisionary studies in the Coryneliaceae, [I], II, H. M. FITZPATRICK.** (Cornell Univ.). (*Mycologia*, 34 (1942), Nos. 4, pp. 464-488, figs. 43; 5, pp. 489-514, figs. 35).—These papers constitute a revision of the writer's earlier monographic treatment of the Coryneliaceae.<sup>4</sup>

**Ecological problems of the southeastern United States coastal plain, B. W. WELLS.** (Univ. N. C.). (*Bot. Rev.*, 8 (1942), No. 8, pp. 533-561).—The main body of this critical review considers salt-spray climaxes, aquatic and marsh communities, swamp forest, peat bogs, shrub bogs, white cedar bogs, savannas, longleaf pine fire subclimax, the problems of the sandhill climax and of longleaf pine forest management, coastal peat deposits, regional climatic climaxes, and Florida hammocks. In this survey nine well-defined major communities are described. In the differentiation of these the principal controlling conditions, aside from the over-all climatic factors, are the soil texture, as this controls water and nutrient (especially Ca), length of exposure to high-water table (hydroperiod), salt spray (near the coast), and fire, involving all except the aquatic. There are 63 references.

**An ecological analysis of the plant communities of Piedmont, North Carolina, H. J. OOSTING** (*Amer. Midland Nat.*, 28 (1942), No. 1, pp. 1-126, figs. 19).—A detailed knowledge of successional trends and the ecological structure of natural plant communities contributes materially to successful silvicultural practice and forest management. This monographic study was undertaken to serve as a foundation toward filling this need, viz. to determine for this area the natural groupings of plants with respect to their habitats and the changes in these communities with respect to time, to learn if possible why these communities occur as they do, and to determine possible plant indicators which would be satisfactory criteria for the character of the various habitats. There are 23 references, and an appendix lists the species mentioned in the text with their authorities, the common names used, and the life forms.

**Lack of available phosphorus preventing normal succession on small areas on Bull Run Mountain in Virginia, H. A. ALLARD** (*Ecology*, 23 (1942), No. 3, pp. 345-353, figs. 3).—In this area small local barren-soil spots occurring on abandoned cultivated land remain more or less destitute of normal vegetative cover for indefinite periods, appearing as naked spots surrounded by broomsedge, forbs, or the woody shrubs and trees which indicate the early stages of a climax woodland. Pot-culture and field-plot studies using additions of essential nutrient salts with various plants (tobacco, legumes, German millet, etc.) as indicators showed that these soils are lacking primarily in P and secondarily in N. Lack of sufficient available P has prevented a timely invasion by wild N-fixing legumes, so that these soils very slowly build up a sufficiency of such reserves and therefore remain practically devoid of a closed plant cover indefinitely. Reference is made to similar barren soils in Scotland (termed "serres"), and it is suggested that chemical deficiencies may be in part responsible for their origin also.

**Ecological relations of plants with ants and termites, J. C. T. UPHOF** (*Bot. Rev.*, 8 (1942), No. 9, pp. 563-598).—"An ecological relationship exists between plants and some species of ants and termites, insects that have reached a rela-

<sup>4</sup> *Mycologia*, 12 (1920), Nos. 4, pp. 206-237, pls. 7; 5, pp. 239-267.

tively high degree of 'mental' and social organization." This monographic review (193 references) considers myrmecophytes, myrmecochores, ants and extrafloral nectaries, the fungus-growing habit among ants and termites, ant fungi, termite fungi, and different hypotheses regarding myrmecophily.

**Infección de la alfalfa con "Rhizobium meliloti" en la Provincia de Santa Fe** [Alfalfa infection by *R. meliloti* in Santa Fé Province, Argentina], E. SCHIEL and A. E. RAGONESE (*Rev. Argentina Agron.*, 9 (1942), No. 2, pp. 114-169, figs. 6; *Eng. abs.*, pp. 166-167).—This extended study is believed to be the first in Argentina dealing with the problem of inoculating alfalfa with pure cultures of the legume nodule organism, the purpose being to extend the practice throughout the Province, where field trials have shown benefits therefrom. The strains used are enumerated, laboratory methods (with suggested modifications) are reviewed, culture formulas are given, and the methods of obtaining pure cultures, sterilizing the seed, growing the seedlings aseptically, and inoculating the plants are detailed. It was found that inoculated seed must be sown as early as possible for best results, and that *Rhizobium* cultures kept in tightly closed tubes retain their virulence for at least 72 days in storage. For selecting the most efficient strains, field trials were conducted with those giving best results in the laboratory, after which those performing best in the field were employed as a polyvalent culture for further inoculations. Six field trials on common soils in three areas appeared to indicate the poor efficiency of local strains of *Rhizobium* as compared with those from outside sources, the better start of inoculated alfalfa, and the relative freedom from weeds with inoculated alfalfa. There are 27 references.

**Studies on nitrogen fixation by blue-green algae.—I, Nitrogen fixation by *Anabaena cylindrica* Lemm.**, G. E. FOGG (*Jour. Expt. Biol.*, 19 (1942), No. 1, pp. 78-87, figs. 2).—*A. cylindrica* in pure culture free of bacteria was shown to fix N from the air. N fixation did not occur in the presence of a sufficient amount of readily available combined N.

**The effect of auxins on protoplasmic streaming, III**, B. M. SWEENEY and K. V. THIMANN (*Jour. Gen. Physiol.*, 25 (1942), No. 6, pp. 841-854, figs. 7).—Continuing the series (E. S. R., 79, p. 460) and using a new method (described) for continuously recording the absolute rate of protoplasmic streaming in epidermal cells of the oats coleoptile, a study was made of the influence of malate and iodoacetate. In the presence of optimum concentrations of indole-3-acetic acid in freshly cut sections, malate had no effect on streaming, but under very low auxin concentrations it increased the range of response. Used alone, malate had no effect on streaming. When coleoptile sections were soaked overnight in sugar solution or water, the acceleration of streaming normally caused by auxin almost disappeared, but the presence of malate caused large accelerations of streaming by auxin. Similarly, in sections of old coleoptiles no longer showing acceleration of streaming by auxin, it was restored by adding malate with the auxin. The effect of iodoacetate was to inhibit the acceleration by auxin and not to affect the basal streaming rate. It is concluded that, just as for growth and respiration, malate is necessary for the response to auxin shown by acceleration of streaming. This further strengthens the triple parallel between the effects of auxin on streaming, growth, and respiration, all of which appear to be mediated by the 4-carbon acid system.

**Plant biochemistry and physiology**, R. NEWTON, N. H. GRACE, J. B. MARSHALL, and J. L. FARRAR (*Canada Natl. Res. Council Rev. Activ.*, 1941, pp. 14-15).—Brief progress notes are given on studies of plant growth factors, hormone treatment of seeds, plant hormone dusts in the propagation of stem cuttings, and propagation of forest trees from stem cuttings.

**A pyrimidine analog of thiamine and the growth of fungi**, W. J. ROBBINS

(*Natl. Acad. Sci. Proc.*, 28 (1942), No. 9, pp. 352-355).—The responses of *Phycomyces blakesleeanus*, *Pythiomyces gonapodyides*, and *Phytophthora cinnamomi* led to the following conclusions: The pyrimidine analog of thiamine does not replace thiamine in their physiology. Its effectiveness as a pyrimidine source for the first two fungi was of the order of 1/500 or 1/1,000 that of thiamine. The action of the analog as a pyrimidine source might be ascribed to the presence of traces of pyrimidine as an impurity or more probably to a slight dissociation into its constituents or to decomposition in sterilization. Neither of the first two fungi appeared able to split the compound and obtain pyrimidine from it. In this respect the pyrimidine analog differs from the pyridine analog studied earlier (E. S. R., 86, p. 452). The latter was about as effective a source of pyrimidine as thiamine.

**Thiamine in some common American trees**, P. R. BURKHOLDER and A. G. SNOW, JR. (U. S. D. A. et al.). (*Bul. Torrey Bot. Club*, 69 (1942), No. 6, pp. 421-428, figs. 4).—The approximate thiamin activity as indicated by the *Phycomyces* assay of buds, leaves, and bark of some common American evergreen and deciduous trees as studied at different seasons of the year is presented. From some of the results obtained it seems possible that girdled trees may ultimately die from vitamin starvation of their root systems. There are 17 references.

**The increase of B vitamins in germinating seeds**, P. R. BURKHOLDER and I. McVEIGH (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 10, pp. 440-446, figs. 2).—Significant increases in concentration of riboflavin, niacin, biotin, and pyridoxine during germination are reported for many kinds of seeds. If the value of germinated seeds is to be judged by their vitamin content, it appears that the common use of sprouted seeds in the diets of orientals rests on a sound nutritional basis.

**Vitamin C content of persimmon leaves and fruits**, C. G. VINSON and F. B. CROSS. (Univ. Mo. and Okla. A. and M. Col.). (*Science*, 96 (1942), No. 2497, pp. 430-431).—Fresh leaves apparently contained about ten times as much vitamin C as the fruits. Tea made from the green leaves was pronounced very acceptable.

**Variations in ascorbic acid and dry matter content of cowpea plants at different times of day**, M. E. REID. (U. S. D. A. et al.). (*Bul. Torrey Bot. Club*, 69 (1942), No. 7, pp. 522-527).—Progressive increases in ascorbic acid and dry matter were found to occur from the beginning of the daily light period and to continue during the day, depending on the carbohydrate-synthesizing power in the tissues. Plants grown under high illumination and much-limited food supply tended to have relatively large reserves of starch and sugars and low carbohydrate-synthesizing ability. Under favorable light such plants tended to have their maximum vitamin C values early in the day. Plants subjected to prolonged periods of cloudy weather, and especially with an abundant supply of mineral nutrients available, tended to have low vitamin C values and a low supply of starch and sugars. These results suggest that for best vitamin C values harvesting of vegetables should be done not before midforenoon following generally clear weather. If it must be done after cloudy weather, collection should be made as late in the day as possible.

**The physiology of incompatibility in plants.**—I, **The effect of temperature**, D. LEWIS (*Roy. Soc. [London], Proc., Ser. B*, 131 (1942), No. 862, pp. 13-26, pl. 1, figs. 9).—Two different genetic systems of incompatibility are known, viz, heterogamety and heterostyly, depending, respectively, on the genotype of the pollen grain and of its parent. Whether the two are physiologically related is unknown; the specificity of heterogamety indicates an immunity reaction. To elucidate their relationship the effect of temperature on pollen-tube growth was studied. Compatible pollinations of both systems exhibited increased growth rate with increased temperature until the lethal point was approached at about

35° C. Incompatible pollinations of both systems showed an optimum growth rate at 15°–20°. The physiological method of inhibition is therefore probably related, although its genetic basis differs. The different growth rates at different temperatures gave different total growth at inhibition, and at the most favorable temperature there may be no inhibition at all. There is therefore no specific inhibitory zone in the plants used, although elsewhere the top of the style may provide such a zone. Certain genotypes of *Oenothera organensis* showed such powerful incompatibility that no temperature sensitivity could be discovered. This extreme modification is determined by the pollen parent's genotype, like the main action in heterostyly. In heterostyled plants thrum pollen has to grow down the longer pin style, being adapted in two ways: In *Primula* it is larger and in *Linum grandiflorum* it has a higher osmotic pressure. In either case, presumably, it has the higher dry weight. In two heterostyled *Primula* spp. thrum pollen grows faster down the long-pin style than pin pollen does down the short-thrum style. However, in the illegitimate matings thrum pollen is more strongly inhibited. There is therefore a differentiation of the mechanisms adapted to secure equal regularity of cross fertilization of the two types. There are 18 references.

**Sand culture methods**, F. M. EATON. (Tex. Expt. Sta.). (*Chron. Bot.*, 7 (1942), No. 5, pp. 200–201). A brief critical discussion of methods in the light of recent work by the author and others (9 references).

**The mineral pattern of stems from vegetative and flowering plants as determined by microincineration**, B. E. STRUCKMEYER. (Wis. Expt. Sta.). (*Science*, 96 (1942), No. 2493, p. 346).—Seeking a fixative which would neither dissolve nor add mineral substances to the ash, the author found absolute alcohol alone or 9 parts in 1 of formalin, cellosolve, and dioxan satisfactory, though the last seemed to have a shrinking effect on the stem material. In an attempt to prevent this shrinkage, "Nevillite 123" proved best suited of several adhesives tried. By these methods the amount and pattern of the ash in the vegetative and flowering stems of several widely separated plant species were found to differ, the greatest difference in amount occurring in the internodes closer to the stem tips. In plants initiating flower primordia under short days, there was also more ash in stems under short- than under long-day treatment.

**Accumulation of salt and permeability in plant cells**, D. R. HOAGLAND and T. C. BROYER. (Univ. Calif.). (*Jour. Gen. Physiol.*, 25 (1942), No. 6, pp. 865–880, figs. 4).—Under conditions favorable for aerobic metabolism comparisons were made of concentrations of K and Br in exudates of barley roots and in expressed sap from the roots, both methods leading to the same general viewpoint on the metabolically governed transport of solutes by living plant cells. Cyanide in low concentration prevented salt accumulation by barley roots, and methylene blue, without decreasing CO<sub>2</sub> production by roots, destroyed the power of salt accumulation. Even with an inward gradient of ionic concentration, K and Br ions entered roots only to a slight extent under an anaerobic condition. Under aerobic conditions lactate or alcohol failed to prevent salt accumulation by root cells. Tests on fluids obtained by suction from tomato roots gave evidence of loss of salt-accumulating power under the influence of N<sub>2</sub> or CO<sub>2</sub> gases, together with probable effects on cell permeability. Using radioactive isotopes on *Nitella* cells, Br gradually moved into the vacuolar sap until the concentration appeared to exceed that of the protoplasm. Accumulation of salt in the vacuole did not occur anaerobically. Some views on the interrelations of permeability, salt accumulation, and metabolism are suggested for further consideration.

**The availability of certain forms of organic phosphorus to plants and their dephosphorylation by exo-enzyme systems of growing roots and by**

**soil catalysts**, H. T. ROGERS (*Iowa State Col. Jour. Sci.*, 17 (1942), No. 1, pp. 108-110).—Abstract of thesis.

**A study of some factors affecting the nitrate content of plants**, E. I. WHITEHEAD and O. E. OLSON. (S. Dak. Expt. Sta.). (*S. Dak. Acad. Sci. Proc.*, 21 (1941), pp. 67-72).—Molybdenum was definitely toxic to Richland oats seedlings, arsenic stimulated growth up to 0.25 p. p. m. but became increasingly toxic above this concentration, manganese stimulated growth and Mn-deficient solutions gave rise to plants extremely high in nitrate, droughty soil conditions increased the nitrate concentration of the plants but at soil moistures exceeding 25 percent the nitrate content was low and apparently constant, and plants receiving continuous light had lower nitrate concentrations than those receiving daylight only. Wherever the  $\text{KNO}_3$  content increased there seemed to be a corresponding decrease in plant growth, apparently indicating a correlation between nitrate concentration and the protein synthesis rate.

**End products of nitrogen metabolism in plants**, H. B. VICKERY (In *Biological Symposia*, V, edited by J. CATTELL. Lancaster, Pa.: Jaques Cattell Press, 1941, vol. V, pp. 3-19).

**The organic acids of the leaves of Bryophyllum calycinum**, G. W. PUCHER. (Conn. [New Haven] Expt. Sta.). (*Jour. Biol. Chem.*, 145 (1942), No. 2, pp. 511-523).—Examination of the organic acids extracted by warm water from a dried leaf sample indicated it to contain at least 8 percent of the dry weight (probably more) of isocitric acid, together with about 7 percent of l-malic acid and 2 percent of citric acid. This plant is said to be by far the richest source of isocitric acid hitherto encountered, and attention is called to the theoretical implications of this observation. There are 19 references.

**Quinoa (Chenopodium quinoa)**, C. GONZENBACH (*Bol. Inst. Bot., Univ. Cent. Ecuador*, 1 (1942), No. 1, pp. 66-84, figs. 5).—This study of quinoa, a plant of the high Andes of value for food and medicinal purposes, deals with its anatomy and chemical composition, with particular reference to its protein, carbohydrate, and fat contents.

**The gaseous exchange of seeds and isolated cotyledons of Cucurbita pepo**, R. BROWN (*Ann. Bot. [London]*, n. ser., 6 (1942), No. 22, pp. 293-321, figs. 8).—Using an apparatus (described) in which a single pumpkin cotyledon was cultured and its gaseous exchange measured, it was found that at 18-48 hr. the rates of  $\text{O}_2$  uptake and  $\text{CO}_2$  production continued to increase and the value of the respiratory quotient to decrease from an initial high value to one of about 0.5. The high value is taken to indicate anaerobic respiration, and the final low values the accumulation of new respiratory carbohydrate. It is suggested that high rates of carbohydrate accumulation and of respiration indicate a high rate of development. Removal of the inner membrane of the seed coat increased both the rates of gas exchange and the value of the quotient. These effects are related to the restricting action of the membrane on  $\text{O}_2$  diffusion to the respiring tissues. Raising the temperature occasioned an increase of exchange for both gases, and its mechanism is discussed. Increase in the level of water availability increased the rates of gas exchange and decreased the value of the quotient. It is shown that these effects are due to the influence of this factor on the water content. Light depressed the value of the quotient without any considerable effect on the rate of  $\text{CO}_2$  production. This is taken to indicate an effect of light on fat mobilization. It is suggested that in the mass of the cotyledon respiration is partially anaerobic in the early developmental stages. When the embryo is attached to the cotyledon the rates of exchange are higher and the value of the quotient lower than in its absence. This appears to indicate a stimulatory effect of the embryo on cotyledonary development. There are 18 references.

**Quantum efficiency of photosynthesis**, E. C. C. BALY (*Nature [London]*, 149 (1942), No. 3773, pp. 218-219).—A brief note.

**Photosynthesis of algae and other aquatic plants**, G. O. BURR. (Univ. Minn.). (In *A Symposium on Hydrobiology*. Madison: Univ. Wis. Press, [1941], pp. 163-181, figs. 14).—Some of the more recent studies in this field are critically reviewed (24 references). Solutes, temperature, light, and CO<sub>2</sub> tension are found to operate simultaneously on the photosynthetic mechanism. In any attempt to describe the environment of aquatics all four should be recorded with the greatest possible precision, and CO<sub>2</sub> tension should be recorded with as great care as O<sub>2</sub> tension and light intensity.

**Respiration studies on germinating white-oak acorns**, R. E. GIRTON and E. R. PARK. (Purdue Univ.). (*Ind. Acad. Sci. Proc.*, 51 (1941), pp. 83-86, figs. 5).—The data presented make it evident that the high moisture content of acorns as compared with many common seeds is related to a high respiratory activity during dormancy. Placed under conditions favorable to germination, white oak acorns may in some cases show increasing O<sub>2</sub> absorption rates from the start. In other cases, apparently associated with higher moisture contents, the initial respiratory rate may fall temporarily, but again rises with time as germination goes on. Increased elongation of the primary root in germination was accompanied by an increased O<sub>2</sub> absorption rate over a considerable period.

**Developmental anatomy of the shoot of *Zea mays* L.**, B. C. SHARMAN (*Ann. Bot. [London]*, n. ser., 6 (1942), No. 22, pp. 245-282, pl. 1, figs. 23).—This detailed account of the development of the corn shoot is examined in relation to the probable movement of nutrients and water in the plant during different growth phases. In the course of the study various points emerged as to development, structure, and morphology, the significance of which is discussed after the observations have been placed on record. There are 29 references.

**Nota sobre o sistema radicular da oliveira** (Note on the root system of the olive tree), J. V. NATIVIDADE (*Agron. Lusitana*, 3 (1941), No. 1, pp. 15-24, pls. 4; *Eng. abs.*, p. 23).—This note deals with the chief characteristics of the root system observed in trees uprooted by a hurricane, the mechanism of resistance to processes of decay, and the behavior of olives grafted on *Ligustrum vulgare*.

**O significado ecológico e fisiológico do sistema radicular aéreo da oliveira** (*Olea europaea* L.) e da alfarrobeira (*Ceratonia siliqua* L.) [The ecological and physiological significance of the aerial root system of the olive and carob], J. V. NATIVIDADE (*Agron. Lusitana*, 3 (1941), No. 2, pp. 85-91, pls. 4; *Eng. abs.*, pp. 89-90).—Physiologically, the cordlike growths or ribs on these trees are said to be aerial roots which, after making their way to the ground, aid in supplying nutrients and in consolidating the trunk and fixing it to the ground. The likeness in behavior of these two species, phylogenetically unrelated but both able to avail themselves of such conditions as dry gravelly soils and climates with low rainfall and high atmospheric evaporation, suggests that the formation of aerial roots may be an accommodation to xerophytic habitats whereby, within certain limits, the growth of roots proceeds in the ground independently of the conditions therein. The root-bearing swellings and the aerial roots also serve as true vegetative propagating organs. These trees form the transition between species which bear root initials on the aerial organs but which grow only under certain narrowly limited conditions, and those which bear typical aerial roots.

**Methods and instruments for use in measuring tree-rings**, H. S. GLADWIN (*Globe, Ariz.: Gila Pueblo*, 1940, pp. [2]+13, pls. 10).—Included in the discussion are collecting specimens of modern and ancient wood, handling cores in

the laboratory, preparation of wood and charcoal specimens, and measuring and photographing tree rings.

**Tree-ring analysis: Methods of correlation**, H. S. GLADWIN (*Globe, Ariz.: Gila Pueblo, 1940*, pp. [2]+63, [figs. 20]).—This discussion includes existing methods; correlation of tree-ring plots; percentage of agreement; trials and errors; plotting variations of tree rings; station district, province, and plateau composites; variable, double, and missing rings; and tree-growth and cycles.

**Parthenocarpy: Natural and artificial**, F. G. GUSTAFSON (*Bot. Rev.*, 8 (1942), No. 9, pp. 599-654).—This is a comprehensive review (174 references) with critical discussion of spontaneous and induced parthenocarpy. As to the latter, data are presented on the methods and chemicals used and on plants having produced parthenocarpic fruits with chemical treatment.

[**Botanical studies**], D. M. WELLER (*Hawaii. Sugar Planters' Assoc. Pld. Rpts.*, 61 (1941), Expt. Sta. Com. Rpt., pp. 42-46).—Brief summaries of progress are included on the effects of colchicine on sugarcane and on the anatomy and histology of the plant including the growing point.

**Certain abnormalities in millets induced by X-rays**, N. KRISHNASWAMI and G. N. RANGASWAMI AYYANGAR (*Indian Acad. Sci. Proc.*, 16 (1942), No. 1, Sect. B, pp. 1-9, pls. 4).—Some of the recessive abnormalities induced by X-rays in *Eleusine coracana* and *Pennisetum typhoides* are described. There are 20 references.

**Dispersion of cellulose strands in cell walls**, R. D. PRESTON (*Nature [London]*, 149 (1942), No. 3786, pp. 580-581).—A brief note.

**Cytological studies of toxicity in meristem cells of roots of *Zea mays***.—II, The effects of lithium chloride, J. K. EDWARDS (*S. Dak. Acad. Sci. Proc.*, 21 (1941), pp. 65-67).—Continuing these studies (*E. S. R.*, 77, p. 599), LiCl at 0.01 M concentration proved toxic to meristem cells of corn root tips. The effects of different concentrations on the cytoplasm, nuclear material, and on cell division, with use of acid and basic fixatives, are described.

**A staining rack for handling cover-glass preparations**, T.-T. CHEN. (Univ. Calif.). (*Stain Technol.*, 17 (1942), No. 3, pp. 129-130, fig. 1).—A porcelain staining rack devised for handling cover-glass preparations is described and illustrated, the design being along the general lines of staining racks for slides commonly sold by commercial houses.

**An electric recording marking counter for the consecutive counting of small objects**, H. W. WOLF (*Science*, 96 (1942), No. 2496, pp. 409-410, fig. 1).—The new counter devised for counting the projected cross sections of wool fibers, and here described, is said to show possibilities of further applications in science and industry where materials of small surface area are to be counted and identified. With the projection apparatus used much of the eye fatigue associated with technics involving direct scrutiny of minute objects through a microscope is eliminated. Utilization of this electric counter has greatly speeded up wool fiber analysis.

## GENETICS

**A new tetraploid wheatgrass from Nevada**, J. H. ROBERTSON and L. WEAVER. (U. S. D. A. et al.). (*Bul. Torrey Bot. Club*, 69 (1942), No. 6, pp. 434-437, figs. 2).—Data on a group of extremely large plants of *Agropyron spicatum* are presented. Considering the lack of definite evidence for hybridization as compared with the occurrence of distinctly tetraploid morphological characters and the double number of chromosomes, it is believed most likely that these plants are a tetraploid form of the species.

**Self-incompatibility in polyploid forms of *Brassica* and *Raphanus***, H. W. HOWARD (*Nature [London]*, 149 (1942), No. 3776, pp. 302-303).—In *B. rapa*, *B.*

*campestris*, and *R. sativus* the autotetraploid and the diploid branches of colchicine-produced diploid-tetraploid sectorial chimeras obtained by the author are both reported always to have been self-incompatible.

**Cytogenetical studies in *Nicotiana*.—II, Morphological features of *Nicotiana glutinosa* and the hybrid between *Nicotiana glutinosa* and *N. tabacum*,** T. S. RAGHAVAN and A. R. SRINIVASAN (*Indian Acad. Sci. Proc.*, 14 (1941), No. 1, Sect. B, pp. 35-46, pl. 1, figs. 43).—Continuing the series,<sup>1</sup> the microsporangial development in *N. glutinosa* is described, the results of a comparative study of the embryo sac and embryo formation in this species and in *N. tabacum*, the two parents of the hybrid, are presented, and the development and behavior of the megaspore in the hybrid is described and compared with that of the parents. There are 24 references.

**Mutation of *Phytomonas stewartii* by X-ray irradiation,** R. E. LINCOLN and J. W. GOWEN. (Iowa Expt. Sta.). (*Genetics*, 27 (1942), No. 4, pp. 441-462, pls. 2).—Under X-irradiation at an intensity such that 100,000,000 viable cells suspended in broth were reduced to about 1,000 in 25 min., survival followed the simple exponential function—survival ratio =  $e^{-ar}$ , where  $a$  is a constant and  $r$  is the roentgens to which the bacteria are exposed. Mutations were observed in colony color, surface appearance, and size. The only difference observed between spontaneous mutations and those induced by irradiation was the increased frequency of the latter. The mutation pattern observed in two widely different stocks of *P. stewartii* was similar. Mutations in colony characters may be accompanied either by increased or decreased virulence for corn. Except for mutations to an unstable form, mutants appeared to be as stable as the parent strains. From the evidence presented it would appear that the terms "mutant," "variant," "saltant," and "dissociant" as applied to bacteria are synonymous and are applied to phenomena resulting from gene mutation. From this standpoint the physical basis of inheritance in *P. stewartii* is similar to that of higher organisms. There are 15 references.

**The inheritance of wavy-leaf character in the peach,** D. H. SCOTT and F. P. CULLINAN. (U. S. D. A.). (*Jour. Hered.*, 33 (1942), No. 8, pp. 293-295, figs. 2).—An unusual foliar character of deeply serrated, very wavy leaves, observed in a selfed progeny of the Gold Drop peach, was found to be controlled by a single pair of alleles, with the wavy character recessive to the normal smooth leaf. The wavy leaf condition is undesirable because plants possessing it tend to grow weakly, with a dwarf habit, and set fruit poorly.

**[Experiments in reproduction of animals and crossing swine by the Ohio Station]** (*Ohio Sta. Bul.* 617 (1940), pp. 49-50, 70).—Results are briefly reported on damage to reproduction in farm animals of vitamin A deficiencies; and crossing three breeds of pigs—Poland China, Hampshire, and Duroc-Jersey.

**Hybrid vigour in sheep as indicated by physiological characters,** A. S. KARPOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 31 (1941), No. 7, pp. 719-721).—Comparisons of measurements and physiological characters of 20-30 purebred Romney and Tsigal ewes over 2.5 yr. of age with crossbreds between them showed that the crosses had richer blood values than the parent breeds. Differences in body size and body weight were insignificant. The breed differences in blood factors were related to growth, development, constitution, and production of the breeds. The higher blood value of the crosses is regarded as one of the physiological causes of hybrid vigor.

**Litter size and weight as permanent characteristics of sows,** J. L. LUSH and A. E. MOLLN. (Coop. 13 expt. stas.). (*U. S. Dept. Agr., Tech. Bul.* 836 (1942), pp. 40, figs. 4).—A statistical analysis based on variance methods is reported for the numbers of pigs farrowed in 7,415 litters, number weaned in 4,920

<sup>1</sup> *Jour. Indian Bot. Soc.*, 20 (1941), No. 5-6, pp. 307-340, pl. 1, figs. 82.

litters, and the weaning weights of 2,144 litters of Poland China, Duroc-Jersey, Chester White, Hampshire, Yorkshire, Berkshire, Tamworth, and Danish Landrace breeds born at eight experiment stations and the Department in conjunction with the Regional Swine Breeding Laboratory projects. Litters were tabulated with reference to the age of the sows at 6-mo. intervals with correction for litter size. It was found that additions of 1 pig to litters born to sows at 1-1.5 yr. of age removed most of the variance resulting from dams' age. Litter sizes increased for sows up to 3.5 yr., but after this period there were declines. The age of the sows had much less effect on the number and weights of pigs weaned than on the number farrowed, and no whole number corrections seemed needed. Variance between litters of the same sows was caused by general environmental changes from one farrowing season to another as indicated by a symmetrical block analysis. Such a method does not lend to determination of the effects of breed differences. In considering further plans for higher productivity, it is pointed out that sows' future abilities will be only about one-sixth as far above the average of the herd as past records were found when selection was based on a single litter. Selection should be based on as many litters as possible produced by the sow. Selection will be 31 percent more effective on 2 than 1, and 50 percent more progress will be made on 3 than on a 1 litter basis. Selection based on production of close relatives may help, but the individual should receive at least three times as much consideration as the characteristics of the dam or each full sister. Pertinent and related literature is discussed.

**Colour-variation in Wessex Saddleback pigs and its relation to the conformation and the economic usefulness of the breed, T. M. OLBRYCHT** (*Natl. Pig Breeders' Assoc. Bul. 2* (1941), pp. 34, figs. 6).—Both hereditary and non-hereditary variations in the color and shape of the saddle of Wessex Saddleback pigs were observed in a study of 2,318 individuals from the record books of the breed born in 1937, 1938, and 1939. The width of the belt near the right shoulder of 328 registered pigs ranged from 0.1 to 16, averaging 6.1 in. Simple segregations were not found in the shape and size of the saddle, and therefore multiple factors and nonhereditary conditions were considered responsible. The main factor *W*, for white belting, was dominant. There were plus and minus modifiers. The extreme effect of the modifiers was respectively to produce all black and all white individuals. The so-called ginger color was recessive. The gene *A*, for white color, was dominant in the hair and recessive in the skin. In crosses of large white boars with Wessex Saddleback sows, there were produced 751 all white among 770 F<sub>1</sub> pigs. Some of those that were white had irregular black spots in the skin, giving a bluish appearance. The relation of the genotype to economic superiority is discussed.

**The anomaly of a normal Duke's and a very prolonged saline bleeding time in swine suffering from an inherited bleeding disease, E. T. MERTZ** (*Mo. Expt. Sta.*). (*Amer. Jour. Physiol.*, 136 (1942), No. 3, pp. 360-362, fig. 1).—In affected animals (*E. S. R.*, 87, p. 361) the saline bleeding time was several times that of normal nonbleeding swine. This test served to distinguish bleeders from normals.

**Chromosomes of the red fox, L. WIPF and R. M. SHACKELFORD**. (*Univ. Wis.*). (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 7, pp. 265-268, figs. 5).—The chromosomes in red, black, and platinum-silver foxes from testes appeared similar in size, shape, and other morphological characteristics, but varied in length. The number was 17 in the haploid and 34 in the diploid. One pair of satellite chromosomes was found. Reference is made to the lethal condition of the platinum-silver character in foxes.

**Studies on an anophthalmic strain of mice.—III, Results of crosses with**

**other strains, H. B. CHASE.** (Univ. Ill.). (*Genetics*, 27 (1942), No. 3, pp. 339-348).—Continuing this series (E. S. R., 86, p. 461), the gene *cy* is suggested as the recessive factor causing the eyeless condition in the strain of mice producing 91 percent eyeless and 9 percent having an intermediate eye condition on one or the other side of 1,054 individuals produced in 17 generations of brother-sister matings. Crosses with four lines which at least produced some eyeless individuals gave only normals in the  $F_1$ . All possible variations and asymmetry occurred in the  $F_2$ ,  $F_3$ , and backcross generations. The left eye tended to be more normal than the right eye, and the eyes of  $\delta$ s were nearer normal than those of  $\phi$ s. Modifiers lowered the expected percentage of normals. The second backcross generations from eyeless segregants mated back to the original eyeless parent produced 100 percent eyeless young or at least young with very small eyes. A considerable amount of nonhereditary variation seemed to exist.

**The crossbreeding of poultry, D. C. WARREN** (*Kansas Sta. Tech. Bul.* 52 (1942), pp. 44).—Comparison of the morphological characteristics, egg production, and viability of reciprocal crossbred birds with purebreds of the Single-Comb White Leghorn, Single-Comb Rhode Island Red, Barred and White Plymouth Rock, White Wyandotte, New Hampshire, Australorp, Black and White Minorca, Ancona, Light Brahma, and Jersey Black Giant breeds showed that cross-breeding seemed to stimulate the vigor of the progeny. A chart based on the 14,566 purebred and crossbred chicks showed cross-breeding tended to improve the hatchability of the eggs, viability of the chicks, rate of egg production, and growth. Greater variation existed in crosses of strains within the same breeds. There was a reflection in the offspring of the quality of the purebreds used to produce the crossbreds. The extensive use of cross-breeding for broiler production is noted, as well as attention to chick and adult mortality, growth rate to 8 weeks of age, egg production, broodiness, egg color, and dressing percentage.

**The relative effect of environment and heredity upon body measurements and production characteristics in poultry.—II, Period of egg production, H. S. GUTTERIDGE and J. B. O'NEIL** (*Sci. Agr.*, 22 (1942), No. 8, pp. 482-491, figs. 6).—Through an interchange of three strains of pullets between three locations climatologically different, environment was found by variance analysis to be a much greater factor influencing egg production than heredity, thus confirming the studies on growth previously noted (E. S. R., 88, p. 37). Both environment and heredity were shown to enter into body weights and egg weights with nearly equal importance.

**Growth and development, with special reference to domestic animals, LIV, LV** (*Missouri Sta. Res. Buls.* 349 (1942), pp. 11, figs. 7; 350, pp. 14, figs. 5).—This series (E. S. R., 87, p. 265) is continued.

**LIV. Age changes in size, energy metabolism and cardio-respiratory activities of thyroidectomized cattle, S. Brody and R. F. Frankenbach.**—Thyroidectomy of a Jersey heifer at 54 days of age was found to reduce mature body weight by over 50 percent and heat production per unit surface area about 40 percent, as contrasted with a normal control heifer. Both respiration volume and frequency were less than normal in the thyroidectomized animal. The metabolic rate was increased to normal or better within a week by feeding an iodized milk protein (thyrolactin). After several months' feeding the hair coat was no longer rough, and heat was experienced with the development of the mammary gland and the horns.

**LV. Resting energy metabolism and ventilation rate in relation to body weight in growing Holstein cattle, S. Brody, H. H. Kibler, and A. C. Ragsdale.**—The resting heat production per square meter of body surface area for 15 Holstein heifers at monthly intervals from birth to 24 mo. of age was plotted by month against age and body weight. After 6 mo. the exponent  $b$  in the equation  $Y=aX^b$

was about 0.6 for this breed as with Jerseys (E. S. R., 87, p. 265). Increasing body weight about 1 percent increased maintenance about 0.6 percent. Resting maintenance per square meter of body surface was about 2,140 Calories in Holsteins, as contrasted with 2,000 Calories in Jerseys. The value of *b* for ventilation rate was 0.77. Increasing body weight 1 percent tended to increase ventilation rate about 0.77 percent.

**The influence of estradiol on the secretion of gonadotropic hormone in adult parabiotic rats,** R. K. MEYER and C. BIDDULPH. (Univ. Wis.). (*Amer. Jour. Physiol.*, 134 (1941), No. 1, pp. 141-146, fig. 1).—In 14 parts of ♀ rats united parabiotically continuous vaginal oestrous was induced, an average of 39 days following ovariectomy of the other partner. The oestrous cycles of the normal ♀s persisted as long as the ovariectomized rat was injected with oestradiol. Hypophysectomy of ovariectomized partners and pairs in continuous oestrus caused replacement of the continuous oestrus of the normal partner by continuous dioestrus. Oestrogen seems to prevent hypersecretion of the gonadotropic hormone of the pituitary gland of the adult ovariectomized rat.

**Androgen production during pregnancy and lactation in the rat,** M. W. BURRILL and R. R. GREENE (*Anat. Rec.*, 83 (1942), No. 2, pp. 209-227, pls. 2, fig. 1).—A series of 116 ventral prostates from ♀ white rats representing each day of pregnancy and lactation showed evidence that during days 1-5 some ♀s produced a physiological effective quantity of androgen. The prostates showed no evidence of androgen in the period 6-10 days of pregnancy. There was an increase of androgen production during the last 4 days of gestation, and the prostates continued to show an effective dose during the first 15 days of lactation. The source of the androgen was not ascertained.

**Pituitary weight of growing male albino rat related to body weight,** J. P. MIXNER and C. W. TURNER. (Mo. Expt. Sta.). (*Endocrinology*, 31 (1942), No. 2, pp. 261-263, fig. 1).—A correlation of  $0.92 \pm 0.01$  was found between the pituitary weights and body weights in 135 ♂ albino rats weighing 60-383 gm. Correlation was also shown by regression equations, all of which emphasized the desirability of varying the size of pituitary hormone injections with the weight of the test animal for assay purposes.

**Relation of thyroid to growth.—I, Effects of crystalline thyroxin upon rate of growth, food intake, and body composition of female albino mice,** M. KOGER, V. HURST, and C. W. TURNER. (Mo. Expt. Sta.). (*Endocrinology*, 31 (1942), No. 2, pp. 237-244, fig. 1).—Doses of 0.007-0.04 mg. of thyroxin per day or double the amount on alternate days were administered subcutaneously to groups of 10-12 10-15 gm. virgin mice for 5 weeks. The thyroxin-injected animals consistently and repeatedly made about 28 percent greater gains and consumed 25 percent more feed than controls during the 5-week period. Thyroxin-treated mice stored more nitrogen and gained more than controls per unit of food intake. After the first few weeks of rapid gains the controls made more efficient feed utilization than the thyroxin-injected animals.

**Mammary growth in male mice fed desiccated thyroid,** W. U. GARDNER (*Endocrinology*, 31 (1942), No. 1, pp. 124-127).—All except 1 of 14 intact ♂ mice fed 1.5 gm. of desiccated thyroid per kilogram of ration showed proliferation of the mammary duct system not apparent without the thyroid treatment. During the seventeenth to forty-seventh day the thyroid-fed animals consumed greater amounts of feed, but the gains made were equal to those of mice on normal diets.

**Some effects of thyroid and gonadotrophic preparations in the fowl,** A. W. GREENWOOD and J. S. S. BLYTH (*Quart. Jour. Expt. Physiol. and Cog. Med. Sci.*, 31 (1942), No. 3, pp. 175-185).—Anterior pituitary extracts and allied

preparations, together with powdered thyroid, were administered to Brown Leghorn hens 2-4 yr. of age at about the molting period. Studies were made of egg laying and the changes in the comb size. The hormones were administered subcutaneously, implanted, or given in pressure tablets, and the thyroid was fed in gelatin capsules or pills. Sheep, horse, and pig pituitary extracts and pregnancy urine were mainly ineffective. Pregnant mare serum, however, caused cessation of egg production and moult in the laying hens in 5 days with an increase in the size of the combs. In nonlaying hens there was little effect. Ovarian stimulation seemed to result from thyroid feeding and some resumed egg production. Most of the hormones were administered to groups of about 15 hens.

**Pairing responses of free-living valley quail to sex-hormone pellet implants, J. T. EMLEN, Jr., and F. W. LORENZ.** (Univ. Calif.). (*Auk*, 59 (1942), No. 3, pp. 369-378).—In two experiments four ♂ and seven ♀ quail were implanted subcutaneously with testosterone or stilboestrol pellets during the nonbreeding season and the effects on sexual behavior noted. The ♂s treated with testosterone became pugnacious and mated, but stilboestrol produced no measurable behavior responses.

**Action of diethylstilbestrol in the chick, W. R. BRENNEMAN** (*Endocrinology*, 31 (1942), No. 2, pp. 179-186).—Continuing studies of the effects of ♀ hormones and limitations of rations on body, gland, and comb growth of chicks (E. S. R., 87, p. 502), the administration of diethylstilboestrol to cockerels had a marked inhibiting effect on comb and gonad development, similar to oestrogen. These studies were conducted with groups of about 15 cockerels, pullets, or capons on adequate and limited diets.

**Fertility in the male domestic fowl, J. E. PARKER, F. F. MCKENZIE, and H. L. KEMPSTER.** (Coop. U. S. D. A.). (*Missouri Sta. Res. Bul.* 347 (1942), pp. 50, figs. 21).—The gross anatomy of the reproductive tract of ♂ fowls is described, and the ratio of testis weight to body weight is noted. The volume of semen from 14 New Hampshire ♂s collected in the avian semen collector (E. S. R., 82, p. 324) varied from 0.05 to 1 cc. in 177 ejaculates made under observation in 15-min. mating trials. Such ♂s were allowed access to from 12 to 18 ♀s once each month, some being kept with the ♀s and others in individual breeding cages. Semen collections by the abdominal massage technic of Burrows and Quinn (E. S. R., 77, p. 180) from 13 New Hampshire ♂s kept in batteries ranged from 0.27 to 1.5 cc. Much variation existed in the number of sperm produced, but there was a tendency for some birds to produce consistently large numbers. Sexual activity and sperm production were greatest by those birds that were kept continuously in breeding pens. In general fowl semen was alkaline in reaction, ranging from pH 7.15 to pH 7.64 for high percentages of fertility. The mean volume, sperm concentration, and number of sperm decreased in succeeding ejaculates and the alkalinity increased. Seasonal variations in semen production were noted. Sexual activity was depressed during January, June, July, and September. Especially in the last month there was heavy molting, and such birds objected to being handled. By artificial insemination of New Hampshire hens fertilization with semen from Barred Plymouth Rock, White Leghorn, and New Hampshire ♂s gave about equal results. From mixed samples it was observed that about equal numbers of chicks were sired by the New Hampshire and Barred Plymouth Rock cockerels, but fewer were sired by White Leghorn ♂s. No fertile eggs were laid by hens on the next day after insemination. The highest percentage of fertile eggs was reached on the third, and the last fertile egg was laid on the twenty-fifth day after insemination.

**On the development of feathers, F. R. LILLIE** (*Biol. Rev.*, 17 (1942), No. 3, pp. 247-266, figs. 5).—The morphology and histology of feather development are

reviewed, including the effects of host and genotype of the transplants and the influence of hormones.

**A defect in the coagulation mechanism of swine blood**, M. E. MUHRER, A. G. HOGAN, and R. BOGART. (Univ. Mo.). (*Amer. Jour. Physiol.*, 136 (1942), No. 3, pp. 355-359).—The hemophilialike condition previously described in swine (E. S. R., 87, p. 361) was especially studied, and a diagnostic test was developed based on fibrin precipitation time of diluted plasma. The usual practices of ringing and castration were frequently fatal in this strain. The coagulation time of valuable experimental animals was reduced by injection of the blood globulin fraction as in hemophilia.

**Results of the haematological study of the hogs at the all-union agricultural exhibition**, H. F. KUSHNER and II. B. ALPEROVICH (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 31 (1941), No. 7, pp. 722-724).—Study of the blood picture of boars and sows of the Large White (English) breed above 2 yr. of age showed the hemoglobin content and number of erythrocytes to be greater in boars than in sows. After 2 yr. of age the changes with age were insignificant. Differences between the breeds based on 14 Large White (English), 4 White Ukrainian, 5 Breit, and 4 Livny sows were not consequential. These data on swine supplemented the blood values of horses, cattle, and sheep previously noted (E. S. R., 86, pp. 313, 610, 611).

**A preliminary note on the temperature of the scrotal skin of the bull and its relation to air, skin, and body temperature**, J. QUINLAN and G. RIEMER SCHMID (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 299-312, figs. 5).—Measurements of the scrotal temperature of a Sussex bull showed direct correlation with skin temperatures, but no correlation was found between scrotal temperature and exposure to sunrays and air temperature.

**Studies of the metabolism of bovine epididymal spermatozoa**, G. HENLE and C. A. ZITTLE (*Amer. Jour. Physiol.*, 136 (1942), No. 1, pp. 70-78, figs. 3).—Appreciable differences in respiration were found in sperm suspensions from individual bovine epididymis due to individual sample differences in concentration of sperm and pH, as well as the place in the testes from which the sperm were removed. Optimum respiration occurred in semen containing 400-800 million cells per cubic centimeter and at a pH of 7.5-8. Seminal spermatozoa showed a slower respiration rate than epididymal sperm. The drop in respiration encountered in concentrated suspensions was ascribed to insufficient diffusion of oxygen into the medium. Seminal fluid did not influence respiration rate.

**Experiments concerning supposed influence of cock's head appendages on size of testes**, W. LANDAUER. ([Conn.] *Storrs Expt. Sta.*). (*Endocrinology*, 31 (1942), No. 1, pp. 78-83).—Removal from cockerels of the comb and wattles, in part or in entirety, was followed by increased testicular weights 7 mo. later. There was no evidence for a specific effect of comb or wattles on the testes size, but the enlargement reported by Buckner et al. (E. S. R., 71, p. 365) and others seemed to be due to the trauma. In the conduct of this study there were employed 7 groups of 44-53 chicks operated at 46 days of age.

**Sex inversion in the peafowl**, T. H. MORGAN (*Jour. Hered.*, 33 (1942), No. 7, pp. 247-248, figs. 2).—Account is given of a peahen which changed partially from the usual drab plumage and egg laying of the ♀ to the characteristics and more vivid plumage of the ♂.

**Bionomic studies on cattle in the semi-arid regions of the Union of South Africa**.—IV, The ovarian cycle of heifers during summer, J. QUINLAN, J. H. R. BISSCHOP, and T. F. ADELAAR (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 213-241, figs. 16).—The duration of oestrus in heifers of the Afrikaner, Fries, Red-Poll, and Sussex breeds was determined

with aproned and teaser bulls at hourly intervals as 7.88, 11.67, 14.0, and 9.0 hr., respectively. Of those tested 94 percent permitted service for less than 18 hr. Variations in the sexual activity of the heifers during oestrus is described. Heifers receiving bonemeal were sexually more active than heifers which received no phosphate supplement.

**Studies on the nature of the onset of oestrus in ewes following a period of sexual inactivity**, J. QUINLAN, H. P. STEYN, and D. DE VOS (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 243-262, figs. 2).—The average duration of 65 oestrous periods in ewes, ascertained by willingness to mate with rams, was 8.2 hr., with the dioestrous period averaging 15.8 days. Irregularities in oestrus were noted. Weak oestrous periods were irregularly followed by ovulation. Seasonal conditions other than nutrition seemed responsible for the low genital activity in October and November. The study was based on observations of 99 Merino ewes at 3-hr. intervals from November 20 to December 20, 1939. The post mortem characteristics of the genitalia and oestrous conditions of 16 ewes slaughtered are given.

**The thecal gland in the guinea pig ovary**, W. T. STAFFORD, R. F. COLLINS, and H. W. MOSSMAN. (Univ. Wis.). (*Anat. Rec.*, 83 (1942), No. 2, pp. 193-207, pls. 2).—Changes in the thecal gland tissue of the guinea pig ovary were observed at, near, and during the oestral period in 19 individuals, which suggests that the gland is probably the most likely source of oestrogenic hormone. In the atretic follicles the theca interna never assumes the typical gland structure.

**Survival of spermatozoa in the female reproductive tract of the bat**, W. A. WIMSATT. (Cornell Univ.). (*Anat. Rec.*, 83 (1942), No. 2, pp. 299-307, pl. 1).—Even though isolated in November the presence of motile sperm in the uteri was shown on autopsy as much as 5 mo. later in *Myotis l. lucifugus*. Development was evidently initiated in ova by sperm of *Eptesicus f. fuscus* that had survived the winter period.

**Normal and experimental mammary involution in the mouse as related to the inception and cessation of lactation**, W. L. WILLIAMS (*Amer. Jour. Anat.*, 71 (1942), No. 1, pp. 1-41, pls. 5).—Histological study of involution of the mammary gland with and without suckling, hypophysectomy, and the administration of hormones to 116 ♀s showed that in the complete absence of suckling involution was rapid and secretion ceased within 24 hr. postpartum and the gland became atrophic. Suckling influenced excretion from the alveolar cells, and when young were removed on the tenth day of lactation did not induce as sudden cessation of lactation as when the young were removed on the fourth day. Rapid involution followed normal removal of the young on the twenty-first day of lactation. These results largely agree with the findings of Turner and Gomez (*E. S. R.*, 69, p. 349). Hypophysectomy accelerated involution of the mammary gland.

**Observations on artificial insemination of sheep with fresh and stored semen**, J. QUINLAN, H. P. STEYN, and D. DE VOS (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1-2, pp. 263-297, figs. 7).—The artificial insemination of Merino ewes with semen stored up to 12 hr. gave satisfactory results. Storage of semen for longer periods decreased in success, and no pregnancies occurred with storage periods longer than 72 hr. In the conduct of the work 196 Merino ewes were artificially inseminated with semen diluted by methods suggested by Winters et al. (*E. S. R.*, 80, p. 330) and stored for 6, 12, 18, 24, 48, 72, and 96 hr. and for longer periods. These results were compared with those of 18 normally mated ewes. In field observations 680 Karakul ewes were inseminated with semen from 1 ram. Of those which suckled lambs 66.2 percent became pregnant, but only 25.8 percent of the ewes not suckling lambs were settled.

**Distinguishing sex of chicks at hatching**, D. C. WARREN (*Kansas Sta. Bul.* 307 (1942), pp. 29, figs. 13).—The general principles of sexing chicks at hatching, based on the behavior of sex-linked characters in breed crosses, especially gold × silver, barred × nonbarred, and rate of feathering crosses are reviewed. The autosexing breeds and the vent method of sexing are noted as other methods which have proven applicable and useful.

## FIELD CROPS

[Research with field crops by the Georgia Coastal Plain Station, 1940]. (Partly coop. U. S. D. A., Ga. Expt. Sta., Univ. Ga., et al.). (*Georgia Coastal Plain Sta. Bul.* 32 (1941), pp. 15-43, 72-77, 113-121, 128-133, figs. 5).—Field crops experiments reported on (*E. S. R.*, 86, p. 179) for 1940 and for different periods of years included variety tests with cotton, corn and hybrids for yield and resistance to weevils, oats, wheat, rye, grain sorghum, sorgo, peanuts, sweetpotatoes, soybeans for seed and forage, cowpeas, velvetbeans, crotalaria, winter cover crops, pasture grasses, and miscellaneous summer forage crops; a production test with Alyceclover; breeding work with corn, cotton, oats, peanuts, and pasture grasses; winter cover and green manure crops for cotton and corn; control of peanut leaf spot; cultural (including planting) experiments with corn, oats, wheat, peanuts, tobacco, and winter cover crops; and development of sea-island cotton production. Fertilizer experiments included formulas and carriers of N, P, and K with cotton and sweetpotatoes, and also fertilizer placement for cotton and tobacco; N and K top dressings for cotton and sweetpotatoes; secondary nutrient elements for cotton, sweetpotatoes, and tobacco; K and S relation, Ca and Mg, plant bed fertilizer, and acid, basic, and neutral fertilizer tests with tobacco; tobacco rotations; ratios of organic:nonorganic N with sweetpotatoes; and experiments with corn, oats, and peanuts, mainly formulas and rates of application. Recommendations on soils, varieties, seedbeds, fertilizers, spacing and topping, and curing for flue-cured tobacco are again included. In addition to the above work with flue-cured tobacco, reports are also made on the progress of studies with cigar wrapper tobacco at the Shade Tobacco Substation near Attapulugus, comprising fertilizer formulas, with variations in N, P, K, Ca, Mg, S, B, and Cl, varying ratios of nutrients and of N carriers, rates of stable manure, and organic N and P carriers; fertilizer placement; plant bed fertilizers; and seed production.

[Farm crops research in Mississippi] (*Miss. Farm Res. [Mississippi Sta.],* 5 (1942), No. 10, pp. 1, 2, 3-4, 5, 6, 7, 8, fig. 1).—Experiments with field crops and related agronomic research are reported in articles entitled October Best for Planting Small Grains, by J. F. O'Kelly (pp. 1, 7, 8); Fall Seedings Begin Year-Round Program for Establishment of Permanent Pastures, by H. W. Bennett (pp. 1, 2); Delayed Harvest of Starch Potatoes Found Practical, by J. M. Lutz and W. S. Anderson (p. 2) (coop. U. S. D. A.); Care in Handling, Storage, Needed to Keep Sweetpotato, by E. A. Curry (p. 7); Phosphorus and Lime Most Profitable Fertilizers for Producing Hairy Vetch, by J. L. Anthony and J. Pitner (p. 7); Inoculation Aids Necessary Growth of Winter Legumes, by W. B. Andrews (p. 8); and Fertilization, Early Seeding, Drainage Important in Growth of Winter Legumes, by C. D. Hoover (p. 8). Brief reports are also made by C. Dorman on agronomic work at substations, including variety tests with cotton, corn and hybrids, oats, wheat, barley, sugarcane (coop. U. S. D. A.), potatoes, soybeans and edible soybeans, cowpeas, and clovers; breeding work and strength tests with cotton; a comparison of Alyceclover and Kobe lespedeza as maintenance feed for beef cattle; cultural tests with corn and oats; fertilizer experiments with cotton, corn, hairy vetch, pastures,

and summer and winter legumes; growing seed of bur-clover and crimson clover; other pasture studies; yields of cotton after various green manures and sorghums v. commercial N; soil improvement crops for corn and cotton; interplanting of corn with legumes; and crop rotations.

[**Agronomic investigations in Ohio**]. (Partly coop. U. S. D. A.). (*Ohio Sta. Bul.* 617 (1940), pp. 7-9, 10-12, 13-15, 39-40, 69, 71, 72, figs. 5).—Brief reports are made on experimentation (E. S. R., 83, p. 480) concerned with progress of the corn breeding program resulting in 40 new hybrids ready for farm trial; wheat root strength as a guide to winter hardiness; limiting of sugar beet yields due to lack of air in soils; potato yields in response to right fertilizers; relation of fertilization and quality of potatoes; increase of potato yields by manure and fertilizer; tests of earlier soybean varieties; production of high tobacco yields in manured and fertilized rotations at the Southwestern Experiment Farm; superiority of timothy meadows on fertile soil at the Washington County Experiment Farm; effects of day length on bluegrass; improvement of grass growth by walnut and locust trees; need of sweetclover rotations for plenty of K; value of white clover in increasing N in pasture herbage and merits of different white clover strains for pastures; development of all-season pasture systems; eradication of field bindweed with sodium chlorate; and killing weed seed in soil with chloropicrin (tear gas).

[**Agronomic studies in Rhode Island**]. (Partly coop. U. S. D. A. et al.). (*Rhode Island Sta. Rpt.* [1941], pp. 10-17, 23-26, 27-30, 47).—Reports of progress are made (E. S. R., 85, p. 753) from variety tests with corn (and hybrids), potatoes, and lawn and turf grasses; fertilizer experiments with potatoes, mangels, onions, carrots, parsnips, alfalfa, clovers, and lawn and turf grasses, particularly varieties and strains of bents; planting, spraying, fertilizer, and pH range tests with potatoes; residual effects from different levels of fertilizer, as shown by yields of corn; effects of crops on succeeding crops; B deficiency in rutabagas and mangels; crop rotations; seasonal development of roots of Colonial bent; breeding work with bentgrasses for pasture; chemical weed control tests on closely cut turf and on fairways; endurance of grasses and grass mixtures on athletic fields and airports; seed production of bentgrass varieties and strains, especially in response to fertilizer treatments; comparisons of Sudan grass, millet, oats, and winter rye and wheat planted at various dates for supplementary pasture; and merits of different forages and mixtures for grass silage.

**An appraisal of range survey methods from the standpoint of effective range management**, E. H. REID, G. D. PICKFORD, and N. T. NELSON (*U. S. Dept. Agr., Forest Serv., Pacific Northwest Forest and Range Expt. Sta., Range Res. Rpt.* 2 (1942), pp. [1]+V+66, pls. 3, figs. 21).—A field test comparing accuracy and costs of the two standard methods of estimating vegetation density and of the grid and aerial photograph range type mapping procedures was made in 1939 to determine which combinations of methods best fulfill requirements of a good range survey method in dependability of forage estimates, reliability of forage type maps, and cost.

The type-sampling reconnaissance and type-sampling square-foot-density methods and the grid reconnaissance method, conducted as in the study, appeared justifiable for use in range surveys from the viewpoint of uniformly dependable forage estimates. The type-sampling reconnaissance method is the cheapest and gives most dependable results of the standard range survey methods if films of aerial photographs and the completed planimetric base map are available without cost, but where these conditions do not prevail the grid reconnaissance method conducted at an intensity of two strips per section is recommended on ranges with gentle topography. If, for reasons aside from obtaining dependable esti-

mates of amount and distribution of range forage, sampling characteristics of the type-sampling square-foot-density method are preferred to those of the type-sampling reconnaissance method its use in range surveys is held justifiable.

Field work with the reconnaissance method cost 9.00 mills per acre when mapping directly on aerial photographs and 9.09 mills when mapping with the grid procedure, with the square-foot-density method 11.53 mills per acre when mapping with type-sampling procedure and 9.88 mills per acre when mapping with grid procedure. Aerial photography and drafting the planimetric base map increased the survey costs about \$5.11 per square mile or 7.98 mills per acre.

**Important plants on national forest ranges of eastern Oregon and eastern Washington, E. H. REID** (*U. S. Dept. Agr., Forest Serv., Pacific Northwest Forest and Range Expt. Sta., Range Res. Rpt. 1 (1942), pp. [1]+64, figs. 91*).—Simple keys, descriptions, and notes are given on the occurrence and forage value of important plants on the national forest ranges of eastern Oregon and eastern Washington. Supplementing the Range Plant Handbook (E. S. R., 77, p. 756), it includes only species that are important forage plants or that are unimportant as forage but are abundant on the range.

**Guides to determine range condition and proper use of mountain meadows in eastern Oregon, G. D. PICKFORD and E. H. REID** (*U. S. Dept. Agr., Forest Serv., Pacific Northwest Forest and Range Expt. Sta., Range Res. Rpt. 3 (1942), pp. [22], figs. 6*).—Stressing the importance of mountain meadows to summer range forage production in eastern Oregon, this progress report gives general guides by which to judge the condition and the proper use of mountain meadow vegetation.

**The effect of different phosphatic fertilizers on the yield, plant population, and chemical composition of pasture herbage on Dunmore and Emory soils, R. E. O'BRIEN and S. S. OBENSHAIN** (*Virginia Sta. Tech. Bul. 80 (1942), pp. 37, figs. 7*).—The relative efficiency of several P fertilizers in increasing yields and improving the N and mineral contents of old pasture sods was determined, 1934–40, at Blacksburg and at Glade Spring, both in the limestone valley region of southwest Virginia. During the first 3 yr. P fertilizers only were broadcast on the surface annually in early spring at the acre rate of 50 lb. of  $P_2O_5$ . In following years 300 lb. of an 8–16–16 fertilizer were applied. One-half of each plat received ground limestone 1 ton per acre every 4 yr.

Herbage yields at Blacksburg rose steadily each year (except for the dry 1936 season) from 1934 to a peak in 1938, then decreased sharply in 1939 due to drought. The sod also steadily improved during the first 5 yr. The peak in both yield and plant population was reached in 1938, and thereafter where plant food was adequate, both depended largely on proper seasonal distribution of rainfall. The more readily available sources of P produced a marked increase in the average yield of herbage at Blacksburg. On limed plats dicalcium phosphate produced the highest average annual yield (air-dry) 4,307 lb., and the limed check 2,759 lb.; on unlimed plats superphosphate produced 4,477 lb., dicalcium phosphate 4,436 lb., and the unlimed check 2,940 lb. Liming resulted in a slight reduction in yield in every case. The relative efficiency of the carriers on a P equivalent basis with and without lime was in the descending order dicalcium phosphate, superphosphate, and triple, basic slag, tricalcium, and raw rock phosphates. Each P fertilizer used increased the weighted average percentage of N, P, and Ca in herbage, but with limed raw rock phosphate the increase was negligible, while several treatments gave very small increases in Ca. Limed and unlimed triple, dicalcium, and superphosphate treatments increased the average P content of herbage by 150 percent over the respective checks. Liming had no appreciable effect on average percentages of the constituents in herbage except with raw rock phosphate. The average annual uptake of P about equaled the amount (48

lb.) applied in the fertilizer where the more readily available P carriers were used, while on check plats it was only about 20 lb. All P treatments gave decidedly higher annual uptakes of N and Ca than the checks.

On fertile Emory silt loam at Glade Spring where the unlimed check averaged 6,263 lb. of air-dry herbage per acre, there was slight response to P and none to liming, but there was marked response to most P fertilizers on the less fertile Dunmore silt loam. Although P fertilizers had little effect on the N and Ca contents of herbage, certain materials appreciably increased the P contents. On Emory soil only triple, dicalcium, and superphosphate treatments gave appreciable increases, but on Dunmore soil all phosphates, except limed raw rock phosphate, produced rather marked increases in the P content of herbage. The annual utilization of P by herbage on Emory soil usually equaled or exceeded that applied annually. With an uptake of about 40 lb. of phosphoric acid on the no-P plats, recovery of applied P was in all cases less than 100 percent. On Dunmore soil where the percentage composition of the herbage was lower and the yields were much lower, the annual utilization of P was only about one-half of the P applied.

**Red kidney beans in California**, F. L. SMITH (*California Sta. Bul.* 669 (1942), pp. 21, figs. 4).—Red kidney bean production in California is discussed, with special emphasis on improvement of types, particularly Red or Western Red Kidney. The State grows only about 12 percent of the national total for this variety, but furnishes seed for New York, which produces the most Red Kidney beans. Production in California is limited largely to river-bottom soils of the Sacramento and San Joaquin Valleys. Cultural and harvesting methods common in the growing of the crop are described, with emphasis upon seed injury during threshing and recleaning and upon its importance in seed production. Diseases and insect pests and their control are discussed briefly. Details are given on the pedigree, yield, and rise to dominance in California of Red Kidney 7811, a superior strain isolated by the station.

**Growing velvet bent grass seed in Rhode Island for commercial use**, J. A. DEFRANCE (*Rhode Island Sta. Misc. Pub.* 12 (1942), pp. [1]+5).—Suggestions for seedbed preparation, fertilization and liming, soil treatment, planting, care, maintenance, harvesting, threshing, and cleaning of velvet bentgrass to obtain pure seed, based extensively on research of the station, are outlined, together with directions by A. E. Stene for control of armyworm.

**Germination of cottonseed as affected by soil disturbance and machine placement of fertilizer**, H. P. SMITH, M. H. BYROM, and H. F. MORRIS (*Texas Sta. Bul.* 616 (1942), pp. 29, figs. 21).—Effects of machine placement of fertilizer and of soil disturbance on the germination of cottonseed were studied, 1936–40. See also an earlier note (E. S. R., 78, p. 407). The best germination and emergence were obtained when cottonseed were planted on a firm, undisturbed soil, and better stands were obtained with fertilizer placed 2 in. to the sides of the seed and 1 or 2 in. below the seed level. The highest yield was obtained at College Station when fertilizer was placed 2 in. to each side and 1 in. below seed level and at Nacogdoches when fertilizer was placed 2 in. to each side and 2 in. below the seed level, although fertilizer applied in any manner significantly increased yield at both stations.

**Cotton irrigation investigations in San Joaquin Valley, California, 1926 to 1935**, F. ADAMS, F. J. VEITHMEYER, and L. N. BROWN. (Coop. U. S. D. A.). (*California Sta. Bul.* 668 (1942), pp. 93, figs. 41).—Further irrigation investigations and experiments with cotton (E. S. R., 68, p. 470) were made, 1931–35, at other locations in San Joaquin Valley on soils of heavier texture than those at Shafter. The soil moisture record, 1927–35, is discussed in some detail for each year, with accompanying soil moisture charts for 1932–35, inclusive. The extent

to which the general objective of wet (the largest quantities of water), medium (intermediate), and dry (unirrigated) treatments was reached is summarized briefly.

When the principal plant responses, 1932-35, were considered as a whole, allowing soil moisture to remain at the permanent wilting percentage for extended periods in the upper 2 or 3 ft. of soil or allowing it to reach the permanent wilting percentage and remain there for extended periods during the last part of the season reduced plant heights and yields. Effects of withholding the first irrigation until August were not shown conclusively. Between the principal wet and medium treatments yields of neither group were consistently higher or lower than those of the other. Blossom counts (1932) and shedding of bolls and squares (1935) varied with irrigation rate, the highest count after the first peak of blossoming being in a wet treatment and the greatest shedding in a treatment receiving the least water. Data included on effects of irrigation on the quality of cotton produced were not considered conclusive.

The records led to the conclusion that on either the heavy or lighter soils of the experiments, cotton in San Joaquin Valley will use the equivalent of about 24 in. in depth, including both surface evaporation and plant transpiration, in producing normal yields. Data on water applied indicated that application of a depth of from 15 to 20 in. for heavy soils and from 20 to 25 in. on the medium and lighter soils is ample for cotton in this valley if there has been a preirrigation to a depth of 5 or 6 ft. of soil. The depth of water necessary to apply to wet the soil to 5 or 6 ft. before planting will depend in part on the depth of wetting by winter rainfall. If these soils are dry to a depth of 6 ft., the maximum preirrigation required should not exceed a depth of about 14 in. for heavier soils or about 11 in. for medium or lighter soils.

**Varieties of flax that resist rust**, T. E. STOA (*North Dakota Sta. Bimo. Bul.*, 5 (1942), No. 1, pp. 29-31).—Varietal differences (E. S. R., 87, p. 217), especially in disease resistance and other agronomic characters, are restated for Buda, Viking, B. Golden, Smoky Golden, Walsh, and Biwing. Other varieties under test and promising experimental varieties being increased are mentioned briefly.

**Annual lespedeza for Florida pastures** (*Florida Sta. Bul.* 375 (1942), pp. 22, figs. 16).—This bulletin is in two sections.

*For northwest Florida*, J. D. Warner (pp. 4-10). Information is given on varieties, soils, and the fertilizer needs of lespedeza, and its use for permanent and temporary or rotated pastures in northwestern Florida.

*For peninsular Florida*, R. E. Blaser (pp. 10-21).—Preliminary fertilizer, inoculation, and variety tests, 1939-41, near Gainesville, Brooksville, Orlando, and Largo are reported, with advice on varieties, fertilizer, and cultural and management practices. Growth and composition data showed that the soil must be supplemented with Ca, P, and K to grow lespedeza. Good growth might be anticipated with a soil treatment of from 0.5 to 1 ton of lime and from 300 to 600 lb. of 0-16-8, 0-14-10, or similar fertilizer. In preliminary tests, high rates of rock or colloidal phosphates furnished ample P for lespedeza on sandy acid soils and also provided part of the Ca requirements, but liming gave improved growth. Treatment of basic slag and K, or lime, basic slag, and K resulted in satisfactory growth. Ca, P, and K contents of lespedeza were increased greatly by fertilization with those elements, and when superphosphate or K was omitted from the fertilizer P or K deficiency symptoms occurred. Kobe, common, and Tennessee 76 lespedezas made excellent growth when inoculated seed was planted on fertilized soil in early spring or late winter, while Korean was found unadapted.

Practical suggestions for establishing annual lespedeza pastures are appended.

**Sorghums for Kansas**, A. F. SWANSON and H. H. LAUDE. (Coop. U. S. D. A.).

(*Kansas Sta. Bul. 304* (1942), pp. 63, figs. 9).—A revision and enlargement of Bulletin 266 (E. S. R., 71, p. 625) with the results of varietal experiments at the station, substations, and outlying fields brought up to date. The better adapted grain sorghums in successive zones from east to west in Kansas include Standard Blackhull kafir, Red kafir, Pink kafir, Club, Western Blackhull, Finney milo, Wheatland, Early Kalo, Westland, and Colby, while feterita may be used as a catchcrop over much of the State. Among the better varieties suited primarily for forage are the larger, later, and higher-yielding sorts Atlas and Kansas Orange and the smaller, earlier types Early Sumac, Norkan, and Leoti Red. Sunrise is intermediate between forage and grain types. Kansas Orange appears best for sirup in eastern, southeastern, and south central Kansas, if planted at the normal time, and Atlas has also been used with success. Early Sumac and Leoti Red are good varieties in western and northwestern Kansas. Black Spanish is the leading standard type and Scarborough the leading dwarf type of broomcorn.

**Soybean production in Kansas**, J. W. ZAHNLEY (*Kansas Sta. Bul. 306* (1942), pp. 31, figs. 7).—This revision of Bulletin 282 (E. S. R., 81, p. 643) reports that the varieties A. K., Hongkong, Illini, Manchuk, and Pinpu currently are considered well suited to seed production in Kansas, and Laredo, Chiquita, Hongkong, and Peking have been good hay producers. Hongkong, A. K., and Laredo continued to be outstanding in southeastern Kansas in cooperative tests with farmers. Besides discussion of varieties, information is given on the adaptation and uses of the crop, methods and practices of growing soybeans for seed and hay and with corn, and on the control of rabbits, very destructive to young soybean plants. Yields of a few varieties of cowpeas, mung beans, and tepary beans are included.

**Continuous wheat culture versus rotation wheat culture**, H. L. WALSTER and T. E. STOA (*North Dakota Sta. Bimo. Bul.*, 5 (1942), No. 1, pp. 2-8, figs. 2).—During the period 1919-41, on unmaured land, wheat after corn averaged 24.4 bu. per acre, after clover 22.9, after peas 22.1, after rye 20.2, and after timothy or millet 16.3 bu. compared to continuous wheat in 6-in. drills 15.1 bu. The data suggested that the long-time effect of a crop sequence or of a rotation cannot be predicted from the results of a single year, either good or bad. Yields and May-July rainfall and temperature during the 10 best years indicated that a relatively dry July following abundant precipitation in June, or the combination of May and June, seems to favor high wheat yields, especially when associated with moderate temperatures that permit maximum filling.

**Production and quality of grain in Knoxville trade area**, C. E. ALLRED, B. H. LUEBKE, and M. B. JOHNSON (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 141* (1942), pp. IV+24, figs. 14).—The importance, trend, distribution, and possibilities of corn and small grain production in the 23 counties in the Knoxville area and the quality of grain received at the markets are reported from area surveys, and suggestions are given for improving the quality of the grain.

**Seed inspection in Kentucky, 1941-42**, W. A. PRICE, M. DIDLAKE, E. C. VAUGHN, E. DEEN, H. TILSON, A. McDANIEL, K. FRIED, M. MORTON, M. L. LITTELL, and L. BAUGH (*Kentucky Sta. Regulat. Ser. Bul. 33* (1942), pp. 35).—Germination and purity percentages and, when present, excessive quantities of noxious weed seed are reported for 544 official samples of agricultural seed obtained from dealers during the year ended June 30, 1942.

**Agricultural seed**, A. S. LUTMAN (*Vermont Sta. Bul. 497* (1942), pp. 15).—Germination and purity guarantees and variations therefrom are tabulated and discussed from tests of 424 samples of field crop seeds and forage mixtures obtained from local dealers in Vermont during 1942.

**Control of poison ivy (*Rhus toxicodendron*) by spraying,** A. F. YEAGER and C. L. CALAHAN. (N. H. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.* 41 (1942), pp. 234-236).—Ammonium sulfamate was found a much more effective killing agent for poison-ivy than was sodium chlorate. The applications were effective when made at any time during the active growing period of the plant. The soil was not so severely sterilized by ammonium sulfamate as by sodium chlorate, and applications could be made to ivy growing on apple trees without injury to the tree provided the apple leaves were not sprayed.

## HORTICULTURE

[**Horticultural studies by the Georgia Coastal Plain Station.** (Partly coop. Ga. Expt. Sta.). (*Georgia Coastal Plain Sta. Bul.* 32 (1941), pp. 77-83, 86-111, 135-139, fig. 1).]—Herein are discussed the results of cultural and fertilizer studies with tomatoes, watermelons, lima beans, lettuce, and cabbage. Variety trials include the lima bean, snap bean, asparagus, beet, carrot, roasting corn, cantaloup, cucumber, peas, onion, and other vegetables, and among fruits the peach, pecan, pear, grape, fig, jujube, citrus, and miscellaneous other species. Some work was done on the adaptation of the blueberry and tung tree and the fertilizer and cultural needs of the pecan.

[**Horticultural activities by the Mississippi Station,** C. DORMAN (*Miss. Farm Res. [Mississippi Sta.],* 5 (1942), No. 10, pp. 4-5, 5 6).]—Included are reports on the results of cultural and variety tests with vegetables and fruits at the Delta Substation; cabbage variety trials at the South Mississippi Substation; fertilizer, variety, and propagation studies with tung trees at the Experimental Tung Field; and fertilizer and variety trials with vegetables at the Truck Crops Substation.

[**Horticultural studies by the Ohio Station**] (*Ohio Sta. Bul.* 617 (1940), pp. 23-34, 34-36, 36-39, 40-44, figs. 4).—Included are progress reports on the following studies: Nutrient requirements of greenhouse tomatoes; movement of potassium fertilizer in orchard soils; production of mulch materials in the orchard; effect of ringing on the fruit set of the apple; the most productive age of apple trees; proper time to pick red strains of apples; use of indolebutyric acid in the production of seedless tomatoes; fertilizers for greenhouse tomatoes; the relation of soil fertility to the food value of the tomato; development of tomatoes, cucumbers, and lettuce varieties for greenhouse culture; comparison of direct seeding and transplanting of tomatoes; relation of midsummer seeding on muck soil to stand of plants; fertilizers for early vegetable crops; gravel and cinder culture of greenhouse flowers; effect of excessive fertilizer applications on flowers; culture of flowers in cloth houses; solutions for prolonging the life of cut flowers; the use of growth substances in the propagation of ornamentals; the use of chloropicrin for sterilizing soil in the greenhouse and in the field; and the effect of soil reaction on outdoor roses.

[**Horticultural studies by the Rhode Island Station**] (*Rhode Island Sta. Rpt.* [1941], pp. 17-23, 34-36, 38-40, 47-49, 52-55).—Included are progress reports upon the following investigations: Fertilizer, variety, and cultural trials with vegetable crops (coop. Mass. and Conn. Expt. Stas.), the breeding of eggplants for resistance to *Phomopsis* blight, the effect of carbon black on germination and yield of table beets, application of nitrate of soda to table beets, rotations for onions, relationship of glutamine and asparagine in vegetable plants, causes of "hollow stalk" in celery, use of hormone sprays to reduce the pre-harvest dropping of apples, soil management of the peach orchard, and apple growth as affected by sprays.

**Inspection, certification, and transportation of nursery stock in Kentucky, with a brief report for the year ended June 30, 1942,** W. A. PRICE

and H. G. THILSON (*Kentucky Sta. Regulat. Ser. Bul. 32* (1942), pp. 18).—As usual (E. S. R., 87, p. 60), this contains administrative information relative to certification, the status of certain insects and diseases, certified nurseries, etc.

**Propagation by grafting and budding**, H. G. SWARTWOUT (*Missouri Sta. Cir. 241* (1942), pp. 11, figs. 7).—Information is offered on the art and practices of various types of grafting and budding.

**Effect of fertilizer placement on snap beans, lima beans, and peas**, M. M. PARKER (*Virginia Truck Sta. Bul. 107* (1942), pp. 1757-1781, figs. 5).—The largest average yields of snap and lima beans and peas were obtained from placing fertilizer in bands 2 in. to each side and 2 in. below the level of the seed. The smallest yields were obtained when the fertilizer was placed in a band directly below the seed and when mixed with the surface soil at the time of planting. Intermediate yields followed the placement of the fertilizer on top of the row after planting or when used as a side dressing. The poorer results of placing fertilizer directly below the seed or mixing it with the surface soil were due principally to injury to the germinating seed and the young seedlings. Side applications were relatively ineffective because of the slowness with which the nutrients became available to the plants. In all placements a 6-12-5 material was used at the rate of 1,000 lb. per acre. Injury was most severe in soils with a low moisture content during the period of germination.

**Depth-of-planting studies with asparagus in California**, G. C. HANNA and H. A. JONES. (Calif. Expt. Sta. and U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 498-500).—At Davis, Calif., Palmetto asparagus plants spaced 2 ft. apart in the row and rows 7.5 ft. apart were planted 8 and 12 in. deep. At Ryer Island plants were set 4 to 5, 7 to 8, and 11 to 12 in. deep. Yield records showed no advantage from deep planting at either location and an actual decrease from deep planting in the heavier soil at Davis. There was a tendency for larger spears from deep planting at both locations. At Davis the shallower-planted crowns tended to produce a larger early crop than did the more deeply planted crowns.

**The Penn State Ballhead cabbage: Some problems encountered in its development**, C. E. MYERS. (*Pennsylvania Sta. Bul. 430* (1942), pp. [2]+52, figs. 48).—A historical account is given of the development of a variety of cabbage which has won wide recognition for its superior qualities. Various difficulties encountered, such as the overwintering of mother plants and the induction of satisfactory sets of seed, are discussed in some detail, with a view to helping other plant breeders. The best method of overwintering, trenching in soil, is described. Comparisons of line-bred and lubred strains with other crosses showed the possible use of the latter method to obtain increased yields of seed. Little, if any, correlation was found between shape and weight of heads.

**Sponges from a vine**, B. Y. MORRISON (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Agr. in Americas*, 2 (1942), No. 11, pp. 215-216, figs. 2).—Information is presented on the culture, handling, and uses of the luffa, or "dishrag" gourd.

**A trial of new varieties of hops for New York**, J. D. HARLAN (*New York State Sta., Better New York Hops*, 3 (1942), No. 4, pp. 28, fig. 1).—This mimeographed report presents the results of variety tests conducted largely in an experimental hopyard located in Oneida County. Information is presented on climatic conditions, cultural operations, yields, resins contents, and general characteristics of the varieties.

**Lettuce production under Mississippi conditions**, I. R. FARISH (*Mississippi Sta. Cir. 107* (1942), pp. 8, figs. 5).—Information is presented on the status of lettuce growing in the State, varieties, climatic requirements, soils, planting methods and practices, culture, and harvesting and marketing.

**Weed control in onions with dilute-sulfuric-acid spray,** A. G. NEWHALL, G. H. M. LAWRENCE, and O. L. JUSTICE ([*New York*] *Cornell Sta. Bul.* 784 (1942), pp. 27, figs. 10).—A method is discussed of spraying onions in late May with dilute sulfuric acid to kill annual weeds with a minimum damage to the onions. A cheap technical grade of acid, testing 66° B., with a specific gravity of approximately 1.84, was used. The most satisfactory dilutions were from 2 to 2.5 percent by volume, and the best quantity per single application was between 90 and 125 gal. of spray per acre. The most effective time to spray was on a warm day between the twentieth and thirtieth days following seeding, the exact date depending on the stage of development of the plants. At least three factors governed the proper timing, namely, the stage of development of the onions and of the weeds and the prevailing weather. Dilute sulfuric acid was found more reliable and less harmful to the onions than iron sulfate, Atlacide, Sinox, or cyanamide. At the strengths and quantities recommended it was necessary to hold the nozzles close to the soil so that a strip of only from 3 to 4 in. wide was sprayed. Considerable difference was noted in various weeds and grasses as to coverage. A certain amount of hand weeding was necessary to supplement the spray.

**Onion seed production in Idaho,** G. W. WOODBURY and C. F. DIETZ (*Idaho Sta. Bul.* 247 (1942), pp. 14, figs. 3).—Information is presented on the methods of producing onion seed, supported by certain experimental findings. In many locations in Idaho, onion bulbs may be set in the field in the fall, and such practice is recommended for the hardier kinds, such as Ebenezer, White Portugal, and Yellow Globe. Records taken at Parma over the 4 yr. 1938-41 showed with few exceptions significant increases in seed yield in favor of fall planting, particularly in White Portugal and Ebenezer. Sweet Spanish, while not as hardy, survived most winters but entailed some chance when planted in the fall. Comparisons of September 15, October 15, and November 15 indicated that the earliest planting date was desirable. With spring planting the early setting was also desirable. There was some evidence that large-sized bulbs were more productive of seed than were smaller sizes. It was clear that bulb size was related directly to the number of flower clusters produced.

**Irrigation of seed and canning peas in the Gallatin Valley, Montana,** O. W. MONSON (*Montana Sta. Bul.* 405 (1942), pp. 23, fig. 9).—Timeliness of irrigating was found to be important, with the largest yields of seed and canning peas being obtained when irrigation was deferred until the plants were in bloom. Earlier irrigations were advisable only when soil moisture was low enough to check growth. Nothing was gained by applying more water than the soil could retain for the use of the crop. Frequent irrigation was unnecessary during years of average rainfall, but when a lack of soil moisture checked growth in the early season follow-up irrigations at intervals of 10 to 14 days were needed to maintain favorable growth. On clay soils flooding caused puddling of the soil, and applications by the corrugation method were more effective. On loam soils, the flooding method was satisfactory. Heavy irrigations were not harmful when good drainage conditions existed, but waterlogging was definitely injurious. Irrigation tended to cool the soil to a depth of at least 16 in., and this effect was measurable for as long as 26 days. Canning peas were found to contain calcium, iron, phosphorus, and nitrogen in various amounts. Irrigation before bloom increased the contents of phosphorus and nitrogen; irrigations at early bloom increased the iron content and irrigations at full bloom increased the amount of calcium. Heavy seeding tended to increase yields sufficiently to more than compensate for the increased cost of seed and at the same time the heavier stands of plants helped to suppress weeds, which were chiefly wild oats and sweetclover.

**The tomato, P. WORK** (*New York: Orange Judd Pub. Co., 1942, pp. 135, figs. 27*).—Prepared by a member of the staff of the [New York] Cornell Experiment Station, this book contains information relating to soils, fertilizers, culture, varieties, control of pests, etc. A list of selected references to the literature is included.

**Some new research phases in greenhouse tomato production, I. C. HOFFMAN.** (Ohio Expt. Sta.). (*Veg. Growers Assoc. Amer. Ann. Rpt., 1941, pp. 215-226*).—Activities in breeding and selection of greenhouse tomatoes, testing of different types of soil, methods of seed sowing and plant production, effect of different light intensities, methods of culture, pollination requirements, etc., are discussed.

**Use of chemicals to stimulate fruitfulness in tomatoes, F. S. HOWLETT.** (Ohio Expt. Sta.). (*Veg. Growers Assoc. Amer. Ann. Rpt., 1941, pp. 203-214, figs. 4*).—Of various chemicals tested as agents for influencing the fruit set and development of tomatoes, indolebutyric acid was found outstanding. Throughout the experiments the fruits produced by this acid were as large as, or larger than, those produced in the same cluster following normal pollination, with the greatest improvement occurring during the period from January through February when little pollen may be viable. Indolebutyric acid in lanolin paste at 0.3 percent concentration was a standard with which other materials and concentrations were compared. Almost invariably the effect of treating flowers during February and March with indolebutyric acid was the development of gelatinous tissue within the locules, despite the absence of seeds. When the paste is used, the style must be largely removed and the material applied at the cut end, a procedure which restricts the commercial adoption of the technic. At present the procedure is largely employed as a means of supplementing pollination and fertilization, since seedless tomatoes are not demanded by the trade. There was some indication that spraying might be the eventual method of application.

**Factors influencing shoulder bruises of green-wrap tomatoes, J. M. LUTZ.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc., 40 (1942), pp. 455-459, figs. 3*).—Shoulder bruising, the most common type of injury to packed tomatoes, does not appear serious on mature green fruits but becomes conspicuous as ripening proceeds. Such injury may be caused by the abrasive action of the rough sides and bottoms of field crates. The tightness of the pack had little effect on the amount of shoulder bruising. Paper wraps tended to reduce bruising in transit. The planing of the boards used in making boxes and the use of corrugated paper or other protective materials tended to reduce injury.

**Time interval between full bloom and fruit maturity for several varieties of apples, pears, peaches, and cherries, H. B. TUKEY.** (N. Y. State Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 40 (1942), pp. 133-140*).—Data assembled from records taken by the station over a long period of years are presented in tabular form, with discussion. The interval of elapsed time between blooming and maturity was more nearly constant for apples, followed in order by the pear, peach, and cherry. That the intervals of elapsed time between bloom and maturity in different seasons more closely approximated each other than do calendar dates, was true whether the seasons were early or late. There appeared to be a greater variation in total elapsed time from bloom to fruit maturity in early-maturing than in late-maturing varieties of a given species. The author suggests that the timing of orchard operations, such as fruit thinning, irrigation, spraying, and cultivation, might well be based on the stage of development of the fruit rather than upon calendar dates.

**The orchard fertility problem during the war emergency (Pennsylvania Sta. Bul. 431 (1942), pp. [2]+12, figs. 10).**—During 34 yr. of tests, legume sods,

kept under control by annual light harrowing and by mowing, and annual legume covers worked down in the spring and immediately reseeded resulted in the production of as satisfactory apple crops without the use of commercial nitrogen fertilizers as nonlegume sods or covers with added nitrogen. In the peach orchard a similar use of annual legume covers with moderate use of commercial nitrogen also proved desirable. Good legume covers required lime, phosphate, and potash. With nonlegumes, or with legumes too thin to supply nitrogen, applications of commercial nitrogen are necessary. During the present emergency, ring applications are suggested as a means of making more effective the smaller amounts of commercial nitrogen available.

**Quantitative distribution of nitrogen and carbohydrates in apple trees,** A. E. MURNEEK (*Missouri Sta. Res. Bul. 348 (1942), pp. 28, figs. 10*).—From October to December, leaf samples were collected for analysis from two trees each of the 18-year-old Grimes Golden, Jonathan, and Delicious. The trees were then dug and the tops and roots separated into various integral portions. The total weight of the trees ranged from 850 to 1,000 lb., of which from 20 to 30 percent was in the roots. Approximately, from 62 to 65 percent of the tops and from 53 to 57 percent of the roots was made up of dry matter. Roughly 30 percent of the dry weight of the tops and 40 percent of that of the roots represented available carbohydrates, such as hemicellulose, starch, and sugars. There was about three times as much starch in the roots as in the tops. The trees contained about 2 lb. each of nitrogen, of which 75 percent was in the above-ground portion. Autumn migration of nitrogen and carbohydrates in the period between October and December was clearly evident in the trees. Nitrogen moved from the leaves into the twigs, and thence into the older wood and roots. Alterations in and migration of carbohydrates in the fall and early winter were somewhat difficult to ascertain. There was a sharp increase in sugar concentration, throughout the tree, between the middle of October and the end of December with a corresponding reduction in starch, ascribed to hydrolysis of the starch caused by the relatively low temperatures.

**Comparison of certain varieties as pollenizers for the Delicious apple,** W. H. GRIGGS and A. L. SCHRADER. (Md. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc., 40 (1942), pp. 87-90*).—Several varieties, including Golden Delicious, Williams, Winter Banana, Jonathan, Lowry, Yellow Transparent, Rome Beauty, Gallia Beauty, and York Imperial, were tested in 1940 as pollenizers for Delicious. Because of the apparent inadequacy of the data, the project was repeated in 1941 with more replications using five pollenizers—York Imperial, Rome Beauty, Gallia Beauty, Jonathan, and Golden Delicious. In this second trial Rome Beauty, Gallia Beauty, and Jonathan gave slightly higher sets than did Golden Delicious and York Imperial. As a result the authors recommend the first three for pollenizers for Delicious, and suggest that some of the earlier pollination work may have been misleading because of inadequate replications or proper statistical treatment of the data.

**Gross morphology and histology of developing fruit of the apple,** H. B. TUKEY and J. O. YOUNG. (N. Y. State Expt. Sta.). (*Bot. Gaz., 104 (1942), No. 1, pp. 3-25, figs. 69*).—The results are presented of a study of the fruits of five apple varieties, Lodi (very early), Early Harvest (early), Twenty Ounce and McIntosh (midseason), and Rome Beauty (late), collected in the station orchard at various stages of development from 1 mo. before full bloom to maturity.

**Influence of boron application on preharvest drop of McIntosh apples,** A. J. HEINICKE, W. REUTHER, and J. C. CAIN. (Cornell Univ.). (*Amer. Soc. Hort. Sci. Proc., 40 (1942), pp. 31-34*).—Records taken on a block of 20-year-old McIntosh trees in the Cornell University orchard indicated that borax applications to trees susceptible to cork reduced the preharvest drop as well as the drop

through harvest as compared with trees not receiving borax. The moderate application of boron to trees previously free from cork had no definite effect. Leaf analyses indicated that boron content was relatively low before application, even in leaves of trees showing no deficiency symptoms. There was a definite increase within 6 weeks, especially on trees which bore few or no apples showing surface cork. The boron content of the leaf tissues of normal trees tended to increase as the season advanced. Determination of boron in apparently healthy fruits from limbs of four trees having at least 5 percent of the apples with cork averaged 2.48 p. p. m. in the dry matter as compared with an average of 5.43 p. p. m. for fruits from limbs on the same trees on which none of the fruits showed deficiency symptoms.

**Some results in controlling the pre-harvest drop of apples, M. B. HOFFMAN, L. J. EDGERTON, and A. VAN DOREN.** (Cornell Univ.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 35-38).—Comparisons of naphthaleneacetic acid applied as a spray and as dust to Williams apple trees revealed both types of application to be about equally effective in reducing preharvest drop. In an experiment with vigorous 16-year-old McIntosh trees in the Hudson River Valley, the dust was fully as effective in drop control as was the liquid spray. With 18-year-old McIntosh trees in western New York the average drop for the checks was 11.9 percent, single application of liquid 5.5, double application of liquid 3, single application of dust 5.2, and double application of dust 2.9 percent. There was some indication that the initial applications were some 4 days too early for optimum effects. In the case of Baldwin apples which had started to drop before attaining satisfactory color, dust and liquid reduced dropping in about the same degree. Some evidence was obtained that naphthaleneacetic acid was beneficial in reducing the drop of Northern Spy apples. Weather conditions were apparently important in influencing the drop of apples, and proper timing of sprays or dusts was important in determining their beneficial effects.

**Further studies on the control of preharvest drop of McIntosh, L. SOUTHWICK.** (Mass. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 39-41).—A comparison of sprays and dust applied in equivalent amounts of active ingredients to McIntosh trees indicated that the sprays were somewhat more effective than the dust in reducing the preharvest drop. In one trial, the use of a small amount of summer spraying oil to the liquid failed to improve control to any significant degree. Unfavorable results were obtained where a satisfactory type of sticker was added to the standard spray. Good results obtained with a late spray gave some indication that hormone sprays, even when applied rather late, may be helpful in decreasing the subsequent dropping of the McIntosh apple. This is a continuation of previous work (E. S. R., 86, p. 45).

**Further studies with preharvest sprayed McIntosh apples, L. M. MURPHY.** (R. I. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 42-44, figs. 2).—All of three experiments, namely, one spray at 5 p. p. m., one spray at 10 p. p. m., and two sprays 4 days apart and of 5 p. p. m. concentration each, reduced the preharvest dropping of McIntosh apples from trees 22 yr. of age and carrying an average crop of 10.2 bu. per tree. The differences between sprays were not significant. Of three spraying dates, namely, September 9, 11, and 13, the first was significantly more effective, emphasizing the importance of proper timing. While the repeated application did not lengthen the effective period, this treatment gave better coverage and increased the chances of correct timing. This is a continuation of previous work (E. S. R., 86, p. 193).

**Temperature in relation to effectiveness of preharvest drop sprays on apples, L. P. BATJER.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 45-48, figs. 2).—In experiments with Williams, Delicious, and Stayman Wine-sap apple trees, in which preharvest sprays of naphthaleneacetic acid were applied

at different times of day when different temperatures existed, it was evident that sprays applied at midday were more effective in certain concentrations than when applied in early morning under cooler conditions. With Williams, a variety extremely responsive to hormone sprays, temperature differences were obtained only when the concentration was below 5 p. p. m. With Delicious and Stayman Winesap, both 2.5 and 5 p. p. m. sprays were generally more effective when applied at the higher temperatures. Early-morning sprays required nearly 1 hr. to dry as compared with 0.5 hr. at noon. Apparently, however, absorption was much more rapid at the higher temperatures. Some work upon the effect of temperature on the persistence of sprayed leaf petioles suggested that approximately 75° F. may represent the critical point above which temperature may not be an important factor.

**More or less water-core, W. A. RUTH.** (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 143-149).—Water core is stated to be a serious problem with Duchess apples in the Ozark section of Illinois and with Willowtwigs in western Illinois. An examination of the fruit of seven Duchess trees at Urbana showed more water core present in the crop of those trees bearing lightly. On all the trees, the well-colored apples and those with red-tinted flesh tended to have more water core. There was no correlation between size of fruit and water core. Apparently a high leaf:apple ratio favored the development of water core, but various other factors were involved.

**External factors affecting water loss from apples in cold storage, S. A. PRIENIAZEK.** (R. I. Expt. Sta.). (*Refrig. Engin.*, 44 (1942), No. 3, pp. 171-173).—The rate of transpiration of apple fruit was found to be directly proportional to the water pressure deficit of the air. The amount of loss per unit of vapor pressure deficit was constant within the ranges of temperature and relative humidity studied. The observations were true only when the transpiration rate was determined for short periods of time directly after the fruits were brought under controlled conditions. When apple fruits are transferred to high temperatures and the low ranges of relative humidity, the time factor became apparent. The effect of air movement on the rate of transpiration of apples is negligible, amounting to about 5 percent at the most provided that temperature and relative humidity are uniform throughout the storage chambers.

**Mealiness and quality in Delicious apples as affected by certain orchard conditions and storage techniques, D. V. FISHER.** (Iowa Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 128-132).—Delicious apples harvested in a mature state had excellent flavor but were susceptible to mealiness. Immature apples, although less susceptible to mealiness, did not develop the characteristic varietal flavor. Iodine tests showed a marked decrease in starch in apples harvested in the mature stage. Respiration rates at 60° F. were twice as great as at 40° and three times as great as at 32°. The disappearance of starch and the hydrolysis of protopectin to soluble pectin were found useful indicators of the progress of ripening in the Delicious apple. The storage of apples in atmospheres containing 2.5 percent O<sub>2</sub> and 97.5 percent N<sub>2</sub> at 32° or 40° inhibited softening and increased greatly storage life. Determinations of sugars, acids, and alcohol-insoluble residues, both at the time of removal from storage and after periods at 60° in air, failed to reveal any significant differences in chemical composition between fruits stored in air or in any of the modified atmospheres used.

**Influence of controlled-atmosphere storage on respiration of McIntosh apples, R. M. SMOCK.** (Cornell Univ.). (*Bot. Gaz.*, 194 (1942), No. 1, pp. 178-184, figs. 4).—McIntosh apples respired approximately one-third as fast in controlled-atmosphere storage at 40° F. as in ordinary cold storage at 32°, and when

removed from storage in controlled atmosphere did not respire as rapidly as those removed from ordinary cold storage. Apples held in cold storage at 32° evolved 2.5 and 3.0 times as much CO<sub>2</sub> during the same period as did controlled-atmosphere fruits.

**Experiments with sprays in the control of preharvest drop of Bartlett pears in California.** A. E. DAVEY and C. O. HESSE. (Univ. Calif. and U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 49-53, fig. 1).—Experiments conducted in two different years showed that preharvest sprays were successful in reducing the drop of Bartlett pears. Under all controls, an average of more than 3 or 4 days was necessary for the expression of the influence of the sprays. The drop after treatment with chemicals at the strengths of 10 and 5 p. p. m. was reduced to about 50 percent of that on untreated trees. In one instance where naphthalenecetic acid was used, the drop was reduced to about 33 percent of that in the checks.

**Initiation of peach flower parts.** B. S. PICKETT. (Tex. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 111-112).—In 1940, the buds of the Dr. Burton peach showed no signs of flower differentiation at Iowa Park, Tex., until August 10. In 1941, no differentiation was observed in Mayflower, Early Rose, Dr. Burton, Frank, Dee Lee Cling, Smith (a honey peach), and an unknown on August 4. On August 15, flower parts were well advanced in Early Rose and were evident in Dr. Burton. On September 3 the typical primary stage was seen in Frank, and on September 13 the varieties Dee Lee Cling, Mayflower, and the unknown showed flower primordia. Mayflower, one of the earliest to mature fruits, was among the latest to develop flower parts, suggesting an absence of any correlation between the time of fruit maturity and flower initiation.

**Comparative transpiration rates of peaches and citrus.** R. F. CAIN. (Tex. A. and M. Col.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 79-83, figs. 2).—Transpiration readings taken on 2-year-old Marsh seedless grapefruit, Valencia orange, and Southhaven and Texaberta peach trees, growing in 5-gal. cans containing Lufkin fine sandy loam, showed marked differences between species and between varieties. The mean daily absolute transpiration of the Texaberta peach was over twice that of the Southhaven variety, and the transpiration of the grapefruit was higher than that of the orange. Orange plants ceased transpiring 2 hr. earlier in the evening and resumed transpiration 1 hr. later in the morning than did the grapefruit. There was no evidence of time differences between the two peaches. The grapefruit and the peaches responded quickly to illumination, while the orange was much slower in response.

**Effect of nitrate of soda on development of the Halehaven peach.** R. V. LOTT (*Illinois Sta. Bul.* 493 (1942), pp. 321-384, figs. 11).—The seasonal development of the fruit from the time of full bloom to maturity was followed in two adjacent 6-year-old Halehaven peach trees, one of which was unfertilized and the other given two 5-lb. applications of nitrate of soda, one on March 28, 17 days before full bloom, and one on June 4 when the stones were beginning to harden. Measurements of fruit diameters, volume, or fresh weight revealed three distinct periods of development. The first, which ended 57 days after bloom, was characterized by a rapid increase in size and fresh weight of flesh, stone, and kernel; the second, which ended about 76 days after bloom, was characterized by a slow rate of increase in size of flesh, stone, and kernel; and the third period, extending to the soft-ripe stage, was characterized by an accelerating increase in size and in dry matter of the flesh. The transition from one period to another was not abrupt. The effect of the nitrate on the fruit was not apparent until about 3 weeks before harvest, when the control fruits developed more rapidly for a few days and were then surpassed by the fertilized fruits. The nitrogen treatment induced greater vigor of growth, larger yields,

larger fruits, and more fruit buds for the succeeding year. There were higher percentages of starch, dextrin, ash, and nitrogen and lower percentages of reducing sugars and hemicelluloses in the flesh of the nitrated fruits.

**The relation between diameter and fresh weight of developing peach fruits,** L. D. DAVIS. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 146-152, figs. 5).—Samples of 50 fruits, harvested at about weekly intervals from a few weeks before pit hardening until maturity, were weighed, and each of the diameters—suture, cross, and length—was measured. When the average cross or suture diameter was plotted against the average weight, a smooth curve resulted which became a straight line when the logarithms of the variables were used. The relation between average length diameter and the average weight was not as regular as that between the other two diameters and the weight. The scatter of points about the calculated line of best fit was such as to suggest that 50 fruits are adequate to represent the population. There was excellent agreement among the equations for replications within a variety, either from different locations in one season or many seasons. When compared with the weight the cross diameter has the greatest seasonal change of the three diameters, the suture next, and the length diameter the least.

**Propagating peach plums by cuttings,** W. L. DORAN and J. S. BAILEY. (Mass. Expt. Sta.). (*Amer. Nurseryman*, 76 (1942), No. 6, p. 7).—Softwood cuttings taken in mid-June and consisting of entire but short new shoots or laterals about 4 in. in length, with the basal cut at the base of the current season's growth, gave good results when treated with a root-inducing substance. The rooting medium was a mixture of two parts of sand and one part of peat moss. In one case 67-percent rooting was obtained in 25 days where the basal ends had been immersed in a solution of indolebutyric acid for 4 hr. prior to planting. Rooted cuttings transplanted to a sandy soil made from 3 to 4 in. of new growth by the middle of August.

**The effect of deflorating or defruiting upon blossom bud differentiation in the Sugar prune,** L. D. DAVIS. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 126-127).—At the approach of full bloom, flowers were removed from unringed branches of the Sugar prune, a variety that often alternates completely. Very small branches, such as individual spurs and up to 1 ft. in length, formed no buds. Branches of intermediate size formed small percentages of flower buds. Branches from 1.5 to 2.0 in. in diameter formed 90 percent, and larger branches formed 100 percent flower buds following defloration. Where half of a tree was deflorated, the treated half produced flower buds and the rest of the tree none. Some of the deflorated portions remained out of phase with the rest of the tree for only a single season. In other cases, 4 or 5 yr. elapsed before normality was resumed. As to the most effective time for defloration or defruiting, flower buds were formed when treatments were applied within a period of from 30 to 40 days after full bloom, except in 1935 when the limit was 14 days. Ringing extended the duration of the effective period for defruiting on 2-in. branches.

**Note on the pollination of the Italian Prune,** L. H. MACDANIELS. (Cornell Univ.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 84-86).—Evidence obtained from self- and cross-pollinations, employing the branch-unit method, indicated that the Italian Prune as grown at Ithaca, N. Y., is at least partially self-fruitful, but that the set may be increased by cross-pollination with compatible varieties. In the 2 yr. 1938 and 1939 flowers exposed to open-pollination set the highest percentage of fruits, and those crossed with varieties such as Stanley, Imperial Epineuse, and Agen set more fruit than did selfed blooms.

**Growing raspberries and blackberries,** H. G. SWARTWOUT and W. R. MARTIN, Jr. (*Missouri Sta. Bul.* 450 (1942), pp. 32, figs. 16).—Information is pre-

sented on the status of production, locating the plantations, soils and their preparation, varieties, methods of propagation, planting, culture, fertilizer requirements, pruning, training, control of diseases and insects, methods of harvesting and handling the fruit, etc.

**Fertilizing strawberries in North Carolina**, R. A. LINEBERRY and E. R. COLLINS. (Coop. U. S. D. A.). (*North Carolina Sta. Bul.* 332 (1942), pp. 20, figs. 11).—Nitrogen at approximately a 5-percent level gave good results when used with 8 percent phosphoric acid and 6 percent potash. In three of the four trials, 8 percent phosphoric acid in the ratio produced higher yields than none or 4 percent. In one of the four trials, increased yields were obtained from the potash contained in the fertilizer. As to time of application, no consistent increases in yield were shown for any specific time of applying a complete fertilizer, whether applied in a single or in split treatments. There was evidence that some of the fertilizer should be applied by September or October, during the fall growing season. Supplementary spring applications of soluble nitrogen increased total yields but delayed ripening and lowered keeping qualities. A relationship was shown between soil reaction and plant survival, with a larger percentage of loss associated with the more acid areas of individual fields. Applications of sulfur and physiologically acid fertilizers increased the number of dead plants. Limestone applications increased yields on the fields included in the investigations.

**Growth and fruiting of the cranberry**, R. H. ROBERTS and B. E. STRUCKMEYER. (Wis. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 373-379, figs. 8).—Large yields of fruits were obtained when the average growth of the upright shoots was between 2.5 and 3.5 in., and when there were between 200 and 300 of such uprights per square foot. As the number of uprights increased the length also increased, apparently caused by shading. The production of a good cranberry crop appeared to depend more upon the set of blossoms than upon blossom bud formation, which was usually abundant. Poor crops on strongly vegetative uprights in dense stands appeared to be due to both shading and poor pollination. Apparently the agitation of the flowers by some agent such as a breeze was sufficient for pollination, which is apparently brought about by wind-borne pollen. Insects function apparently by jarring the blossoms rather than contacting the stigmas. The pollen grain is a tetrad capable apparently of developing into four functional pollen tubes. Fruits may form with very few seeds, in fact seedless fruits were not uncommon. Cranberry pollen does not shed readily when the blossoms are in damp situations.

**Effect of nutrients, media, and growth substances on the growth of the Cabot variety of *Vaccinium corymbosum***, A. KRAMER and A. L. SCHRADER. (U. S. D. A. and Md. Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 7, pp. 313-328, pl. 1, figs. 5).—Cabot plants grown in crocks containing quartz sand and quartz sand plus a top layer of peat were supplied nutrient solutions so modified as to cause deficiencies in various nutrients. With complete nutrients the plants grew vigorously and developed large green leaves similar to those of plants grown outdoors under optimum conditions. The plants in the peat-on-sand series were even more vigorous, and this was true both for those receiving the full nutrient solution and those deprived of a single element, except K. Nutrient deficiencies of certain elements did not appear as early in the peat-sand as in sand alone. The absence of Ca, Fe, or of S did not cause deficiency symptoms in the peat-sand cultures throughout the life of the experiment. With the above exceptions, deficiency symptoms appeared after different lengths of time in both media in the following order: N, K, S, Ca, B, Mg, P, Fe, and Mn. The beneficial effect of peat was due partly to the presence of Ca, B, and S in the available form and partly to undetermined

causes. The deficiencies, particularly of N, K, B, S, Mg, and P, were sufficiently characteristic to be easily identified. The shoot: root ratio of plants in peat-on-sand was increased greatly when Mg, Fe, Ca, B, or Mn was omitted and decreased when S, B, P, or N was withheld from the sand cultures. A lack of N increased significantly the rapidity with which terminal growing points aborted. Weekly applications of thiourea and vitamin B<sub>1</sub> had no significant effect on deficiency symptoms, fresh or dry weight of the plants, or growing-point abortion. Eight other substances applied to plants growing in silt loam had no significant effect.

**Crown budding for healthy Hevea**, H. G. SORESENSEN (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Agr. in Americas*, 2 (1942), No. 10, pp. 191-193, figs. 5).—The production of rubber in Latin America is impeded by the leaf blight fungus *Dothidella uli* which is carried from tree to tree by wind-blown spores. The development of clones or strains of *H. brasiliensis* with combined resistance and high yield is the ultimate object, but in the interim crown budding offers a workable means of utilizing imported clones that could not otherwise exist in disease-ridden areas. In crown budding, a disease-resistant crown is budded on a high-producing trunk which, in turn, has been budded on a seedling rootstock. The result is a three-part rubber tree consisting of a root, trunk, and top all derived from different sources. The technic of developing such composite trees is described in detail. In addition to aiding in disease control, crown budding is useful in breeding as the tops come into flower within 3 yr. as compared with 6 or 7 yr. when budded on ordinary rootstocks.

**Fertilizer results with tung trees and recommended cultural methods**, W. D. KIMBROUGH, J. C. MILLER, and W. F. WILSON (*Louisiana Sta. Bul.* 352 (1942), pp. 16, figs. 3).—In connection with information on culture, propagation, methods of transplanting, harvesting, storage, etc., the authors present the results of fertilizer experiments. In a series of plats on Ruston fine sandy loam near Bogalusa, there was noted a direct positive correlation between the amount of fertilizer applied and increase in growth and yield. P and N were found to be especially deficient, with no benefit from K. The need of N became more acute after the first crop of nuts was harvested. In another experiment a complete fertilizer was found necessary for the best growth and highest yield, with indications that K, though beneficial, was less necessary than P and N. No consistent significant differences were found in the oil content of the nuts or in the quality of the oil attributable to differential fertilizer treatments. Records on yield of individual trees showed great variation under comparable conditions.

**Effects of growth-regulating substances on shoot development of roses during common storage**, P. C. MARTIN. (*U. S. D. A.*). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 26-49, figs. 14).—Experiments conducted during two storage seasons indicated that growth-regulating substances will inhibit vegetative buds so that the plants remain dormant through the normal storage season. Three compounds, naphthalenemethylacetate, naphthalenethylacetate, and naphthaleneacetonitrile, inhibited effectively the growth of buds for from 40 to 60 days in common storage. In general an application appeared to be most effective when a continuous supply was present at or near the inhibited buds. The food reserves (starch) of treated bushes were conserved while in storage, either by direct inhibition of the treatment on starch hydrolysis or by the prevention of shoot growth which utilizes the available reserves. As a result, treated plants after storage produced much greater root and top growth and more and better flowers than did the untreated controls.

**Growing ornamental greenhouse crops in gravel culture**, D. C. KIPLINGER and A. LAURIE (*Ohio Sta. Bul.* 634 (1942), pp. [1]+52, figs. 24).—This revision

of an earlier bulletin (E. S. R., 84, p. 765) presents, in the same general manner, information regarding the growing of greenhouse plants with nutrient solutions, with added facts relative to recent developments in methods and applications.

**Herbaceous perennials for North Carolina**, G. O. RANDALL and J. G. WEAVER (*North Carolina Sta. Bul. 333 (1942), pp. 40, figs. 35*).—Information is presented on propagation by seeds, cuttings, division, and layerages; soils and fertilizers; planting and culture; and on various perennials which have been tested and found adapted to North Carolina conditions.

**An illustrated guide to identification and landscape uses of Mississippi native shrubs**, F. S. BATSON (*Mississippi Sta. Bul. 369 (1942), pp. [2]+61, figs. 60*).—Information is presented on the growth and flowering habits and possible landscape values of a number of Mississippi plants.

## FORESTRY

**Farm forestry studies by the Delta Branch Station**, C. DOERMAN (*Miss. Farm Res. [Mississippi Sta.], 5 (1942), No. 10, p. 4*).—Information is presented on timber stand improvement, planting trials, and fence post tests.

**[Forestry activities by the Ohio Station]** (*Ohio Sta. Bul. 617 (1940), pp. 73-78, figs. 2*).—General information is presented with reference to forest protection activities, recreational developments in the State forests, survey of forest plantations, etc.

**Sex and vegetative propagation**, A. G. SNOW, JR. (U. S. D. A.). (*Jour. Forestry, 40 (1942), No. 10, pp. 807-808*).—Cuttings taken from male trees rooted better on the average than those from female red maple trees, although there were both high- and low-rooting clones in both sexes. The possibility is suggested that this relationship is associated with nutritional factors conditioned by the increased drain on foods in the maturing seeds.

**Changes within the seeds of *Juniperus scopulorum* during the processes of after-ripening and germination**, M. AFANASIEV and M. CRESS. (Okla. A. and M. Col.). (*Jour. Forestry, 40 (1942), No. 10, pp. 798-801*).—Observations on the seed of *J. scopulorum*, a species which does not germinate during the first spring but does germinate freely during the second, showed the food reserves in the dormant seeds to be in the form of fats and proteins. Neither sugars nor starch were detected. Peroxidase was found in small amounts, while oxidase was absent or inactive. Catalase activity was very pronounced, even in dormant seeds. The kernel of the seed was slightly acid, 6.4 to 6.9 pH. The changes recorded in afterripened seeds just before and during germination were a rapid increase in moisture, a slight increase in sugar and oxidase, an increase in peroxidase, and a marked increase in catalase activity. During germination starch appeared in the growing embryo, and the moisture content of the seed decreased slightly. Seeds treated with concentrated sulfuric acid and stratified at 60° F. for 53 days showed a marked increase in catalase activity, suggesting rapid progress in afterripening.

**Value of small-crowned ponderosa pines in reserve stands in the Southwest**, F. H. WADSWORTH. (U. S. D. A.). (*Jour. Forestry, 40 (1942), No. 10, pp. 767-771, figs. 3*).—A study of the growth of 25 formerly suppressed ponderosa pines, located in an area on the Fort Valley Experimental Forest (Ariz.) which was logged for the first time in 1909, showed a marked effect of the release upon diameter increment. The 25 trees which ranged from 5 to 12 in. d. b. h. in 1909 were, after 30 yr., between 12 and 20 in. d. b. h. The growth increases in percentage were nearly the same for each of the three decades following cutting. The rapid growth of old, small-crowned trees following release led

to the following deductions: Ground space and position in the crown canopy greatly influenced diameter growth; and, within the limits encountered, there is little relationship between age or crown size and diameter growth. Apparently, any subordinate tree, regardless of age, whose bole has the making of a high-grade butt log and whose crown shows no sign of physiological decline is worth releasing.

**The effect of openings in a young lodgepole pine forest on the storage and melting of snow.** C. H. NIEDERHOF and E. G. DUNFORD. (U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 10, pp. 802-804, figs. 4).—Snow storage and the rate of melting were influenced by the size of crown openings between trees. Because of high losses from crown interceptions, small openings provided less snow for storage. Where prolonged melting is desirable in addition to maximum winter accumulation, crown openings between 16 and 17 ft. in size appeared optimum in the stands under study. Cuttings which provide a maximum number of shaded, sheltered openings in young lodgepole pine stands should result in optimum conditions for snow storage and slow melting.

**Ice damage to slash pine, longleaf pine, and loblolly pine plantations in the Piedmont section of Georgia.** A. D. McKELLAR. (Univ. Ga.). (*Jour. Forestry*, 40 (1942), No. 10, pp. 794-797, fig. 1).—Observations in a plantation of longleaf, slash, and loblolly pines near Athens, Ga., following a severe ice storm in January 1940 showed significantly greater damage to longleaf and slash pine than to loblolly pine. The final net loss resulting from broken stems, uprooted trees, and badly bent trees that failed to recover was 24 percent for longleaf, 29 for slash, and 4 for loblolly pine. The probable cause of the greater injury to the first two species was their denser and more persistent foliage, which accumulated a greater ice load.

## DISEASES OF PLANTS

**The Plant Disease Reporter**, [November 1 and 15, 1942] (U. S. Dept. Agr., Bur. Plant Indus., *Plant Disease Rptr.*, 26 (1942), Nos. 20, pp. 421-439; 21, pp. 441-468, figs. 2).—In addition to the host-parasite check list revision, by F. Weiss (No. 20, *Thuja* to *Tsuga*, and 21, *Turnera* to *Ungnadia*), the following are included:

No. 20.—Soybean diseases in Iowa in 1942, by I. E. Melhus; tobacco diseases in Virginia in 1942, by S. B. Fenne; diseases of bright tobacco in Pittsylvania County, Va., during the 1942 season, by W. A. Jenkins; and brief notes on the bad potato late blight situation in the Upper Mississippi Valley, beet scab in New York fields, a canker disease of *Crotalaria spectabilis* in Texas associated with *Sclerotium* [*Rhizoctonia*] *bataticola*, and bitter pit in McIntosh.

No. 21.—Fruit and vegetable diseases on the Chicago market in 1940 and 1941, by G. B. Ramsey; a single-virus streak disease of greenhouse tomatoes in Illinois, by M. B. Linn and H. W. Anderson; a latent virosis on Lombard plum in New York, by E. M. Hildebrand; prevalence of *Helminthosporium* leaf spot of oats in Arkansas in 1942, by H. R. Rosen; corn leaf blight (mostly *Helminthosporium turcicum*) very severe in Virginia, by S. B. Fenne; and *Fusarium moniliforme* ear rot in sweet corn, by P. E. Hoppe.

**Bureau of plant pathology**, D. G. MILBRATH (*Calif. Dept. Agr. Bul.*, 30 (1941), No. 4, pp. 374-384).—The work of 1941 is briefly summarized relative to control of white root rot (*Dematophora necatrix*) on alfalfa, chestnut blight, virus-induced western celery blight, peach mosaic, Pierce's disease of grape, bacterial wilt and virus dwarf of alfalfa, potato virus diseases, meadow nematode (*Pratylenchus pratensis*) on citrus, and alfalfa stem nematode (*Ditylenchus dipsaci*).

[Studies in plant pathology by the Georgia Coastal Plain Station]. (Partly coop. U. S. D. A. and Univ. Ga.). (*Georgia Coastal Plain Sta. Bul.* 32 (1941), pp. 83-86, 111-113, 122-128, 133-134, 135, figs. 2).—Brief notes are given on the progress of studies in relation to seed treatments, sprays, spore dissemination, physiological factors, and transportation as they affect the spread and development of early blight (*Alternaria solani*) on tomato seedlings; bacterial wilt (*Phytophthora solanacearum*) and the shipping of tomato plants; tests of chemicals and hot water as nematocides, effect of root knot on plants, resistant peach trees, and root knot and cover crops in peach orchards; flue-cured tobacco diseases (downy mildew, root knot, damping-off (*Rhizoctonia* and *Pythium*), and various other diseases), including control of downy mildew by sprays, gas treatment, and culture practices and root knot control in plant beds and tobacco fields; and shade tobacco diseases, including downy mildew control, avoidance of root knot in plant beds and control by rotations and culture practices, chemical treatment of soil in tobacco fields for disease control, irrigation, dates of planting, and breeding for resistance to black shank and root knot.

[Phytopathological studies by the Ohio Station] (*Ohio Sta. Bul.* 617 (1940), pp. 16-18, 19-23, 78-79, fig. 1).—Reports of progress are included on control of cherry leaf spot by fixed coppers and bordeaux; bordeaux and fixed copper sprays or dusts in control of vegetable diseases, including *Alternaria* and *Septoria* leaf spots of tomato, early blight of celery, carrot diseases, bacterial wilt of cucumbers, and leaf spots of lima and snap beans; dependence of fungicide flow on density; varying of copper deposits from fungicides; control of *Cercospora* leaf blight of sugar beets; outbreak of infection by new form of tomato leaf mold fungus (*Cladosporium*); control of *Verticillium* wilt of chrysanthemum; aster rust control by wettable sulfur; insoluble coppers for *Septoria* leaf blight of pompons; hot-water treatment failing to eliminate root knot on peony; development of corn hybrids resistant to various fungus diseases; bacteriophage sign of bacterial wilt resistance in corn; and progress in white pine blister rust control (coop. U. S. D. A. et al.).

[Work on plant diseases by the Rhode Island Station] (*Rhode Island Sta. Rpt.* [1941], pp. 26-27, 41-47).—Reports are given on progress relative to control of turf diseases, including brown patch, dollar spot, snow mold, and pink patch; vegetable seed treatment recommendations based on local trials; a "pre-cleanup" control for tomato root knot in greenhouses and the effect of chloropicrin soil treatment and fungicides on fruit production; apple scab development in 1941 and the relative values of fungicides for its control; survey of the apple black rot situation in 1941; seed and soil treatments for seed rot and root rots of sweet pea, and control of powdery mildew by fungicides and resistant varieties; response of bleeding cankered maples to chemotherapy and fertilization; rose black spot and powdery mildew control in commercial plantings; and a new aster disease, silver blight, of unknown cause.

Check list of diseases of economic plants in Canada, I. H. CROWELL, E. LAVALLÉE, ET AL. ([Ottawa]: Dominion Dept. Agr., 1942, pp. [1]+68).—This is a compilation of data on diseases of economic plants accumulated over many years in the literature and in the notes and records of many Canadian plant pathologists. An introductory statement in English and French is presented, and for each disease the English and French common names and the Canadian distribution are given. The arrangement is by scientific names of host plants and pathogens, and bacterial, fungus, and virus diseases are included. English and French indexes to the common names of hosts are provided.

Fungicides in relation to the national defense program, H. W. ANDERSON. (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 168-173).

**Developments with fungous diseases and fungicides during the past seventy-five years**, H. C. YOUNG. (Ohio Expt. Sta.) (*Ohio State Hort. Soc. Proc.*, 75 (1942), pp. 125-135).—This is a brief review of progress in fruit disease control over a 75-yr. period, divided into three phases, viz, (1) the time before the discovery of fungicides, (2) that of the discovery of bordeaux and of other fungicides following in rapid succession, and (3) the modern period of rapid development in control measures and in detailed information concerning the parasites themselves.

**A toximetric study of some eradicant fungicides**, J. B. CARPENTER. (Wis. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 10, pp. 846-857, figs. 3).—The toxicities of four potential eradicant fungicides were studied in vitro by an agar-plate method described, six test fungi being used. Limited studies were made of the suppression by Elgetol of *Venturia inaequalis* ascospores in overwintered apple leaves. *Coccomyces hiemalis* was constantly one of the more susceptible test fungi, followed in order by either *V. inaequalis* or *Valsa cincta*. *Cladosporium carpophilum*, *Corpusculum beijerinckii*, and *Sclerotinia fructicola* proved more resistant. The relative susceptibility of the fungi varied with each toxic preparation. Each isolate of a fungus species reacted quite uniformly in a series of tests, differences among them not being noteworthy. Under the conditions imposed, Lignasan proved most toxic, followed in order by a phenyl mercury oleate preparation, Elgetol, and a toluene derivative preparation. These materials usually killed at relatively low concentrations. Except Elgetol, each had a toxic vapor at the concentration used, an advantage to be considered in interpreting relative toxicities. Specificity of toxic action was clearly shown only by the toluene derivative. *Venturia inaequalis* w. s killed within 3 hr. by Lignasan and within 24-48 hr. by Elgetol at the highest concentrations used. *C. beijerinckii* proved more resistant, and *S. fructicola* was the most resistant to both fungicides. Although Elgetol killed more slowly than Lignasan, the apparent difference in rate becomes less important if the relation between the minimum lethal dose and the concentration used for each fungus and fungicide is considered. Five-tenths percent Elgetol at 600 gal. per acre usually suppressed more than 99 percent of the ascospores of *V. inaequalis* in naturally overwintered apple leaves. Suppression was as complete 3 hr. after treatment as later. In these tests it was possible to limit drastically the ascospore discharge from perithecia containing ripe spores. The importance of the time required for adequate suppression of the ascosporic inoculum of certain fungi is discussed. The results obtained give additional evidence that Elgetol is capable of rapid and drastic suppression for *V. inaequalis*. There are 29 references.

**The composition and field performance of some silver sprays**, L. W. NIELSEN and C. E. WILLIAMSON. (Cornell Univ. and U. S. D. A.). (*Phytopathology*, 32 (1942), No. 11, pp. 1026-1030).—In a field experiment there was no significant difference between silver-lauryl sulfate and bordeaux mixtures in controlling late blight (*Septoria apii*) of celery. The three silver sprays tested (composition and preparation given) were not so efficient as bordeaux against late blight of potatoes. Both the silver-lauryl sulfate and silver-manganous sulfate mixtures were as good as bordeaux against tulip "fire" (*Botrytis tulipae*) in one season's test. None of the silver sprays left an objectionable residue on the foliage. Judging from the tulip experiments, these sprays may be considered more promising as fungicides for certain plants that are susceptible to copper injury.

**Chloropicrin as a disinfectant for plant beds**, R. W. LEUKEL. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 11, pp. 1034-1036, fig. 1).—Chloropicrin soil disinfection effectively prevented "milo disease" of Colby milo in greenhouse and outdoor beds infested with *Pythium arrhenomanes*.

**Fungicidal value of the salicylates, E. E. CLAYTON.** (U. S. D. A.). (*Science*, 96 (1942), No. 2494, p. 366).—In the past 10-yr. search for sprays effective against tobacco downy mildew, the most promising results have been obtained with salicylates. The best so far tested is bismuth subsalicylate, followed by benzyl salicylate. Other materials showing promise are butoxyethyl salicylate, dinitrosalicylic acid, and salicyl salicylic acid.

**The adherence of fixed copper fungicides as influenced by spray supplements, A. A. NIKITIN and E. G. ANDERSON** (*Phytopathology*, 32 (1942), No. 11, pp. 953-964, figs. 5).—In studies of the performance of protein-containing supplements from the standpoint of their effects on the adherence and activation of basic copper sulfate, laboratory and field tests with soy and wheat flours, albumin, skim milk, and calcium caseinate indicated that according to protein content they exert a dissolving action on the fungicide. The soluble Cu released is sorbed by the protein to form a gelatinous sorption complex, which increases the adhesiveness of the spray deposit. A certain correlation was found to exist between the dissolving action of the supplement on the fungicide and the subsequent liberation of soluble Cu from the sorption complex.

**A comment on Dr. Johnson's "Virus Nomenclature and Committees," F. O. HOLMES** (*Chron. Bot.*, 7 (1942), No. 5, pp. 201-202).—A critique of the paper previously noted (E. S. R., 87, p. 530).

**Recent evidence regarding the nature of viruses, T. E. RAWLINS.** (Univ. Calif.). (*Science*, 96 (1942), No. 2497, pp. 425-426, figs. 2).—From references to the literature and statistical studies showing that virus particles of a given rod-shaped virus (strains of tobacco mosaic) have various lengths and that the longer lengths do not appear to be multiples of the most characteristic length, it is believed that viruses are not molecules. Length-width proportions are compared with those of bacteria.

**The isolation and crystallization of plant viruses and other protein macro molecules by means of hydrophilic colloids, S. S. COHEN** (*Jour. Biol. Chem.*, 144 (1942), No. 2, pp. 353-362, pl. 1, fig. 1).—The author describes the applications of this reaction in (1) crystallizing tobacco mosaic virus and its strains, tomato bushy stunt virus, and a snail hemocyanin, (2) separating two plant viruses, and (3) rapidly isolating crystalline tobacco mosaic virus from infectious juice. The tomato virus assumed a new crystalline form in the presence of heparin. Precipitation of the tobacco and tomato viruses by heparin at pH 7 did not seem to involve chemical combination. The effect of electrolytes and the charge of three colloids of similar structure on the precipitation of the tobacco virus was examined, and other properties of the colloids are considered in relation to its precipitation. There are 27 references.

**An alignment chart for the computation of ultracentrifugation results, H. K. SCHACHMAN** (*Jour. Biol. Chem.*, 143 (1942), No. 2, pp. 395-402, figs. 2).—The chart constructed and here described proved accurate, convenient, and capable of effecting a considerable economy of time.

**The germination of fungous spores in relation to controlled humidity, C. N. CLAYTON.** (Univ. Wis.). (*Phytopathology*, 32 (1942), No. 11, pp. 921-943, figs. 8).—Using a method developed (and described) for accurately controlling high relative humidities for spore germination tests and with visible condensation precluded except to a limited degree at 100 percent, the following results were obtained: *Sclerotinia fructicola* conidia germinated well in redistilled water, but failed to germinate in 72-hr. tests on glass, paraffin, or quartz at relative humidities of 100 percent or below. It was demonstrated for the first time that ascospores and conidia of *Venturia inaequalis* could germinate on dry glass at 99-100 percent. The mean germination percentage of urediospores of *Puccinia coronata*, *P. graminis tritici* (race 56) and *P. graminis avenae* (race 2) on glass

was high in water, lower at a relative humidity of 100 percent, considerably lower at 99, and practically zero at 98. It was shown for the first time that chlamydospores of *Ustilago hordei* and *U. nuda* on dry glass or paraffin could germinate at 95-100 but not at 93 percent or below. Long basidial hyphae of *U. hordei* were produced at relative humidities of 100-95 percent, whereas sporidia were produced from basidia of spores germinating on water. *Erysiphe polygoni* conidia from red clover, cabbage, and evening primrose on dry glass germinated at 0-100 percent, but the germ tubes and survival time were very short at low relative humidities. There are 35 references.

**Studies in the genus *Colletotrichum*.—I, Saltation in *Colletotrichum capsici* (Syd.), T. S. RAMAKRISHNAN** (*Indian Acad. Sci. Proc.*, 13 (1941), No. 1, Sect. B, pp. 60-70, pl. 1).—A strain of *C. capsici* isolated from *Carthamus tinctorius* gave rise to six saltants, four of which, studied comparatively, exhibited differences in growth characters, size of acervuli, presence or absence of setae, sporulation, and pathogenicity. It is suggested that in creating new species of this genus pathogenicity alone should be given little prominence.

**A new station for *Orobancha ludoviciana*, A. T. GUARD and W. H. SILVER**. (Purdue Univ.). (*Ind. Acad. Sci. Proc.*, 51 (1941), pp. 116-117, fig. 1).—In addition to *Ambrosia trifida* and *Nicotiana tabacum* as hosts of this angiospermic parasite, the authors report its occurrence in Indiana on *A. elatior*, *Lycopersicon peruvianum*, and *Xanthium* sp., believed to be new hosts.

**Experiments toward the control of the take-all disease of wheat and the *Phymatotrichum* root rot of cotton, F. E. CLARK**. (*U. S. Dept. Agr., Tech. Bul.* 835 (1942), pp. 27, figs. 4).—In greenhouse experiments, organic materials giving excellent take-all (*Ophiobolus graminis*) control (e. g., chicken manure and alfalfa tops) markedly increased the nitrate-N and available-P content in soils, when applied at adequate rates. When partially composted and fresh or noncomposted manures were compared, only the latter appeared effective. When naturally infested soil in which wheat had been grown successfully under adequate fertilization was recropped to wheat under conditions favorable for *O. graminis*, failure of fertilization to eliminate the parasite was revealed but it was eradicated after maintenance for 3 mo. under moisture and temperature conditions favoring microbial activity and devoid of susceptible roots.

The activity of the saprophytic soil microflora appeared essential for destroying *P. omnivorum* sclerotia in artificially infested organic-amended soil. Under suitable incubation conditions, sclerotia were destroyed with either low- or high-N types of amendments. Increasing the organic material applied rendered nonviable greater percentages of sclerotia, and temperatures favoring general microbial activity were more destructive than low-temperature incubations. Attention was also given to the importance of favorable soil moisture and possibly also of aeration and soil reaction. Recovery of *P. omnivorum* was more difficult from parasitized roots that had been subjected to plant injury, and especially difficult from roots cut below the crown. From plants parasitized but not mechanically injured, *Penicillium* and *Trichoderma* spp., Dematiaceae, and sterile mycelium types were encountered with greater, and *Aspergillus* spp. and Mucorales with less relative frequency. Following infliction of mechanical injuries either above or below the crown, a similar shift in the fungus flora of nonparasitized roots and an accentuated shift in the flora of parasitized roots was evident.

Antibiotic effects are not necessarily the only contribution of organic amendments to soil sanitation. For take-all, antibiosis appeared of prime importance only in the absence of the host plant. For wheat-cropped soil, the fertility contributions of organic manures appeared responsible for observed reductions in take-all following manurial treatment. Evidence is considered sufficient that

a root-rotting parasite can be eliminated from soil devoid of susceptible roots. Activity of the saprophytic soil microflora appeared responsible for the marked destruction of *P. omnivorum* sclerotia in organic-amended soils, and competition for N did not appear to be the factor limiting its survival in manured soil. The development of agronomic procedures exploiting microbial antagonisms is believed to offer a practical line of attack against root-rotting parasites. There are 39 references.

**The take-all disease of cereals**, S. D. GARRETT (*Imp. Bur. Soil Sci. [Harpenden], Tech. Commun. 41 (1942), pp. [3]+40, pl. 1*).—This comprehensive outline of current knowledge (nearly three pages of references) on the disease due to *Ophiobolus graminis* considers early records, geographical distribution, economic importance, symptoms, and diagnosis of the disease; physiology, morphology, pathogenicity, and life cycle of the fungus; field observations and experiments on the prevalence of the disease and on its origin and dispersal; interpretation of some pot experiments; and a summary of control measures.

**The downy mildew disease of oats, caused by *Sclerospora macrospora***, L. E. MILES and J. M. EPPS. (Miss. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 10, pp. 868–879, figs. 2).—This is believed to be the first record of *S. macrospora* on oats in the United States, as well as the first record of the disease in Mississippi. The symptoms on oats are described and compared with those on wheat. Affected oats plants are characterized by stiff, curled, and fleshy leaves, the rachis is usually short and twisted with few spikelets (mostly sterile), and many diseased plants fail to produce heads and apparently die early in the season. Spores are produced in all plant parts except the roots but are much more abundant in the leaves and glumes. The average diameter of 335 oospores from oats collected in Mississippi (1939–40) was 55.6 $\mu$ . There are 30 references.

**Effective methods of inoculating seed barley with covered smut (*Ustilago hordei*)**, V. F. TAPKE and W. M. BEVER. (Idaho Expt. Sta. coop. U. S. D. A. and [N. Y.] Cornell Expt. Sta.). (*Phytopathology*, 32 (1942), No. 11, pp. 1015–1021, fig. 1).—The spore-suspension and vacuum methods of inoculating seed barley were devised and tested under field conditions in Idaho and New York, both proving far more effective than the well-known technique of inoculating seed by coating the surface with spores. By the two new methods (1) the seed is first treated for 1 hr. with formaldehyde solution, then washed in water and dried, which eliminates superficially foreign inoculum, loosens the hulls around the caryopsis, and materially increases the effectiveness of inoculation; (2) the seed is covered with spores in suspension, spores thus being carried beneath the hulls and coming to lie close to the point of attack; and (3) inoculated seed is then stored 16–20 hr. while still moist, thus promoting spore germination and spread of inoculum before the seed is dried and sown. The vacuum method has been slightly superior in smut production, but with large-scale inoculations, particularly in studies of physiologic races, the spore-suspension method appears to be easier and safer to apply.

**Brown necrosis and *Alternaria* blotch of wheat**, T. JOHNSON and W. A. F. HAGBORG (*Sci. Agr.*, 22 (1942), No. 12, pp. 746–760, fig. 1).—*Puccinia graminis tritici* and *A. tenuis* were proved capable of inducing melanistic discolorations on certain rust-resistant wheats derived from crosses with Hope and II-44. Stem rust induced on the outer glumes the “brown necrosis” described by McFadden (*E. S. R.*, 81, p. 659), resembling bacterial black chaff and with similar symptoms on lemma tips, rachides, peduncles, and on the internodes immediately below the nodes. Rust infection produced discoloration most readily in the first few days after heading. Penetration of entrance hyphae into the substomatal cavities was found, but no further development.

*A. tenuis* caused on the lemmas a grayish-brown discoloration resulting from

growth of the fungus within the florets. Mycelial growth commonly occurred on unextruded anthers but frequently also involved the ovary, in which case the floret was sterile and the whole lemma discolored. Lemma discoloration was apparently associated with floret sterility. Cultures isolated from diseased florets have failed to produce floret sterility in the greenhouse but in some of the field tests have caused a significant increase in sterility. In discolored lemmas there was abundant mycelial growth along their inner surfaces but very rarely any penetration. The discoloration is possibly due to excreted toxic substances from the fungus growth within the floret.

**Scab of wheat and barley and its control**, J. G. DICKSON. (Coop. Wis. Expt. Sta.). (U. S. Dept. Agr., *Farmers' Bul.* 1599, rev. (1942), pp. II+22, figs. 19).—Information on the disease and its cause, *Gibberella saubinetii*, including occurrence, losses, use of scabbed grain for feed, environal factors, and control, is given in this revision (E. S. R., 62, p. 236).

**Observations on antagonism in inoculation tests of wheat with *Helminthosporium sativum* P. K. & B., and *Fusarium culmorum* (W. G. Sm.) Sacc., R. J. LEDINGHAM** (*Sci. Agr.*, 22 (1942), No. 11, pp. 688-697).—In inoculation tests by the author and others, each of these root rot fungi used alone almost invariably caused a reduction in emergence and frequently in yield of wheat. On the other hand, in the tests here reported where the two pathogens were mixed, the injury as reflected in emergence and sometimes in yield as well was noticeably less, indicating antagonism. It was further shown that this antagonism was more marked where the oats-hull method of inoculation was used. In laboratory tests the germination of *H. sativum* conidia was reduced by the presence of *F. culmorum* conidia. There are 21 references.

**Varietal resistance of alfalfa and sweet clover to root- and crown-rotting fungi in Alberta**, M. W. CORMACK (*Sci. Agr.*, 22 (1942), No. 12, pp. 775-786).—On the basis of present information, including the results of this study, the pathogens of alfalfa and sweetclover attacking in early spring are, in their order of destructiveness, *Cylindrocarpum ehrenbergii*, *Sclerotinia sativa*, and *Fusarium avenaceum*. Similarly, those attacking growing plants of sweetclover are *Phytophthora cactorum*, *F. culmorum*, *F. avenaceum*, and *S. sativa*. Alfalfa was markedly more resistant than sweetclover to all these fungi, except the undetermined low-temperature basidiomycete from Alberta and Saskatchewan. Of the varieties tested for resistance to *C. ehrenbergii* and *S. sativa*, *Medicago falcata* stood highest, and Cossack and Viking ranked somewhat below it but probably only slightly above the other varieties, which included Grimm. Some resistance to the basidiomycete was probably indicated in the first three varieties, but present indications are that all sweetclover varieties are highly susceptible to it. Of the sweetclovers tested for resistance to *S. sativa*, varieties of *Medicago alba* were more susceptible than those of *M. officinalis*. Redfield Yellow (*M. suaveolens*) was only slightly less susceptible than varieties of *M. alba*. This variety and Arctic (*M. alba*) were the only ones appearing to possess some resistance to *C. ehrenbergii*, and inconclusive results were obtained with *F. avenaceum*. A strain of Alpha sweetclover (developed at Saskatoon) proved "quite resistant" to *P. cactorum*, the original Alpha variety was moderately susceptible, and Arctic and all other varieties tested were highly susceptible.

**Relative concentrations of two strains of curly-top virus in tissues of susceptible and resistant beans**, C. F. LACKEY. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 10, pp. 911-913).—The two virus strains 1 (virulent) and 4 (much less so) were used to infect the two bean varieties Great Northern U. I. 81 (resistant) and Bountiful (extremely susceptible). Nonviruliferous leafhoppers were fed on 5-percent sucrose solutions in which 20 root tips of each variety were macerated for each test. These vectors were then caged singly on

susceptible sugar beet seedlings or shoot tips. Virus strain 1 from the susceptible bean variety produced much more infection than when taken from the resistant variety. Strain 1 from the susceptible bean consistently produced a much higher percentage of infection than did the less virulent virus strain 4. Virus strain 1 in the resistant bean appeared to be promptly inactivated or its multiplication quickly inhibited. The reactions of virus strain 1 in the resistant and strain 4 in the susceptible bean are in direct contrast to their reaction in resistant and susceptible sugar beets.

**Fusarium yellows of beans, J. B. KENDRICK and W. C. SNYDER.** (Univ. Calif.). (*Phytopathology*, 32 (1942), No. 11, pp. 1010-1014).—A vascular *Fusarium* disease of field beans characterized by gradual yellowing of the leaves from the base upward, dwarfing, eventual dropping of the leaves, and final death of the plant is reported to have been present in the Sacramento Valley, Calif., since 1929. A form resembling the cowpea wilt organism (*F. oxysporum* f. *tracheiphilum*) in culture was consistently isolated from diseased tissues, but inoculations indicated it to be pathogenic only to varieties of common beans and not to lima beans, cowpeas, or soybeans. The causal agent of bean yellows is thus apparently an undescribed form of *Fusarium* and is designated as *F. oxysporum* f. *phascoli* n. f. The pathogen is often transmitted with the seed and can be controlled by seed treatment with Semesan or Ceresan.

**Effect of diseases upon survival of white clover, *Trifolium repens* L., in Alabama, H. R. ALBRECHT.** (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 8, pp. 725-730, figs. 3).—Studies of white clover diseases in pastures and strain tests at several Alabama locations suggested diseases as responsible for much of the failure of this crop during summer. Thus far, 10 diseases have been recognized, of which southern blight (*Sclerotium rolfsii*) has proved the most destructive to date. Leaf spots (*Stagonospora mcliloti* and *Cercospora* sp.) and root knot (*Heterodera marioni*) were also highly destructive to white clover in pastures. The tests indicated that some degree of resistance to most of the diseases occurs. Diseases became most destructive after mid-June, when the main seed crop had matured. In overgrazed or sparsely vegetated pastures, white clover was not generally severely attacked by disease. Only in pastures characterized by heavy growth were diseases found abundantly, the only exceptions being root knot and *Cercospora* leaf spot, which occurred usually in late summer. The observations suggested that disease prevalence may actually have resulted from good pasture management. Heavy growths of winter weeds became established on all plats at Auburn which had suffered extensive stand reductions due to diseases.

**Biological technique for the evaluation of fungicides.—II, The evaluation of seed disinfectants for the control of seed-borne diseases of flax, A. E. MUSKERT and J. COLHOUN** (*Ann. Bot. [London]*, n. ser., 6 (1942), No. 22, pp. 219-227).—In continuation,\* an account is given of field and laboratory methods devised for evaluating seed disinfectants for use against seed-borne flax diseases, *Polyspora lini* (stem break and browning) and *Colletotrichum lini* (seedling blight) being especially considered. The laboratory procedure, based on the Ulster method for examining seed samples for seed-borne parasites, can be completed within 7 days at any time of year. Statistical analysis of the results indicated a high correlation between the two tests. Thus the laboratory method may be regarded as reliable and accurate.

**Potash deficiency symptoms in Napiergrass, *Pennisetum purpureum*, G. W. BURTON and C. L. LEFEBVRE.** (U. S. D. A. and Ga. Coastal Plain and Ga. Expt. Stas.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 4, pp. 372-375, figs. 2).—A reasonably dependable index of K starvation in Napier grass consists in the

\* *Ann. Bot. [London]*, n. ser., 2 (1938), No. 7, pp. 699-715, pl. 1.

formation of irregular brown spotting and sometimes "firing" of the tips and margins of the leaves. Probably because of its tremendous leaf production, this grass has a high K requirement and must be supplied with rather large amounts if the loss of leaves from K deficiency is to be avoided. That this species is an unusually strong feeder for K is indicated by the severe K-deficiency symptoms developed by velvetbeans following it in rotation. Very leafy strains of Napier grass developed K-deficiency symptoms earlier and to a greater degree than the less leafy types.

**Nomina de las enfermedades y pestes de la papa cuya existencia se ha comprobado en el pais** [List of diseases and pests of the potato known to be present in Chile], F. MUJICA R. (*Bol. Sanid. Veg. [Chile]*, 1 (1941), No. 1, pp. 70-72).—Virus, bacterial, and fungus diseases and animal parasites (insects and nematodes) are included.

**La "alternariosis" de la patata** [Early blight of potato], L. RODRIGUEZ LZ (*Bol. Inst. Bot., Univ. Cent. Ecuador*, 1 (1942), No. 1, pp. 85-124, figs. 7).—This is a general account of early blight (*Alternaria solani*) of potato, with particular reference to the Sierra provinces of Ecuador. There are 26 references.

**Apical leaf speck of potatoes**, G. B. SANFORD (*Sci. Agr.*, 22 (1942), No. 12, pp. 772-774, fig. 1).—A malady apparently due to certain soil factors favoring faulty nutrition of the plant is briefly described and named "apical leaf speck." Numerous small black dots on the apical leaves, local necrotic areas in the pith of the upper half of the stem, and the absence of internal necrosis in the tubers or break-down during storage appear to distinguish it from internal rust spot and sprain.

**La "anguilulosis" de las papas** [Root knot of potato], L. RODRIGUEZ LZ (*Bol. Inst., Bot., Univ. Cent. Ecuador*, 1 (1942), No. 1, pp. 160-168, figs. 4).—A general account on *Heterodera radiculicola* on potato and its control.

**Potato scab gardens in the United States**, F. J. STEVENSON, L. A. SCHAAAL, C. F. CLARK, R. V. AKELEY, ET AL. (U. S. D. A. and Expt. Stas.). (*Phytopathology*, 32 (1942), No. 11, pp. 965-971).—The 22 potato varieties tested in 4 potato-scab gardens exhibited highly significant differences in reaction to *Actinomyces scabiei* for pustule-type and tuber-surface coverage. The pustule type and percentage of tuber surface covered with pustules were highly correlated, indicating that in the majority of cases the relative varietal reactions to infection could be estimated by either criteria. In general, the varietal reactions were quite constant over the 2 yr. and four places involved, with the highly resistant varieties showing less tendency to vary between years or among places than the slightly resistant or susceptible. Interactions between variety and place were significant and could be due to environal factors or physiological forms or to both. The highly significant interaction for pustule type between place and year indicated the influence of environment rather than of physiologic form. From the breeding standpoint it would appear possible to select varieties highly resistant to scab in Maine that would perform similarly elsewhere, but before generalized statements are made they should be tested under a wide range of environal conditions.

**Effect of environment on the prevalence of soil-borne Rhizoctonia**, O. H. ELMER. (Kans. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 11, pp. 972-977, fig. 1).—Wide differences were noted in the prevalence of soil-borne *Rhizoctonia* (*Corticium vagum*) in Kansas potato fields during the 13 yr. under study. It survived in the soil only in those years when there was enough summer rainfall to prevent desiccation and death of the fungus in its mycelial stage. Sclerotia were absent during the critical summer months, because their formation requires cooler weather than usually occurs in Kansas during July and August. The

organism can persist parasitically on infected host plants during summers when the soil is so dry that it cannot survive saprophytically.

**An unknown potato disease (possibly virus in nature)** (*N. J. State Potato Assoc., Hints to Potato Growers*, 23 (1942), No. 4, p. [4]).—Because of the urgency of determining the nature, destructiveness, and control of this new disease observed on the Sequoia, Houma, Sebago, Katahdin, Chippewa, and Cobbler varieties near Vincentown, N. J., the symptoms are summarized. Among them are a shortening of the internodes and reduction of the angle between petiole and stem, a mild thickening of the main stem of the plant, and premature activity of many normally dormant buds.

**Elworm disease of potatoes**, A. HOWARD (*Gard. Chron.*, 3. ser., 111 (1942), No. 2890, p. 207).

**Susceptibility of *Solanum* species to *Fusarium solani* var. *cumartii***, R. W. GOSS and J. H. JENSEN. (*Nebr. Expt. Sta.*). (*Phytopathology*, 32 (1942), No. 10, p. 914).—*Solanum* sp. from Chile, P. I. 129381, *S. acule*, *S. demissum*, *S. chacoense*, *S. commersonii*, and *S. antiporiczii* proved susceptible on soil inoculation.

**Pathology**, J. P. MARTIN (*Hawaii. Sugar Planters' Assoc. Ptd. Rpts.*, 61 (1941), *Expt. Sta. Com. Rpt.*, pp. 28–42).—This report presents a brief summary of work by the pathology department, including, besides routine matters, studies of “foreign” sugarcane diseases and of diseases present in Hawaii (brown stripe, chemical and mechanical injuries, chlorotic streak, lightning injury, eyespot, leaf scald, malgrowthis, pokkah boeng, root rots, and physiological disorders).

**Internal breakdown of sweet potatoes due to exposure to cold**, W. D. KIMBROUGH and M. F. BELL (*Louisiana Sta. Bul.* 354 (1942), pp. 9, figs. 2).—It is concluded from the experimental evidence presented that sweetpotatoes are injured by exposure to cold temperatures above the freezing point and that the effects may not become readily apparent for some time afterwards. Where the roots are severely injured very little latex or none will appear on the cut surface, which also has an abnormal appearance. A temperature of 40° F. for 1 week proved injurious, and the indications are that pinkiness appearing later in the storage season may be at least partly due to slight exposure to cold. Control of the minimum temperature in storage thus becomes highly important, and 50° should be the lower limit. During some winters in southern Louisiana little or no artificial heating may be necessary, but in others it becomes imperative if the roots are to be kept successfully.

**Control of blue mold of tobacco by a new spray**, P. J. ANDERSON. (*Conn. [New Haven] Expt. Sta.*). (*Science*, 96 (1942), No. 2496, p. 409).—Sensing a definite need for a simple, safe, inexpensive but effective spray or dust for control of *Peronospora tabacina* in the beds a long list of chemicals were tested, among which one, ferric dimethyl dithiocarbamate (trade name “Fermate”), appears to fill the requirements, as based on the experimental results during one winter in the greenhouse and one spring in the seedbeds. The most successful dosage was 1.5–2 gm. in 1 liter of water, with an equal amount of lime added. With 100 percent infection the rule among controls, 95–100 percent of the sprayed plants were disease-free. Before drawing final conclusions, however, it is believed this treatment should be repeated over several seasons and by practical growers in different sections.

**The molecular size and shape of the nucleic acid of tobacco mosaic virus**, S. S. COHEN and W. M. STANLEY (*Jour. Biol. Chem.*, 144 (1942), No. 3, pp. 589–598, fig. 1).—Data are presented on the electrophoresis, partial specific volume, diffusion, sedimentation, viscosity, electron microscopy, osmotic pressure, optical properties, and elementary composition of protein-free ribonucleic acid and its derivatives, isolated from heat-denatured tobacco mosaic virus. Freshly isolated nucleic acid had an average particle weight of 300,000 and was highly

asymmetric. It decomposed spontaneously to form asymmetric particles with a molecular weight of about 61,000. Both these molecules appeared to be too long to lie within the width of 150 a. u. of the virus molecule. These materials may be converted with cold alkali to particles with a molecular weight of 15,000 and an axial ratio of 10. Problems of virus structure and properties of ribose- and desoxyribosenucleic acid are discussed. There are 39 references.

**The fractionation of the amino acids of tobacco mosaic virus protein,** A. F. ROSS. (*Jour. Biol. Chem.*, 143 (1942), No. 3, pp. 685-693).—Of the amino acids previously reported in this virus protein, arginine, phenylalanine, tyrosine, and proline were isolated from its hydrolysates and, as expected, the amounts actually isolated were less than those previously found. In addition, the presence of at least 5.3 percent glutamic acid, 2.6 aspartic acid, 6.1 leucine, 3.9 valine, and 2.4 percent alanine was established by isolation procedures. This brings the known constituents of tobacco mosaic virus to about 68 percent of the total. There are 31 references.

**A comparison of the alkaline cleavage products of two strains of tobacco mosaic virus,** C. A. KNIGHT and M. A. LAUFFER (*Jour. Biol. Chem.*, 144 (1942), No. 2, pp. 411-417).—Nucleic acid was removed by alkali from common and ribgrass strains of tobacco mosaic virus, and the nucleic acid-free protein components were examined in the Tiselius electrophoresis apparatus, analytical ultracentrifuge, and electron microscope. Although it was shown that the protein components differ in amino acid composition, a mixture of the proteins at pH 7.1 and pH 10 migrated in an electrical field as though composed of a single component. From these results it is concluded that the electrophoretic technique cannot be depended on to distinguish between biologically related but chemically different proteins. Under certain conditions sedimentation constants were obtained, and thus estimates of the average size of the protein particles in several preparations could be made. The smallest and largest materials represented by different preparations corresponded to molecular weights of  $5 \times 10^4$  and  $7 \times 10^5$ . Electron micrographs of the proteins showed particles of many sizes, some corresponding to those calculated from sedimentation data.

**The concentration and purification of tobacco mosaic virus by means of the Sharples super-centrifuge,** W. M. STANLEY (*Jour. Amer. Chem. Soc.*, 64 (1942), No. 8, pp. 1804-1806).—This apparatus, equipped with a regular clarifier bowl operating at 50,000 r. p. m. by compressed air proved satisfactory. It was found advantageous to use a cooling coil, a celluloid and a filter paper liner in the bowl, and a modified delivery jet constructed from a small hypodermic needle. Using the clarified juice from mosaicked Turkish tobacco plants as starting material, it was possible to prepare 10-15 gm. of virus sufficiently pure for most purposes in 10 hours' time.

**The effect of mosaic virus infection on the protein content of susceptible and resistant strains of tobacco,** C. H. HILLS and H. H. MCKINNEY. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 10, pp. 858-867).—Virus infection caused a marked increase in the total-N content of susceptible tobacco (Wisconsin-Havana Seed) grown under conditions of low-, medium-, and high-N nutrition. Grown under a reduced-N supply, the resistant tobacco (T. I. 448A) showed a decrease in total N in the virus-infected plants, but when grown with a more adequate N supply no decrease in total-N content was found. Mosaicked leaves of the susceptible tobacco contained 30 percent less chlorophyll and had a lower chlorophyllase activity than healthy leaves, but there was no change in the chlorophyll or chlorophyllase of infected leaves of T. I. 448A. The oxidase activity of both resistant and susceptible strains was decreased by the virus, and, while the changes in enzyme activities caused by the infection were slightly

less in the resistant than in the susceptible variety, it is evident that a very small amount of virus nucleoprotein was sufficient to produce measurable alterations in the metabolism of the resistant tobacco. There are 17 references.

**The preparation and use of tobacco mosaic virus containing radioactive phosphorus.** W. M. STANLEY (*Jour. Gen. Physiol.*, 25 (1942), No. 6, pp. 881-890, pls. 2).—Normal and mosaic-ticked Turkish tobacco plants were grown in sand for several weeks while fed daily a complete nutrient solution plus disodium phosphate containing radioactive P. Determinations were made of the distribution of radioactive P in different fractions such as the wash from the sand and roots, the press cake obtained on pressing the juice from the plants, the protein and protein-free portions of the supernatant liquids obtained on ultracentrifugation of the juices, and the purified virus. Chemical analyses as well as radiographs of the normal and diseased leaves indicated them to contain the same amount of P. Approximately 30 percent of the radioactive P absorbed by the diseased plants was combined with the purified virus isolated therefrom. Following inoculation of purified virus of high radioactivity to normal plants, most of the radioactivity was associated with nonvirus components of which about 40 percent was in the inoculated and 60 percent in the uninoculated portions. Although a small amount of radioactive virus was isolated from the uninoculated portions of the plants, it was impossible, because of complicating factors (discussed), to draw from the results any reliable conclusions regarding the mode of reproduction of this virus.

**Control of the common mosaic disease of tobacco by breeding.** W. D. VALLEAU. (Ky. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 11, pp. 1022-1025).—Though it has been known for 15 yr. that common mosaic of tobacco can be controlled successfully if the hands of workers are freed of virus before weeding and pulling plants (E. S. R., 60, p. 54), growers have not always been successful in controlling hired help. The development of resistant varieties thus becomes especially to be desired. From his own experimental evidence, here briefly summarized, the author believes it safe to conclude that both the Ambalema (A) and the glutinosa (N) types of resistance, either singly or together, will prove satisfactory for practical control of tobacco mosaic if satisfactory commercial varieties containing these factors in a homozygous condition can be produced.

**Vegetable disease studies.** C. DORMAN (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 10, p. 6).—Brief progress reports are included with respect to the relation of soil fertility to wilt in tomatoes and the development of resistant varieties, early blight (*Alternaria*) susceptibility increased by wilt infection and its fungicidal control, cabbage seed treatment and seedbed fumigation against damping-off, and seed treatments of garden pea, spinach, and lettuce.

**The reaction of cantaloupe strains to powdery mildew.** D. E. PRYOR and T. W. WHITAKER. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 11, pp. 995-1004, fig. 1).—Cantaloup strains differing in resistance were inoculated in the greenhouse with *Erysiphe cichoracearum* (race 2) and the symptoms noted. Duplicate plantings of 18 cantaloup strains were made in the greenhouse and at three different dates in field plots, comprising selections from Hale Best (susceptible to mildew races 1 and 2), Powdery Mildew Resistant Cantaloupe No. 45 (resistant to race 1 but not to race 2), several strains believed tolerant to both races, and a strain highly resistant to both. In the greenhouse all strains (except the last) were very severely attacked. The majority of the tolerant strains were significantly better than No. 45 in the first field planting, several were superior in the second, and all lines except the highly resistant one were very badly diseased in the third. Data from individual-plant reactions in the greenhouse and from the same plants after setting in the field indicated the

greenhouse method to be much more reliable than field trials for selecting highly resistant plants, provided all macroscopic leaf and stem symptoms are taken into account.

**The influence of vitamin B<sub>1</sub> on the development of cantaloupe powdery mildew.** D. E. PRYOR. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 10, pp. 886-896, fig. 1).—When various concentrations of this vitamin were added to soil in which cantaloup varieties resistant and susceptible to race 2 of *Erysiphe cichoraccarum* were growing, the average number of fungus colonies on the susceptible variety was 1.3-1.5 times that of the control, and the amount of necrosis on the resistant one was 2.1-2.8 times that of the control. When healthy leaves of the susceptible variety were excised, inoculated, and maintained on a sucrose solution to which various amounts of thiamin were added, there was no significant effect on mildew development as compared with the control, but there was a tendency toward increased mycelial development with the lower thiamin concentrations. Thiamin solution applied to soil supporting mildew-free plants of the susceptible variety from which leaves were finally excised, inoculated, and maintained on a sucrose solution significantly increased mildew growth at 0.01 p. p. m., but higher concentrations were without significant effects. Various concentrations of thiamin added to soil had no significant effects on the green weight or height of cantaloup tops.

**Control of fungi in mushroom casing soil by sterilization with chloropicrin.** A. M. KLIGMAN (*Phytopathology*, 32 (1942), No. 11, pp. 978-985, fig. 1).—Chloropicrin (2 cc. to 1 cu. ft. of soil) was found to kill spores of *Mycogone perniciosa*, *Verticillium malthousei*, and *Dactylium dendroides*, and a method is described by which sufficient soil for a standard house (contained in a bin 9 by 11.5 by 3 ft.) can be sterilized with 3 cc. to 1 cu. ft. Direct field sterilization was accomplished by covering the treated area with canvas. The yield of chloropicrin-treated soil was comparable to formaldehyde- and steam-treated soils.

**The value of Spergon as a seed protectant for canning peas.** E. G. SHARVELLE, H. C. YOUNG, JR., and R. F. SHEMA. (Minn. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 11, pp. 944-952, figs. 4).—Seed treatment with Spergon in 1940 resulted in an average increase in stand of plants amounting to 23 percent, New Improved Ceresan in one case gave the same increase, while nitrogen inoculation gave an increase in stand of 10 percent over the untreated plot. The increases in total vine length obtained in 1941 were statistically insignificant; those in 1940 were not. Root development on plants from seeds treated with Spergon appeared to be stimulated materially, and the incidence of root rot was greatly reduced. Increased yields of 300-800 lb. of green shelled peas to the acre were obtained at three locations by treating seed with Spergon, the average increase amounting to 357 lb., or 18 percent, over controls in 1940. Pea root rots were present in epidemic proportions in the locations involved during both years. Results obtained in 1941 substantiated the findings of 1910.

**Fusarium wilt of radish.** J. B. KENDRICK and W. C. SNYDER. (Univ. Calif.). (*Phytopathology*, 32 (1942), No. 11, pp. 1031-1033).—A vascular *Fusarium* wilt of White Chinese Winter radish (*Raphanus sativus longipinnatus*) characterized by symptoms resembling those of cabbage yellows due to *F. oëysporum* f. *conglutinans* occurred in a seed field in California (1934). The fungus was shown to be pathogenic also to common radishes, but to be distinct from the cabbage yellows *Fusarium*. It is here described as *F. oëysporum* f. *raphani* n. f.

**Control of bacterial canker of tomatoes.** H. L. BROWD. (U. S. D. A. and Utah Expt. Sta.). (*Canning Age*, 23 (1942), No. 4, pp. 221-223, figs. 2).—A general summary on the disease due to *Phytomonas michiganensis* and its control.

**Collar rot resistance in tomatoes.** C. F. ANDREWS, G. B. REYNARD, H. JORGEN-

SEN, and J. EADES. (U. S. D. A.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 7, pp. 339-346, figs. 2).—Using a method (described) of dipping foliage of 4-week-old tomato seedlings in a water suspension of macerated *Alternaria solani* culture at the time of transplanting, 100 percent collar rot was produced on the most susceptible varieties and 100 percent freedom from it on the most resistant. In this way a large number of standard varieties and clonal selections were rated according to collar rot reactions, complete resistance apparently occurring in 23 varieties and accessions. This resistance is correlated with lesser degrees of susceptibility to *Alternaria* leaf spot. The method of determining collar rot resistance should facilitate the breeding of tomatoes resistant to defoliation.

**A new strain of the tomato leaf mold fungus (*Cladosporium fulvum*)**, L. J. ALEXANDER. (Ohio Expt. Sta.). (*Phytopathology*, 32 (1942), No. 10, pp. 902-905, fig. 1).—Leaf-mold lesions were observed on the second crop after introduction of the resistant tomato variety Globelle, and observations indicated the presence of a new strain of the fungus. In cross-inoculation tests, Globe and three other standard varieties were used as susceptible, and the resistant parent *Lycopersicon pimpinellifolium* and the three resistant varieties (Globelle, Bay State, and Veto-mold) developed from it as resistant varieties. All plants of the standard varieties proved susceptible alike to both strains of the fungus. All plants of the resistant varieties were highly resistant or immune to the Globe strain of the fungus, but were all susceptible to the Globelle strain. Observational evidence indicated Globelle to be less susceptible than standard varieties such as Globe. *C. fulvum* is not limited in its parasitism to the one host species *L. esculentum*.

**A strain of tobacco-mosaic virus causing a necrosis and shriveling of tomato foliage**, S. P. DOOLITTLE and F. S. BEECHER. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 11, pp. 986-994, figs. 2).—Greenhouse tomatoes in the vicinity of Washington, D. C., at times have been affected by a virus causing reddish-brown leaflet necrosis followed by gradual shriveling of the older foliage, but without symptoms on stems or fruit. As far as determined, its physical properties and host range are the same as those of ordinary tobacco mosaic, and the symptoms are the same on tobacco and on nearly all other hosts tested. Serological tests also indicated a relationship. On *Nicotiana glauca*, where the tomato virus produces lesions like those of aucuba mosaic, previous infection by tobacco mosaic virus protects against infection by the virus from tomato. Since all comparative evidence indicates that the virus causing leaf-shriveling of tomato is a strain of the tobacco mosaic virus, it has been classified as *Marmor tabaci siccans* n. var. Seed transmission has occurred in tomato seedlings grown from freshly extracted seed of infected fruits, but no such transmission has been noted from seed dried for more than 10 days. The virus has appeared sporadically in the greenhouse for several years, but the sources of primary infection remain in doubt.

**Apple blotch**, F. M. ROLFS (*Oklahoma Sta. Bul.* 261 (1942), pp. 15, figs. 4).—Pertinent data are presented on the history, host plants, symptoms, cause (*Phyllosticta solitaria*), dissemination, and control. There are 13 references.

**Eradicant sprays for apple blotch**, H. W. ANDERSON and D. POWELL. (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 391-400).—On the basis of the one season's experiments (1941) reported, it is believed that blotch control cannot be expected by use of an eradicant spray, such as Elgetol, without supplementary summer sprays. Since the efficiency of Elgetol depends on the advanced stage of pycnidial development, it is necessary to time the application just previous to the opening of the buds. From a practical standpoint, it is believed doubtful if expensive eradicant sprays would pay unless they served other purposes. For

example, Elgetol is effective in killing aphid eggs and an application at this stage would effectively clean up that pest.

**Studies of crown rot of apple trees**, M. F. WELSH (*Canad. Jour. Res.*, 20 (1942), No. 9, Sect. C, pp. 457-490, pls. 3, fig. 1).—The form of crown rot occurring in irrigated orchards of British Columbia is confined to the below-ground bark tissues and has been encountered in trees of all ages and of all commercial varieties grown there. Definite proof of the causal relation of *Phytophthora cactorum* is presented. Isolation has been possible only from the margins of active lesions, and there is evidence that the fungus is inhibited in rotted tissues by the antagonistic effects of one or more secondary organisms. The effects of soil moisture and temperature on the disease seem to be interrelated, with the highest incidence in an almost saturated soil and at the highest temperature (32° C.) imposed. The influence of soil moisture is exerted particularly in the subsoil rather than in the locus of attack. Certain apple varieties were found to differ in resistance. Deep wounds have proved necessary for bark invasion.

**Moldy core of apples in Wisconsin**, J. B. CARPENTER. (Univ. Wis.). (*Phytopathology*, 32 (1942), No. 10, pp. 897-901, fig. 1).—The symptoms in the Dudley and Delicious varieties are given for this disorder, which is of minor economic importance but occurs in a high proportion of the fruit of these varieties in Wisconsin. Size of fruit seemed to have no influence on the incidence of the trouble, but undesirable morphological fruit characters in these two varieties predispose them to infection. A fungus of the *Alternaria tenuis* group predominated, but species of other genera were found either alone or associated with it. Inasmuch as several fungus species were found growing in the calyx basin on dead floral remnants, it seems that *Alternaria* sp. may be peculiarly adapted for entering the core and establishing itself.

**Some factors influencing the epidemiology of apple scab**, D. POWELL and H. W. ANDERSON. (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 278-288, figs. 2).—From the observations reported, including the influence of climatic conditions and the effect of insecticides on primary inoculum, it appears probable that a spore may be carried many miles, by chance lodge on the correct host, and, with moisture relationships conducive to development, cause infection. However, the greater number of spores were found to infect within the immediate vicinity of the point of discharge.

**The use of eradicant sprays for the control of apple scab in Illinois, 1941 results**, D. POWELL and H. W. ANDERSON. (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 195-212, figs. 3).

**Developments in peach virus disease investigations**, H. H. THORNBERRY. (Univ. Ill.). (*Ill. State Hort. Soc. Trans.*, 75 (1941), pp. 326-343, figs. 9).—"The purpose of this paper is to bring to attention recent developments in research and control measures pertaining to peach viruses and to report the work in progress in Illinois."

**A progress report on western X-disease, a virus disease of peaches**, E. L. REEVES and L. M. HUTCHINS. (U. S. D. A.). (*Wash. State Hort. Assoc. Proc.*, 37 (1941), pp. 27-30).

**Russet and protuberances on prune fruit in 1941**, E. E. WILSON. (Univ. Calif.). (*Calif. Dept. Agr. Bul.*, 30 (1941), No. 3, pp. 282-285, figs. 2).

**La antracnosis de la vid** [Grape anthracnose], S. J. TARTAKOWSKY H. and S. T. ARENTSEN S. (*Bol. Sanid. Veg. [Chile]*, 1 (1941), No. 1, pp. 7-18).—The authors discuss the geographical distribution of the disease due to *Elsinoe ampelina*, the conditions favoring its development, estimated damage caused in different parts of Chile, and methods of control.

**Antracnosis de la vid en Chile** [Grape anthracnose in Chile], A. E. JENKINS and A. A. BITANCOURT. (U. S. D. A. et al.). (*Bol. Sanid. Veg. [Chile]*,

1 (1941), No. 1, pp. 19-53, figs. 3).—The authors present a detailed discussion of the history of grape anthracnose in Chile beginning with the early study of the disease in 1874 and its definite diagnosis in 1876, including the original description of the disease and its cause by R. F. Lefevre, together with other pertinent landmarks in its early history and the taxonomy of the causal fungus *Elstonia ampelina*. There are 46 references.

**La lepra explosiva del naranjo [Orange leprosis]**, M. J. FREZZI (8. Amer. Sci. Cong., Washington, 1940, Proc., vol. 5, pp. 239-241).—It is concluded from evidence presented that this disease is due to a virus transmitted by mites (acaros).

**Yeasts occurring on dates**, E. M. MEAK, H. J. PHAFF, and R. H. VAUGHN. (Univ. Calif.). (Jour. Bact., 43 (1942), No. 6, pp. 689-700).—From California and Egyptian dates undergoing microbiological deterioration 67 yeast cultures were isolated, most of them being referable to *Zygosaccharomyces*, *Hanseniaspora*, or *Candida*. Other perfect genera obtained were *Saccharomyces*, *Pichia*, and *Hansenula*. In the genus *Torulopsis* (three cultures), *T. dactylifera* n. sp. is described. Detailed identities are presented, and the sugar tolerance of all yeasts isolated is compared. All cultures of *Zygosaccharomyces* were more sugar-tolerant than the other yeasts isolated. There are 28 references.

**Structural and chemical factors in relation to fungus spoilage of dates**, F. M. TURRELL, W. B. SINCLAIR, and D. E. BLISS. (Calif. Citrus Expt. Sta.). (Date Growers' Inst. Rpt., 17 (1940), pp. 5-11, figs. 8).

**Chrysanthemum diseases curbed by propagating practices**, P. P. PIRONE (New Jersey Stat. Nursery Disease Notes, 15 (1942), No. 4, pp. 13-16).—Notes on control of the foliar nematode (*Aphelenchoides ritzema-bos*) and *Verticillium* wilt by propagating practices.

**The reaction of thirteen California species of Delphinium to powdery mildew**, G. A. L. MEHLQUIST. (Univ. Calif.). (Amer. Soc. Hort. Sci. Proc., 39 (1941), pp. 411-415).—Resistance to *Erysiphe polygoni* was found to range from very high in *D. scopulorum glaucum* to extreme susceptibility in *D. uliginosum*. Relatively high resistance was found in *D. cardinale*—a fortunate circumstance since this species possesses several horticulturally desirable characteristics and may thus prove valuable in the development of varieties particularly adapted to the Southwest. From F<sub>1</sub> hybrids already obtained between *D. cardinale* and susceptible species, it was deemed evident that susceptibility to this disease is a dominant character.

**Control of powdery mildew of roses in the greenhouse**, W. D. McCLELLAN ([New York] Cornell Sta. Bul. 785 (1942), pp. 39, figs. 5).—Determining the toxicity of 50 fungicides to conidia of *Sphaerotheca pannosa rosae* on excised rose leaves by spore-germination tests, the marked superiority of sulfur-containing over copper-containing materials was clearly demonstrated. Of 14 coppers, only ammoniacal copper carbonate, Palustrex Sulfonate-B, and Eau Céleste reduced spore germination 75 percent or more, whereas of the sulfurs a similar reduction occurred in all but one test. Of 20 miscellaneous materials, Hellone Green, Hellone Yellow, malachite green, and Shirilan D reduced germination 75 percent or more. A method devised for comparing the toxicity of fungicides to conidia on rose leaves involves the germination of spores from the same population on different portions of the same excised leaf. Testing 10 materials, including a particulate S, soluble and insoluble coppers, and Ag, on conidia on rose leaves, when the conidia were not wet by the fungicide only S reduced spore germination appreciably, but when wet for a short time the soluble coppers as well as S markedly reduced germination. In commercial greenhouses, S dust proved ineffective, but good control was obtained with the 5 wettable sulfurs and the 1 Cu material tested when they were used in a protective-spray program

in combination with IN 438 at a concentration of 1:1,000, but marked differences between these and other materials occurred when used as eradicant sprays.

Data are presented to show that surface tension and contact-angle measurements, when used as criteria of wetting agents, do not always rate wetting agents in the same order. Using a method described, the contact angles of 40 liquid materials on rose leaves were compared, and the age, surface, and variety of rose leaf used were all found to affect contact-angle measurements. When rose leaves first unfolded they were not especially difficult to wet, but became increasingly so up to the sixth day, after which they gradually became easier to wet. Marked differences in toxicity were found when 15 spray supplements were compared, IN 181 being most toxic. When compared in combination with the same particulate S in each test in an eradicant-spray program under commercial-greenhouse conditions, striking differences in mildew control occurred. In a preliminary study of S vaporization for controlling mildew, it was found that although not enough S was deposited on rose leaves to inhibit germination, only 6.8 percent of the lesions remained active after a 3-day exposure to S vaporized at 112°-115° C., whereas 77.4 percent of the lesions remained active after a similar 3-day exposure to S vaporized at 85°. Data from a commercial greenhouse test showed that a considerable reduction in mildew can be obtained by syringing. The results of the whole investigation are presented in detail. An appendix indicates the sources and composition of materials used in this study. There are 40 references.

**Defoliation of American holly cuttings by *Rhizoctonia*, J. S. COOLEY.** (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 10, pp. 906-910, figs. 2).—The leaf drop of American holly (*Ilex opaca*) cuttings described was found due to *R. solani*. A restricted temperature range of the fungus in culture was indicated, with the optimum at 25°-30° C. Prior treatment of contaminated cutting beds with disinfectants failed to give satisfactory control, but thorough sanitary measures were effective.

**Plant pathology in relation to northeastern forest wildlife cover, J. PEARCE and P. SPAULDING.** (Univ. Maine and U. S. D. A.). (*Jour. Wildlife Mangt.*, 6 (1942), No. 3, pp. 194-202, pl. 1).—This contribution points out the significance of some common diseases of northeastern trees and shrubs used in wildlife management, and the important diseases of these plants that are of interest from this standpoint are tabulated and discussed. Mention is also made of the benefits to birds and other animals from forest fungi and insects.

**Crown gall on species of Taxaceae, Taxodiaceae, and Pinaceae, as determined by artificial inoculations, C. O. SMITH.** (Calif. Citrus Expt. Sta.). (*Phytopathology*, 32 (1942), No. 11, pp. 1005-1009, figs. 3).—From inoculations with *Phytoplasma tumefaciens* on 21 different conifers, galls developed on (Taxaceae) *Podocarpus elongata*, *Taxus baccata erecta*, *T. brevifolia*, *T. media*, and *Torreya californica*; (Taxodiaceae) *Cunninghamia lanceolata*, *Sequoia gigantea*, *S. sempervirens*, and *Sciadopitys verticillata*; and (Pinaceae) *Abies cephalonica*, *A. concolor*, *A. firma*, and *A. holophylla*.

**Recent advances in our knowledge concerning the oak mildew disease, P. A. MILLER.** (Calif. Expt. Sta.). (7. *West. Shade Tree Conf.*, Los Angeles, Calif., 1940, *Proc. Ann. Mtg.*, pp. 64-70, figs. 3).—On powdery mildew of the coast live oak (*Quercus agrifolia*) and its control.

**An undescribed *Atropellis* on cankered *Pinus virginiana*, M. L. LOHMAN, E. K. CASII, and R. W. DAVIDSON.** (U. S. D. A.). (*Jour. Wash. Acad. Sci.*, 32 (1942), No. 10, pp. 296-298, fig. 1).—The fungus is described as *A. apiculata* n. sp.

**Muerte del tamarisco, ocasionada por "Botryosphaeria tamaricis," en Corrientes, Argentina [Tamarisk canker due to *B. tamaricis* in Corrientes,**

Argentina], M. J. FREZZI (*Rev. Argentina Agron.*, 9 (1942), No. 2, pp. 110-113, pls. 2, figs. 2).—This study concerns a canker of *Tamarix gallica* due to a fungus provisionally identified as *B. tamaricis*, which is described, along with its behavior in culture and on the host tree.

Three new *Cuscutas* from western North America, T. G. YUNCKER (*Bul. Torrey Bot. Club*, 69 (1942), No. 7, pp. 541-543, figs. 2).—Two new species and one new variety of these phanerogamic parasites are described.

A comparison of *Diplodia natalensis* from stained wood and other sources, A. F. VERRALL (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 10, pp. 880-885).—Considerable variation was found among the isolates used in rate of growth at 37° C., spore size, and general cultural appearance, but in no cultural characteristic studied did the isolates from stained lumber or logs differ materially from those from other sources. All of 13 isolates tested on pine and sweet gum sapwood were vigorous stainers, the 14 tested on citrus fruit caused rapid decay, and all 11 isolates tested on cotton caused black boll rot. None of the 10 isolates inoculated into small tung trees was sufficiently pathogenic to cause more than small temporary cankers. It thus seems that the *D. natalensis* causing stain in lumber and logs is, at least from a practical point of view, the same fungus as the strains secured from several other plants. Little fruiting of *D. natalensis* was observed on stained logs and lumber from which it was isolated. Because of the similarities among isolates of this fungus from stained wood and other sources, it seems probable that some of the inoculum inducing wood stain in logs and lumber is derived from spores produced on such plants as cotton.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

Late fall and winter food of foxes in central Massachusetts, A. E. MACGREGOR (*Jour. Wildlife Mangt.*, 6 (1942), No. 3, pp. 221-224).—A study of the contents of 70 stomachs and 164 droppings of foxes collected in and around the Harvard Forest, Petersham, during the fall and winter of 1937 and 1938, here reported upon, indicates that they were not of great importance in that locality as predators of game birds. They drain heavily on the cottontail rabbit population, but this is balanced by the number of field mice they destroy.

Fluctuations in numbers of the muskrat (*Ondatra zibethica*) in Canada, C. ELTON and M. NICHOLSON (*Jour. Anim. Ecol.*, 11 (1942), No. 1, pp. 96-126, figs. 21).—This contribution is presented with a list of 27 references to the literature.

Parasitological survey of Louisiana muskrats, G. H. PENN, JR. (*Jour. Parasitol.*, 28 (1942), No. 4, pp. 348-349).

Home range of the cottontail rabbit, A. O. HAUGEN (*Ecology*, 23 (1942), No. 3, pp. 354-367, figs. 6).

Body weight and sex ratio of cottontail rabbits, W. H. EIDER and L. K. SOWLS. (Univ. Wis.). (*Jour. Wildlife Mangt.*, 6 (1942), No. 3, pp. 203-207, fig. 1).

The habitat distribution of the grey squirrel (*Sciurus carolinensis*) in Savernake Forest, M. K. COLQUHOUN (*Jour. Anim. Ecol.*, 11 (1942), No. 1, pp. 127-130).

The winter food habits of the short-tailed weasel [*Mustela cicognanii*] in northern Minnesota, S. E. ALDOUS and J. MANWEILER (*Jour. Mammal.*, 23 (1942), No. 3, pp. 250-255).

Studies of waterfowl in British Columbia: Buffle-head, J. A. MUNRO (*Canad. Jour. Res.*, 20 (1942), No. 6, Sect. D, pp. 133-160, pls. 2).—Record is made of the distribution, numerical status, and seasonal movements of *Charitonetta albcola* in British Columbia, where it is a common summer visitant of the interior, as

well as its plumage sequence, behavior, and food as determined through the study of stomach contents. Aquatic insects formed the principal food in the summer and autumn diet in much of the area surveyed.

**Protein requirements of bobwhite quail chicks for survival, growth, and efficiency of feed utilization**, R. B. NESTLER, W. W. BAILEY, and H. E. MCCLURE. (U. S. D. A. et al.). (*Jour. Wildlife Mgmt.*, 6 (1942), No. 3, pp. 185-193, pl. 1, figs. 5).

**Ecological and mortality factors affecting the nesting of the Chinese pheasant [*Phasianus colchicus torquatus*] in the Willamette Valley, Oregon**, C. R. EKLUND. (Oreg. Expt. Sta. et al.). (*Jour. Wildlife Mgmt.*, 6 (1942), No. 3, pp. 225-230).

**Food habit trends of the wild turkey in Missouri as determined by dropping analysis**, P. D. DAIKE, W. K. CLARK, JR., and L. J. KORSCHGEN. (Univ. Mo. et al.). (*Jour. Wildlife Mgmt.*, 6 (1942), No. 3, pp. 237-243, figs. 3).—Report is made of a study of the food habits of the wild turkey, based upon data obtained from the examination of 3,244 droppings collected at random from wildlife refuges in the Ozark Mountains from September 1938 to October 1940. Trends in the seasonal food habits are shown to correspond with availability of the different classes of food. Plant foods comprised approximately 75 percent of the annual subsistence, grass seeds and blades and acorns being most important. Insect foods made up the remaining 25 percent of the diet, beetles, grasshoppers, and ants comprising nearly four-fifths of all the animals eaten.

**Earthworms of the northeastern United States: A key, with distribution records**, T. H. EATON, JR. (Cornell Univ.). (*Jour. Wash. Acad. Sci.*, 32 (1942), No. 8, pp. 242-249, fig. 1).—This contribution includes a key to the earthworms of the northeastern United States, distribution records, and a list of 32 references to the literature.

**A modification of zinc sulfate centrifugal flotation method for recovery of helminth ova in formalinized feces**, W. A. SUMMERS (*Jour. Parasitol.*, 28 (1942), No. 4, pp. 345-346).

**Applied entomology: An introductory textbook of insects in their relations to man**, H. T. FERNALD and J. H. SHEPARD (*New York and London: McGraw-Hill Book Co.*, 1942, 4. ed., [rev.], pp. IX+400, figs. 383).—A revised edition of this work (E. S. R., 73, p. 641).

**A device for marking fields on microscope slides**, C. OLSON, JR. (Mass. Expt. Sta.). (*Jour. Lab. and Clin. Med.*, 27 (1942), No. 7, pp. 939-940, fig. 1).

**The use of the square root transformation and analysis of variance with contagious distributions**, W. M. UPHOLR. (S. C. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 536-543, figs. 2).

[Notes on economic insects and their control] (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 507, 593-608, figs. 8).—Contributions presented (E. S. R., 88, p. 72) are: Mexican Fruitfly Found in Illinois, by C. L. Metcalf (p. 507) (Univ. Ill.); Notes on the Biology of *Microbracon hebetor* [Say], by A. W. Morrill, Jr. (pp. 593-594), Effect of Insecticidal Drift in Small Plots Upon Boll Weevil and Cotton Aphid (pp. 594-595) and Notes on the Control of Cotton Aphids (pp. 598-599), both by G. L. Smith, A. L. Scales, and J. A. Fontenot, Notes on the Effect of Arsenicals Upon the Cotton Aphid, Predators, and Other Insects, by G. L. Smith and J. A. Fontenot (p. 596), Methods of Rearing the Pink Bollworm Parasites *Chelonus* and *Microbracon*, by L. W. Noble and W. T. Hunt (p. 597), Laboratory Tests on the Toxicity of Insecticides to the Strawberry Weevil, by H. N. Pollard and W. A. Thomas (pp. 599-600), Effect of Sterile and Unsterile Foods on Rate of Development of Wireworms, by M. W. Stone (pp. 600-601), An Insect Rearing Box With Electric Barriers, by M. C. Swingle and A. M. Phillips (pp. 603-604), and Life-History of the Corn Sap Beetle in Rice, by A. I. Balzer (pp.

606-607) (all U. S. D. A.); An Amphipod Household Pest *us sylvaticus* [Haswell] in California, by A. Mallis (p. 595), Ambrosia *tracking De-*

Entomological progress, III, assembled by C. O. EDDY. (Partly coop. U. S. D. A.). (*Louisiana Sta. Bul.* 350 (1942), pp. 52).—This third group of papers (E. S. R., 84, p. 357) presents results of station work on insect pest control in the State as follows: Cotton Flea Hopper Control in Louisiana, 1940, by I. J. Becnel (pp. 3-9); Cryolite as an Insecticide, II (pp. 9-11) (E. S. R., 84, p. 357). A New Practice for Red Spider Control on Strawberries (pp. 39-40), Peach Insects (pp. 45-47), The Sand Wireworm (p. 51), and Potato Tuber Injury (p. 52), all by C. O. Eddy; Notes on the Biology and Seasonal History of the Sweet Potato Weevil in Louisiana, by E. H. Floyd (pp. 12-16); Notes on the Biology and Control of the Velvetbean Caterpillar (*Anticarsia gemmatilis* Hbn.), by L. O. Ellisor (pp. 17-23); Insecticidal Tests Against Cabbage Caterpillars, by C. E. Smith and R. W. Brubaker (pp. 23-31); Losses Caused by Sugarcane Borer to Sugarcane in Louisiana in 1940, by A. L. Dugas and J. W. Ingram (pp. 32-34); A Summary of Recent Investigations of Sugarcane Borer Control With Cryolite and Other Insecticides, by J. W. Ingram and A. L. Dugas (pp. 34-39); Toxicity of Poison Baits to the Sweet Potato Weevil *Cylas formicarius* Fab., by E. H. Floyd and L. D. Newsom (pp. 40-45); and Notes on the Reaction of the Sweet Potato Weevil Under Different Qualities of Light (pp. 47-50).

[Entomological investigations by the Ohio Station] (*Ohio Sta. Bul.* 617 (1940), pp. 25-33, 69, figs. 5).—A progress report (E. S. R., 83, p. 518) noting new materials that control peach tree borer safely, new sprays for apple aphids, development of potatoes resistant to leafhoppers, wireworm investigations, insect control in relation to squash yields, iris borer killed by insecticide, tomato fruitworm and corn borer investigations, the two-queen hive system superior, and influence of sunflowers on wireworm populations.

[Insect investigations by the Rhode Island Station] (*Rhode Island Sta. Rpt.* [1941], p. 27).—A progress report (E. S. R., 85, p. 787) noting attack of cutworms and webworms and means for their control.

Distribution and origin of some eastern oceanic insects, E. C. ZIMMERMAN. (Univ. Hawaii et al.). (*Amer. Nat.*, 76 (1942), No. 764, pp. 280-307, figs. 10).

Insect problems resulting from changes in agriculture in Arkansas, D. ISELY. (Univ. Ark.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 473-477).

Cotton insect investigations. (Coop. U. S. D. A.). (*Georgia Coastal Plain Sta. Bul.* 32 (1941), pp. 70-72).—Progress is again noted (E. S. R., 86, p. 216) on the control of boll weevil, bollworms, and aphids on upland and sea-island cotton.

Calcium arsenate with and without aphicides for control of boll weevil and cotton aphid, M. T. YOUNG, G. I. GARRISON, and R. C. GAINES. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 490-492).—It was found in experiments with the boll weevil and cotton aphid near Tallulah, La., in 1941 that "calcium arsenate, zinc-safened calcium arsenate, mixtures of calcium arsenate contain-

ing 0.5 percent of rotenone, and mixtures of calcium arsenate containing 0.5, 1, and 2 percent of nicotine were equally effective against the boll weevil, and each was followed by significant boll weevil control over the checks. Zinc-safened calcium arsenate did not prevent the aphid infestation from increasing to injurious numbers. The calcium arsenate and rotenone mixtures made from derris, cube, or timbo were equally effective against the cotton aphid and gave highly significant decreases in aphid infestation and increases in yield when compared with calcium arsenate alone. A mixture of calcium arsenate and 0.5 percent of nicotine applied in the late afternoon gave better aphid control and a greater yield than either a similar mixture or a mixture of calcium arsenate and rotenone applied in the early morning. Mixtures of calcium arsenate and nicotine gave better aphid control and a greater yield than a mixture of calcium arsenate and rotenone. Dust made with nicotine sulfate was more effective in controlling aphids than that made with free nicotine. Alternate applications of calcium arsenate and a mixture of calcium arsenate and 2 percent of nicotine were much more effective in controlling aphids and gave greater yields than alternate applications of calcium arsenate and a mixture of calcium arsenate and 1 percent of nicotine or a mixture of calcium arsenate and 0.5 percent of nicotine."

Effect of boll weevil and cotton aphid control on yield as shown in a factorial experiment in 1941, R. C. GAINES. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 493-495).

[Contributions on fruit insects] (*N. Y. State Hort. Soc. Proc.*, 87 (1942), pp. 25-34, 42-56, 170-172, 200-206, 291-303).—Among the contributions presented at the annual meeting held in January 1942 are the following: Fruit Insect Problems in 1941, by J. A. Evans (pp. 25-34) (Cornell Univ.); Recent Developments in the Use of Petroleum Oils as Insecticides, by P. J. Chapman (pp. 42-44), Control of Bud Moth and Rosy Apple Aphid, by F. Z. Hartzell (pp. 45-51), Latest Developments in Codling Moth Control, by S. W. Harman (pp. 51-56), The Status of Peach Tree Borer Control in New York State, by E. H. Smith (pp. 170-172), and Possibility of Controlling Oriental Fruit Moth With Insecticides, by R. W. Dean and E. H. Smith (pp. 200-202) (all N. Y. State Expt. Sta.); Early Season Vs. Summer Control Measures for European Red Mite (pp. 202-206) and Emergence, Migration, and Control of the Apple Maggot (pp. 291-295), both by R. W. Dean; and Making Codling Moth and Apple Maggot Sprays Effective, by O. B. Hammer (pp. 295-303).

Insects of the pecan in middle Georgia, T. L. BISSELL. (Ga. Expt. Sta.). (*Southeast. Pecan Growers Assoc. Proc.*, 36 (1942), pp. 54, 56-58).—Particular mention is made of the shuckworm, black aphid, fall webworm, flat-headed borer, and twig girdler as insects of importance in middle Georgia. Tables are given which show the damage caused by the shuckworm in this area in 1929, 1931, and 1932.

Annual report of the forest insect survey, 1941, A. W. A. BROWN (*Canada Dept. Agr., Forest Insect Survey Ann. Rpt.*, 1941, pp. 23, figs. 10).—A report of the occurrence of forest insects in 1941 accompanied by nine maps and a chart summarizing the occurrence of outstanding forest insects in each district and a tabulated summary arranged by hosts.

Some notes on the integument of insects in relation to the entry of contact insecticides, V. B. WIGGLESWORTH (*Bul. Ent. Res.*, 33 (1942), No. 3, pp. 205-218, figs. 6).—It was found that insects immersed in oils exude minute droplets of water over the surface of the cuticle. "These appear more rapidly in light oils than in heavy oils and are more numerous in young insects than in old. Immersed in mixtures of oils and alcohols which separate in contact with water, they show a vigorous effervescence at those regions where the mixture penetrates

most rapidly to the water in the cuticle. There is a delay of varying duration at different parts of the cuticle when heavy oils are used. This delay disappears if the lipid layer is first extracted with petroleum ether. Factors controlling the rate of entry of pyrethrum through the cuticle have been studied by the application of pyrethrum in oil to a restricted area of the abdomen of nymphs and adults of *Rhodnius*. Entry is more rapid in light than in heavy petroleum oils; it is much accelerated if the cuticle is first treated with petroleum ether. Entry is very slow in vegetable oils. There are great individual variations, due chiefly to the thickness of the endocuticle, which in turn is determined by the size of meal taken before molting, the age and the amount of food taken after molting, and the degree of stretching of the cuticle. There is evidence that the pore canals are important in the passage of pyrethrum through the endocuticle. Histological examination of the integument shows that in the nymph of *Rhodnius* oils are taken up first by the epidermal cells in the zone around the bristles, later by the general epidermis. The uptake of oil is greatly increased if 5 percent of oleic acid is added to refined petroleum. In the adult *Rhodnius* soon after molting, oils are taken up by the general epidermis. In old insects they are taken up solely by the dermal glands. There is no visible entry through the sockets of the bristles. The entry of pyrethrum in oils is accelerated by the addition of oleic or other fatty acids."

**A method for determining insecticidal effectiveness using *Aphis rumicis* and certain organic compounds**, W. MOORE and C. I. BRISS. (Conn. [New Haven] and [Conn.] Storrs Expt. Sta. et al.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 544-553, figs. 2).—Report is made of the quantitative comparison of 5 substituted glycinonitriles and a mixture of 1 of the 5 with dioctyl fumarate with a standard nicotine insecticide, following preliminary tests with more than 400 chemicals in contact sprays against the bean aphid. "By a simplified procedure, which is described, parallel dosage-mortality curves in terms of log-concentrations and empirical probits were computed for the three tests of all 7 chemicals and from them the log-concentration killing 95 percent of the aphids. The mean log-LD95 for each chemical was then corrected for differences in the over-all susceptibility of the aphids between days. The calculation of these relative toxicities and their experimental errors is described in full. The 2 amyl phenyl glycinonitriles were less than half as toxic as the dibenzyl, benzyl phenyl, and diphenyl glycinonitriles, which compared favorably with Black Leaf 40, a standard 40-percent solution of nicotine."

**Compatibility of copper fungicides with nicotine bentonite insecticides**, J. E. FAHEY. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 517-520).—A laboratory study was made of the effect of copper fungicides and nicotine bentonite insecticides on the water-soluble nicotine and water-soluble copper contents of the water phase of spray mixtures of these materials. The chemical analyses of 17 copper fungicides are reported. Preliminary experiments show that a  $\frac{1}{32}:\frac{1}{16}:100$  bordeaux mixture has a measurable effect on the water-soluble nicotine content of nicotine bentonite sprays. As the bordeaux concentration is increased there is a corresponding increase in the pH and the water-soluble nicotine content of the spray mixture. Copper fungicides that produce strongly alkaline (above pH 8.5) spray mixtures, alone or in combination with nicotine bentonite insecticides, will result in a large increase in the soluble-nicotine content of nicotine bentonite spray mixtures. Nicotine bentonite insecticides that contain or are used with unaltered bentonite reduce the soluble-copper content of the copper fungicide sprays. A factory-processed nicotine bentonite insecticide was found to increase the soluble-copper content of the fungicide spray mixtures. It is pointed out that these results apply only to spray mixtures and should not be interpreted as applying to spray residues.

**Carriers of rotenone dusts**, II. F. WILSON and R. L. JANES. (Univ. Wis.). (*Soap and Sanit. Chem.*, 18 (1942), No. 4, pp. 103, 105).—A brief report is made of a study of 37 different samples of talc and pyrophyllite obtained from nine States. Five of the samples examined were classified superior, 6 fair, and the remainder very poor. Of the 3 samples of pyrophyllite that were examined, 1 was superior, 1 fair, and 1 very poor.

**Sodium fluoride**, II. L. SWEETMAN and H. LAUDANI. (Mass State Col.). (*Soap and Sanit. Chem.*, 18 (1942), No. 4, pp. 90-93, figs. 3).—The results of studies of the toxicity of sodium fluoride for the American cockroach, including the lethal effects of injections into the digestive tract and the observed responses following such injections, the effects of sodium fluoride on American and German cockroaches after running through a runway dusted with the poison, and the relationship between the time required to kill and the amount of sodium fluoride observed on German cockroaches, are reported in tables. Sodium fluoride is shown to be an active stomach poison in the gut of the American cockroach, but these cockroaches are repelled by food containing it. Neither the American nor the German cockroach appears to swallow a lethal dose during the cleaning processes after running over surfaces dusted with the poison. The authors feel justified in concluding that in the practical control of these pests it is of little or no value as a stomach poison, but that it is effective as a contact poison. See also a previous note (E. S. R., 85, p. 87).

**Insecticidal action of some pyrrolines and pyrrolidines on *Thermobia domestica***, J. G. KIRCHNER and C. H. RICHARDSON. (Iowa Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 525-530).—In a laboratory study of 14  $\alpha$ -substituted pyrroline and pyrrolidine derivatives as contact insecticides against the firebrat, the physiological action of these compounds was found to resemble that frequently observed for nicotine.

**Circulation of hemolymph in the wings of the [German] cockroach (*Blattella germanica* L.)**.—I, In normal wings; III, Circulation in the articular membrane: The significance of this membrane, the pteralia, and wing folds as directive and speed controlling mechanisms in wing circulation, S. CLARE and O. E. TAUBER. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 14 (1940), No. 2, pp. 107-127, figs. 3; 16 (1942), No. 3, pp. 349-356, figs. 2).

**Circulation of hemolymph in the wings of the [German] cockroach (*Blattella germanica* L.)**.—II, Effects of cutting hemolymph channels in the normal tegmen and hind-wing, S. CLARE and O. E. TAUBER. (Iowa State Col.). (*Ann. Ent. Soc. Amer.*, 35 (1942), No. 1, pp. 57-67, figs. 4).—No. 2 of this series (see above).

**Circulation in the wings of the [German] cockroach (*Blattella germanica* L.)**.—IV, Circulation in unsclerotized wings under normal and experimental conditions, O. E. TAUBER and S. CLARE. (Iowa Expt. Sta.). (*Amer. Micros. Soc. Trans.*, 61 (1942), No. 3, pp. 290-296, figs. 2).—A further contribution.

**Host distribution of lice on native American rodents north of Mexico**, W. L. JELLISON (*Jour. Mammal.*, 23 (1942), No. 3, pp. 245-250).

**Insecticidal control of legume bugs in seed alfalfa**, R. A. FISHER and W. E. SHULL. (Idaho Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 503-507, figs. 4).—The results of experimental control work with legume bugs, particularly *Lygus hesperus* Kngt. and *L. elisus* Van D., which are a contributing factor to many of the failures in the production of alfalfa seed in the Western States, are reported. A dust mixture of Dry Pyroicide and cube, containing 0.125 percent pyrethins and 0.50 percent rotenone, gave good kills of the nymphs and adults in laboratory experiments. Kills approaching 90 percent were obtained in the field with a pyrethrum-cube dust, but the fields were soon heavily reinfested, and no benefit was derived from the control operations. A 20 percent sodium

arsenite dust gave good laboratory control of the insects and may be of value in field control.

**A new chinch bug from Argentina (Hemiptera: Lygaeidae)**, C. J. DRAKE (*Rev. Ent.*, 12 (1941), No. 3, pp. 514-515).—Under the name *Blissus penningtoni* description is given of a new chinch bug from Argentina, the third species of the genus to be recorded from that country.

**Time of planting susceptible beans in relation to curly top injury in south-central Idaho**, A. O. LARSON and H. C. HALLOCK. (U. S. D. A. coop. Idaho Expt. Sta. et al.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 565-569, figs. 3).—The experiments reported have shown that garden bean varieties planted just before or at about the start of the spring migration of the beet leafhopper in the Twin Falls district of Idaho and in the district immediately east of Twin Falls should nearly always escape severe injury from curly top disease. The planting of garden varieties, susceptible Great Northern, or pinto beans at any time in the west districts, such as beyond Flier and around Buhl, Castleford, and Clover, is attended by a very high degree of risk, but some chance of reducing losses from damage by curly top is afforded by early planting.

**Rotenone in combination with calcium arsenate for cotton aphid control**, C. F. RAINWATER. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 500-503).—Experiments conducted at seven locations in six States during 1941 in which rotenone was added to calcium arsenate for control of the cotton aphid are reported. Calcium arsenate plus 0.5 percent rotenone was found to be effective in keeping the aphid population at or below that in untreated check plots and caused a significant increase in yield over plots treated with calcium arsenate alone under conditions of heavy boll weevil injury. A mixture of equal parts of calcium arsenate and sulfur plus 0.25 percent of rotenone was not significantly different in effectiveness from calcium arsenate plus 0.5 percent of rotenone, but the latter combination generally caused significant increases in yield over calcium arsenate alone, whereas the former did not. Less than 0.5 percent of rotenone in calcium arsenate and less than 0.25 percent in calcium arsenate-sulfur were not very effective in keeping the aphid population down. Calcium arsenate plus 0.5 percent of rotenone gave larger but not significant increases in yield and fewer aphids than calcium arsenate-sulfur plus 0.25 percent of rotenone. The records obtained at Tallulah, La., showed that derris, cube, and timbo were equally effective as sources of rotenone. The records at Florence, S. C., showed that sulfur, diatomaceous earth, clay, pyrophyllite, and walnut-shell flour were equally effective as diluents for calcium arsenate and rotenone.

**Relation of fertilizers to the development of the cotton aphid**, R. L. MCGARR. (U. S. D. A. coop. Miss. Expt. Sta. et al.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 482-483, fig. 1).—The author's findings indicated that nitrogenous fertilizer causes a definite increase in aphids when cotton is dusted with calcium arsenate, but that there is no appreciable increase when this insecticide is not used.

**Amphorophora osborni (Homoptera: Aphididae)**, G. F. KNOWLTON. (Utah Expt. Sta.). (*Pan-Pacific Ent.*, 18 (1942), No. 3, p. 143, fig. 1).—A new aphid found associated with *A. ribellu* (Davis) on the black currant in Utah is described as *A. osborni* n. sp.

**Laboratory fumigations of the California red scale with methyl bromide, alone and with hydrocyanic acid**, H. R. YUST, R. L. BUSBY, and L. B. HOWARD. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 521-524).—Female scales of all developmental stages and many different ages killed by methyl bromide fumigation were slower to develop visible characteristics of death than were those killed by hydrocyanic acid fumigation. "Scales in the early second stage, early gray adults, and mature females were most difficult to kill. Scales in the

second molt, which are especially difficult to kill with hydrocyanic acid fumigation, were killed relatively easily with methyl bromide fumigation. Complete mortality was obtained upon fumigation with a methyl bromide concentration of 40 mg. per liter for 3 hr. at a constant temperature of 77° F. A concentration that gave 99.5-percent kill of mature female scales at 77° gave only a 16.4-percent kill at 50°. Fumigation with a mixture of hydrocyanic acid and methyl bromide resulted in a synergistic action on the scales in the gray adult stage and an antagonistic action on the mature female scales. The difference in the reaction of two developmental stages of the same insect suggests the importance of studying more than one stage in insecticide tests. Prefumigation with a sublethal dosage of methyl bromide reduced the kill of the California red scale produced by hydrocyanic acid."

**The life history of *Phyllophaga farcia* and *P. crassissima*, H. J. REINHARD.** (Tex. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 576-582).—The life cycle of a generation of *Phyllophaga farcia* and *P. crassissima* in Texas is reported upon, the details being given in tables.

**Symposium on wireworm investigations** (*Ann. Appl. Biol.*, 29 (1942), No. 2, pp. 144-196, figs. 15).—Contributions presented at a symposium held on October 10, 1941, include Investigations on Wireworms—Introductory, by J. C. F. Fryer (pp. 144-149); Wireworms and Crop Production, by S. G. Jary (pp. 150-155); Statistical Problems in Field Sampling for Wireworms, by F. Yates and D. J. Finney (pp. 156-167); Observations on Some Factors Influencing Growth in Wireworms of the Genus *Agriotes* Esch., by A. C. Evans and H. C. Gough (pp. 168-175); Wireworms and Agriculture, With Special Reference to *Agriotes obscurus* L., by H. W. Miles (pp. 176-180); and Observations on the Biology of *Agriotes obscurus* L.—The Adult Insect, by M. Cohen (pp. 181-196).

**Biological notes on the basswood leaf-miner *Baliosus ruber* (Weber).** A. C. HOBSON. (Minn. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 570-573, figs. 2).—Observations of *B. ruber*, a beetle leaf miner which attacks the basswood (*Tilia americana*) throughout its range, are reported.

**Biology of two native coleopterous predators of the mountain pine beetle in sugar pine, G. R. STRUBLE.** (U. S. D. A.). (*Pan-Pacific Ent.*, 18 (1942), No. 3, pp. 97-107, figs. 3).—Two native important coleopterous predators of bark beetles commonly associated with infestations in many conifers in the West, studies of the biology of which are here reported, are *Tennochila virescens* (F.), of the family Ostomatidae, and *Enoclerus sphaegeus* (F.), of the family Cleridae. In sugar pine they are associated with infestations of the mountain pine beetle. Their habits and life histories with this host were investigated as a preliminary step to determine their importance as control factors.

**Four new species of white-fringed beetles (subgenus *Graphognathus*) from the southeastern part of the United States (Coleoptera: Curculionidae), L. L. BUCHANAN** (*Bul. Brooklyn Ent. Soc.*, 37 (1942), No. 3, pp. 107-110).—Four species of the genus *Pantomorus* (to which the white-fringed beetle belongs), all thought to be accidentally introduced from South America, are described as new.

**Further tests of dichloroethyl ether and of jarring to control plum curculio, O. I. SNAPP.** (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 514-516, figs. 3).—Experiments in the laboratory and on caged peach trees have shown dichloroethyl ether to be effective against the plum curculio in the soil. In a commercial peach orchard two applications of dichloroethyl ether on the soil under the spread of the trees, plus 12 jarrings, gave as good control of the plum curculio as the regular schedule of lead arsenate sprays on the fruit. No injury to vegetation under the spread of the peach trees or to any part of the

trees or foliage could be discerned from the two applications of dichloroethyl ether on the soil.

**Experiments on time to begin dusting with calcium arsenate and number of applications for boll weevil control**, M. T. YOUNG, G. L. GARRISON, and R. C. GAINES. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 484-486).—Report is made of work conducted near Tallulah, La., in 1940 and 1941 with a view to securing information on the time to commence dusting with calcium arsenate and the number of applications for the most economical control of boll weevil in that locality, the details being given in a table.

**Boll weevil control with calcium arsenate applied at different times of day and at different time intervals**, M. T. YOUNG, G. L. GARRISON, and R. C. GAINES (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 487-489).—In experiments conducted near Tallulah, La., from 1934 to 1941, inclusive, during 6 of the 8 yr. applications of calcium arsenate applied during the early morning gave an average increase over the checks of 309 lb. of seed cotton per acre, those applied near midday 311 lb., and those during the late afternoon 264 lb. From 1934 to 1941, inclusive, applications of calcium arsenate made at 4-day intervals gave an average increase over the checks of 208 lb. of seed cotton per acre, those at 6-day intervals 143 lb., and those at 8-day intervals 100 lb.

**Boll weevil hibernation, survival, and emergence under South Carolina conditions**, F. F. BONDY and C. F. RAINWATER. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 495-498).—Studies made of the factors that influence the boll weevil's abundance with particular reference to hibernation, survival, and emergence, conducted in the vicinity of Florence, S. C., are reported. They included cage tests, examination of Spanish moss and woods trash, and trap-crop emergence.

**Mopping, dusting, and combination treatments for boll weevil control in South Carolina**, F. F. BONDY. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 498-499).—The results of 187 field experiments conducted against the boll weevil at Florence, S. C., over a 14-yr. period, 1928-41, to determine the comparative value of (1) a 1-1-1 mopping mixture of calcium arsenate, molasses, and water applied to cotton in the presquare stage, (2) calcium arsenate dust applied after 10 percent of the squares had been punctured, and (3) a combination of these two treatments are reported. The average increases in yield over comparable untreated check plats were 39, 286, and 331 lb. of seed cotton per acre, respectively, with average net profits of \$1.10, \$9.60, and \$11.40 per acre for the three treatments.

**The pepper weevil**, J. C. ELMORE (U. S. Dept. Agr. Leaflet 226 [1942], pp. 8, figs. 6).—Both larvae and adults of this weevil cause damage to peppers. Eggs are deposited in blossom buds where hatching occurs in 3 or 4 days. The small grubs feed inside the buds or among the seeds of the immature pods and reach maturity in from 8 to 10 days. After 4 to 6 days the pupae become adults, which crawl to the outside through round holes made in the rind of the pods. In California from five to eight generations develop annually. Two or 3 weeks are required for complete development in warm weather and 5 to 6 weeks in cool weather. Adults remain on green pepper, nightshade, or other hosts during the winter. Dusting plants at weekly intervals with cryolite containing 50 percent sodium fluoaluminat is a suggested control. The control value of certain cultural practices such as disking or plowing when the crop is harvested, destroying nightshade and other hosts not later than January 15, early planting and the use of early-maturing varieties is mentioned.

**The influence of lime on the toxicity of lead arsenate to cabbage worms**, G. E. R. HERVEY and G. W. PEARCE. (N. Y. State Expt. Sta.). (*Jour. Econ. Ent.*,

35 (1942), No. 4, pp. 554-558, figs. 3).—The results of experiments in 1940 and 1941 for the control of the cabbageworm, aimed at determination of the comparative effectiveness of dusts containing hydrated lime, Loomkill Talc, Pyrax ABB, and Bancroft Clay as diluents and lead arsenate sprays with and without lime, are reported. All treatments containing lime showed markedly lower control efficiencies. Data on the arsenical residue loads of the various treatments are presented to show that the effect of lime on control is not accounted for by differences in arsenical load but to an actual reduction in the toxicity of the lead arsenate. A brief discussion of the possible mechanism of this observation is included.

Two treatments for the control of peach tree borer, T. H. JONES (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 10, p. 7).—A practical account.

*Epicallima coloradella* (Wals.), an inhabitant of perennial apple cankers in the Northwest, M. A. YOTHERS. (U. S. D. A.). (*Jour. Econ. Ent.* 35 (1942), No. 4, pp. 573-576, figs. 3).—A study of the oecophorid moth *E. coloradella*, one of the most common inhabitants of the perennial apple canker in the Wenatchee, Wash., district, made during the course of a study of the woolly apple aphid.

Ovicidal value of light mineral oils for the codling moth, R. L. WEBSTER and E. C. CARLSON. (Wash. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 530-533).—The data presented indicate that light petroleum oils (viscosity 50-55) with a high unsulfonatable residue and at a concentration of 0.5 percent have a high ovicidal value (92 percent mortality or better) for the codling moth.

Recent progress in codling moth control in British Columbia, I, II (*Sci. Agr.*, 22 (1942), No. 10, pp. 571-583).—Progress in control work with the codling moth as relates to killing of the mature larva is reported upon by A. D. Heriot (pp. 571-576) and to killing the adult, by A. A. Dennys (pp. 577-583). The laboratory and field control investigations with the adult, conducted at Vernon, B. C., have shown that a considerable measure of control can be obtained by the use of summer sprays that do not kill the larva but kill the moth itself. So far, two derivatives of dinitrophenol have been used in the field, namely, ammonium dinitrocresylate and sodium dinitrocresylate. It is possible other compounds will prove more suitable. The effects of these substances may be additive to those of the customary larvicides. Very little material is used, so the cost is low. Substances such as lead arsenate or cryolite that are toxic to the larva seem to be relatively nontoxic to the moth. On the other hand substances toxic to the moth at low concentration may be innocuous to the larva. Perhaps the fact that the reaction of the alimentary tract is alkaline in the larva and appears to be acid in the moth has some bearing on that point.

The main experiment with the larvae here described, which involved 5.5 acres, has shown that under conditions of heavy infestation and where the trees have not been scraped a single dormant application of an oil solution of dinitrocresol to trunks and main limbs is highly effective in reducing the degree of codling moth infestation at harvest. Such a procedure in fact appears to be a valuable supplement to the usual summer sprays. It has a serious fault, however, in the tendency of the oil carrier to injure the trees, but this fault does not appear to be insurmountable, and further experiment along two lines is indicated.

Manual infestation of corn strains as a method of determining differential earworm damage, R. A. BLANCHARD, A. F. SATTERTHWAIT, and R. O. SNELLING. (U. S. D. A. coop. Ill. Nat. Hist. Survey and Ill. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 508-511).—Description is given of a method of controlled infestation of the corn earworm for use in investigational work.

Control of earworms in corn by birds, G. W. BARBER. (U. S. D. A.). *Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 511-513).—Description is given of a 5-acre field

of corn in which birds had fed to an unusual extent upon larvae of the corn earworm and the fall armyworm infesting the ears.

**The wheat field survey for 1942**, T. H. PARKS and R. H. DAVIDSON (*Ohio Sta. Bimo. Bul.* 218 (1942), pp. 156-159, figs. 2).—A continuation of this annual wheat field survey (*E. S. R.*, 86, p. 216) as to hessian fly status.

**Breeding habits of a rice field mosquito**, W. R. HORSFALL. (*Ark. Expt. Sta.*). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 478-482).—A study of *Psorophora confinnis* (Ly. Arrib.), the dominant and most important pest in the rice-growing areas of Arkansas, is reported upon, the details of the abundance of the larvae in rice fields in 1940 and 1941 and in ditches in 1940 being given in tables. It occurs all summer as a general pest, and at times livestock suffer severely.

**Observations on the macroscopic species—identification of larval Anopheles in Georgia**, R. E. BELLAMY (*Jour. Parasitol.*, 28 (1942), No. 4, pp. 299-310).

**Mosquito studies in military establishments in the Seventh Corps Area during 1941**, S. J. CARPENTER (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 558-561, fig. 1).

**Measurements of larval populations of Anopheles quadrimaculatus Say**, M. H. GOODWIN, JR., and D. E. EYLES (*Ecology*, 23 (1942), No. 3, p. 376).

**Observations on the biology of the carrot [rust] fly (*Psila rosae* Fab.)**: Assembling and oviposition, F. T. BAKER, I. E. KETTERINGHAM, S. P. V. BRAY, and J. H. WHITE (*Ann. Appl. Biol.*, 29 (1942), No. 2, pp. 115-125, figs. 6).—Observations on the movement and oviposition of carrot rust flies in and near fields of carrots in north Lincolnshire led to the conclusion that there is no evidence to indicate migration. Dispersal is general and is influenced by the wind. When the wind is not too strong some flies leave the hedges and when again seeking shelter tend to fly down wind. This results in a temporary spread in the direction in which the wind is blowing. The flies remain assembled in large numbers in the hedges surrounding the previous year's crop for a considerable period of time. Eggs are laid in  $\frac{1}{2}$ -1-in. crevices in proximity to the carrot drill row.

**Studies of fluctuations in insect population.—IX, The carrot-fly [carrot rust fly] (*Psila rosae*) in 1936-41**, H. F. BARNES (*Jour. Anim. Ecol.*, 11 (1942), No. 1, pp. 69-81, pl. 1, figs. 3).—This ninth contribution (*E. S. R.*, 86, p. 214) deals with the fluctuations in insect populations studied in an outdoor unheated insectary, the previous eight having dealt with various species of gall midges. The data given cover the years 1936-41, inclusive.

**Filth flies as transmitters of *Endamoeba histolytica***, A. C. PIRKIN (*Soc. Expt. Biol. and Med. Proc.*, 49 (1942), No. 1, pp. 46-48).—From the evidence here cited it is considered highly probable that the five species of filth flies employed in the experiments, namely, *Sarcophaga misera*, *Phormia regina*, the secondary screwworm, *Lucilia pallidescens*, and the housefly, play no important role as transmitters of trophozoites or cysts of *E. histolytica* by external carriage. However, the viability of cysts for periods as long as 3.5 hr. after initial ingestion and later defecation indicates a potential natural method of transmission.

**The effect of some organic halides on the housefly**, L. D. GOODHUE, W. N. SULLIVAN, and J. H. FALES. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 533-536, fig. 1).—Description is given of a small chamber devised for testing aerosols on a laboratory scale, and determinations made of the toxicities of 39 organic halides to the housefly are reported. Some of the more complex compounds such as 3-chloroacenaphthene, 2-chlorofluorene, and 9-bromophenanthrene were found to be effective at 0.01 or 0.02 lb. per 1,000 cu. ft. Some of the more volatile compounds such as methyl bromide, which do not form aerosols, are not effective when applied by this method.

**Control of stablefly, or "dog fly," breeding in shore deposits of bay grasses.** W. E. DOVE and S. W. SIMMONS. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 582-589, figs. 3).—A further report of studies of the stablefly, commonly known in Florida as the dog fly (E. S. R., 85, p. 798). In grass deposits along the shores of bays and sounds of northwestern Florida eggs were commonly found at the rate of 1,000 per square foot of grass and larvae at the rate of 15.4 per square foot. From material in three cages 38.5, 22.3, and 25.7 flies emerged per cubic foot of grass. Spray treatments of infested grasses with creosote in diesel oil resulted in a complete kill of eggs, larvae, and pupae, and there was no subsequent breeding of the flies in the treated grasses. The creosote was observed to remain in the grass for 18 to 30 days, or long after the time for fermentation had passed. Large-scale spray operations reduced the fly population in the treated area to less than 2 flies per animal on cattle. Predatory dragonflies identified as *Anax junius* (Drury), *Pachydiplax longipennis* (Burm.), and *Tramea lacerata* (Hagen) were observed to feed on dog flies.

**Creosote oil with water for control of the stablefly, or "dog fly," in drifts of marine grasses.** S. W. SIMMONS and W. E. DOVE. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 589-592).—A further report on the control of this pest (see above), which breeds extensively in tide drifts of grasses that are deposited along the shores of certain bays, inlets, and sounds of northwestern Florida. Tests with 17,750 gal. of material on 14.07 miles of grass tide drifts have shown that a mechanically prepared creosote-water emulsion can be used successfully and economically in treating bay grass for its control. Bay grass treated with creosote and bay water remains treated for 1 mo., and grass once well treated does not subsequently breed any dog flies. By eliminating the cost of diesel oil, by reducing transportation costs, and by speeding up spray operations, at least \$15,000 can be saved by the use of the creosote-water emulsion instead of creosote and diesel oil solution for a dog fly control program extending from Pensacola to Apalachicola, Fla.

**Ants as probable agents in the spread of *Shigella* infections.** S. D. GRIFFITHS (*Science*, 96 (1942), No. 2490, pp. 271-272).—In laboratory experiments in Puerto Rico, briefly noted, the fire ant transmitted *Shigella flexner* V from inoculated food in a container to sterile plates 24 hr. after having fed upon or traversed the infected material.

**A new species of *Tiphia* from California (Hymenoptera: Tiphidae).** K. V. KROMBEIN. (U. S. D. A.). (*Pan-Pacific Ent.*, 18 (1942), No. 3, pp. 139-143).—Under the name *T. shastensis* a species taken at Old Station in Shasta County is described as new, and a tablet is given separating it from *T. rugulosa* Mallach and *T. odontogaster* Viereck.

**On the bionomics of *Aphidius matricariae* Hal., a braconid parasite of *Myzus persicae* Sulz.,** E. J. VEVAI (*Parasitology*, 34 (1942), No. 2, pp. 141-151, figs. 6).—This study relates to an internal parasite of the green peach aphid, the most efficient vector of the potato viruses leaf roll and "Y," also found parasitizing *M. circumflexus* Buckt. and *Aulacorthum solani* Kalt. "The percentage of aphids successfully parasitized increased with an increased number of strikes per host. A single female can lay up to 350 eggs, and one female successfully parasitized 309 *M. persicae*. The female parasite reaches its maximum activity during the second or third day of oviposition, and this activity has no correlation with light intensity. The disappearance of supernumerary larvae due to cannibalism has been observed. The species is arrhenotokous. Mating takes place from 2 hr. after emergence. In the progeny of early matings the females preponderated; in later matings the sex ratio was approximately 1 : 1. The parasite appears to fly under the same conditions as those generally favorable for aphids. It is generally disseminated by flight of the

adult itself and through localized movements of parasitized apterous aphids. The host is unable to reproduce if 'struck' in the third instar or earlier."

**Control work on European spruce sawfly in 1939**, H. B. PIERSON and R. W. NASH (*Maine Forest Serv. Bul. 12* (1940), pp. 19, pls. 2, figs. 2).

**The larval Trombiculinae (Acarina: Trombididae)**, with descriptions of twelve new species, C. D. RADFORD (*Parasitology, 34* (1942), No. 1, pp. 55-81, figs. 106).—A catalog list of the recognized larval forms of Trombiculinae, with their known hosts, known localities of occurrence, and the number and arrangement of the dorsal setae and measurements of the 12 new species. A key to the genera of Trombiculinae, based on larval characters according to Ewing (*E. S. R.*, 80, p. 377), and pen drawings of the dorsal setae of 106 forms are included.

**Lethal temperatures for *Dermacentor andersoni* Stiles and other ticks in British Columbia**, G. A. MAIL (*Jour. Econ. Ent.*, 35 (1942), No. 4, pp. 562-564).—Experiments conducted have shown that unfed *D. andersoni* ticks have an average freezing point of between  $-10^{\circ}$  and  $-14^{\circ}$  C. except where exposed to unusually severe or protracted winters, when they appear to develop a greater resistance to freezing. Engorged ticks of several species have high freezing points, between  $-5^{\circ}$  and  $-7^{\circ}$ . An exception is found in the bird tick, which normally overwinters in an engorged state. The average freezing point of five engorged bird ticks was  $-11.3^{\circ}$ , so this tick exhibits a greater resistance to freezing than engorged ticks of most species. Eggs of *D. andersoni* freeze at  $-28^{\circ}$  and seed ticks of the same species at about  $-23^{\circ}$ . Macerated eggs freeze at  $-8^{\circ}$ . Unfed *Ixodes californicus* Banks freeze at  $-12.5^{\circ}$  and unengorged *I. texanus* Banks freeze about  $-23^{\circ}$ . When engorged these two species freeze near  $-7^{\circ}$ . The lethal high temperature for unfed *D. andersoni* is between  $45^{\circ}$  and  $46.5^{\circ}$ .

**Tick control with special reference to *Dermacentor andersoni* Stiles**, G. A. MAIL (*Sci. Agr.*, 23 (1942), No. 1, pp. 59-67).

**Note on a toxic principle in eggs of the tick *Dermacentor andersoni* Stiles**, E. A. STEINHAUS (*Pub. Health Rpts. [U. S.]*, 57 (1942), No. 35, pp. 1310-1312).—In the experiments reported it was found that when large numbers of eggs of normal ticks (*D. andersoni*) were inoculated into animals characteristic toxic symptoms followed by death in 2 or 3 days usually resulted. The active principle was filtrable, resistant to drying, alcohol, and acetone, and apparently non-dialyzable.

## ANIMAL PRODUCTION

**General science of livestock**, M. M. SMITH (*Boerne, Tex.: Boerne Star*, [1941], pp. [7]+381, [figs. 105]).—General descriptions of the breeds, management, and feeding of beef cattle, dairy cattle, sheep, goats, swine, and horses are presented.

**Livestock management**, J. S. COFFEY and L. E. JACKSON (*Chicago: J. B. Lippincott Co.*, [1940], pp. XI+500, [figs. 217]).—A presentation of the elements of production, management, and feeding of horses, cattle, sheep, swine, and poultry, and of disease control.

[**Animal husbandry studies by the Georgia Coastal Plain Station**]. (Partly coop. U. S. D. A.). (*Georgia Coastal Plain Sta. Bul. 32* (1941), pp. 43-67, figs. 2).—Brief results are presented on seeds, management, and fertilizers for permanent and annual summer pastures such as soybeans, velvetbeans, lespedeza, kudzu, and millet, and the annual winter pastures such as oats and vetch, abruzzi rye, and oats following lespedeza, for wintering and breeding native grade and purebred polled and horned Hereford beef cows; creep feeding calves; steer feeding comparisons of velvetbeans, cottonseed meal, and peanut

meal as protein supplements for different grades of steers; the establishment of superior strains of Polled Hereford cattle; management and breeding of sows, gilts, and their suckling pigs; and hogging off oats, corn, soybeans, sunflowers, chufas, peanuts, popcorn, and sweetpotatoes.

**Herds and flocks at the North Dakota Agricultural College, J. H. LONGWELL** (*North Dakota Sta. Bimo. Bul.*, 5 (1942), No. 1, pp. 33-35).—General description is given of the leading animals in the breeding sheep, cattle, and swine herds of the station.

[**Experiments in livestock production by the Ohio Station**] (*Ohio Sta. Bul.* 617 (1940), pp. 51-55, 55-58, 59, 70, fig. 1).—Reports of projects are given briefly on open-pollinated and hybrid corn for steers; the prevention of apoplexy in lambs by the inclusion of cane molasses in the ration; plant and animal proteins for pigs; removal of toxicity in cottonseed meal by iron treatment; liver meal as a protein supplement for swine; the preference of pigs for hybrid and open-pollinated corn due to lack of moisture; protein poisoning and protein levels for swine; milk in chick rations; riboflavin needed by pigs; ultraviolet lights as a source of vitamin D for chickens and turkeys; relation of humidity of holding rooms to market quality of eggs; rations and management for feeding laying hens; improved rations and management for poults; relation of ration deficiencies to hog cholera immunization; studies of digestion in steers through windows in their sides; and stage of maturity of corn for silage.

**Commercial feeding stuffs—report of inspection, 1941, E. M. BAILEY** (*Connecticut [New Haven] Sta. Bul.* 459 (1942), pp. 329-422).—There are presented the guarantees and analyses of the 797 samples of commercial feeding stuffs and 42 samples of vitamin D carriers officially examined; the results of examinations of 86 specimens for poisons, by C. E. Shepard, D. C. Walden, and E. M. Bailey; and analyses of 45 samples of native seeds, grains, berries, etc.

**Commercial feeds in Kentucky in 1941, J. D. TURNER, S. B. RANDLE, W. G. TERRELL, and J. J. ROSE** (*Kentucky Sta. Regulat. Ser. Bul.* 31 (1942), pp. 52).—There is presented a summary of the chemical and microscopical analyses of 1,601 samples of feeds officially examined (E. S. R., 87, p. 100) with appropriate comments. Pertinent facts on the feeds sold in the State are included. The calcium, phosphorus, and manganese, as well as the vitamin A, thiamin, and riboflavin in several feeds are presented.

**Inspection of commercial feedingstuffs, 1942, T. O. SMITH and H. A. DAVIS** (*New Hampshire Sta. Bul.* 342 (1942), pp. 58).—The guaranteed and found analysis and contents of 461 samples of feeds officially inspected during the year ended June 1942 (E. S. R., 86, p. 664).

**Feed control service ruling permits additional grade of cottonseed meal, F. D. FULLER and G. S. FRAPS** (*Texas Sta. Cir.* 97 (1942), pp. 15).—To better comply with the lower protein content of some cottonseed a revision in the State feed law regulations was adopted to authorize a new grade of cottonseed meal and cottonseed cake containing not less than 41 percent protein and not more than 12 percent crude fiber.

**The use of wheat in livestock feeding, W. L. QUAYLE** (*Wyoming Sta. Bul.* 256 (1942), pp. 11).—In a series of tests conducted over 6 yr. with pigs and for a like period with lambs, wheat fed singly or in combination with barley or corn proved satisfactory for fattening animals. Considering the wheat eaten from free choice, wheat was more palatable than corn for pigs. For lambs a 50-percent mixture of wheat and corn was 88 percent as efficient as shelled corn alone and 99 percent as efficient as barley alone in producing gains. In each of the pig experiments there were 3 lots of about 10 head each fed for 55-80 days, and in the lamb experiments there were 50 head in each of 3 lots with feeding periods of 100-136 days.

**Electrode potentials in laboratory silage**, R. H. COMMON and W. BOLTON (*Jour. Agr. Sci. [England]*, 32 (1942), No. 3, pp. 338-348, figs. 6).—Study of the electrode potentials of ordinary and molasses silages prepared in glass jars showed that they tended to assume values of the order  $-0.05$  to  $-0.1$  from about the third day. The pH of the silages was in the range of 4.0-5.5. The electrodes were buried in the grass silage, which was chopped in half-inch lengths, and treated with water, molasses, sugar, hydrochloric acid, or formic acid, and packed firmly in glass jars.

**The effect of heat and moisture on the feeding value of pilchard meal**, W. B. LANHAM, JR., and H. W. NILSON (*U. S. Dept. Int., Fish and Wildlife Serv., Res. Rpt. 3* (1942), pp. 11+10).—The inclusion of commercial and spoiled pilchard meal in the ration of rats and chicks for 60 days and 6 and 7 weeks, respectively, showed no significant differences in the rate of gain or gain per unit of protein supplied. The meal was spoiled by holding a paste for 1 week at  $50^{\circ}$  C., and was incorporated in amounts as great as 31 percent of the ration without bad effects. A recommendation was made that pilchard meal may be successfully included in farm animal rations. The vitamin K content of the spoiled product was increased, and occurrence of some perosis in the chicks made it advisable that the rations be properly balanced with necessary minerals.

**Meat products in feeding program**, H. R. KRAYBILL (*Flour & Feed*, 43 (1942), No. 6, pp. 28-30).—Attention is called to the fact that meat products may provide certain deficiencies of proteins, minerals, and vitamins in rations from plant sources for nonruminants.

**Studies on carotene in relation to animal nutrition**, III, IV, P. A. SESHAN, and K. C. SEN (*Jour. Agr. Sci. [England]*, 32 (1942), No. 3, pp. 275-293, fig. 1). Two papers in continuation of this series (*E. S. R.*, 88, p. 232) are presented.

**III. Stability of carotene in plant material with special reference to hay making and storage** (pp. 275-285).—Carotene destruction in green plants during storage was found to result mainly from oxidation, which was accelerated by heat, light, and moisture. In ordinary combinations carotene in hays was mainly destroyed by spontaneous oxidation. Studies were made of the carotene contents of fresh, heated, and vacuum dried grasses after different storage periods. Mold growths did not seem to increase the losses.

**IV. Carotene balance experiments with cows and bullocks** (pp. 286-293).—Complete carotene balance studies were conducted with four cows receiving Napier grass and berseem. Considering the 14-day tests the cows secreted milk with fair amounts of carotene, though they themselves were in negative carotene balances. With increased amounts of carotene and vitamin A in the diet the quantity of these substances in the milk was increased. In four steers which were on low carotene diets for 6 mo. there was a consistently negative carotene balance. After two doses of fresh berseem there was a rise in the retention and the blood carotene. The negative carotene balances were thought to result from a withdrawal of body reserves.

**Riboflavin: Its history and properties**, T. S. HAMILTON. (*Univ. Ill.*), (*Flour & Feed*, 43 (1942), No. 5, pp. 14, 16-18).—This is a brief survey of the research that led to the discovery and identification of riboflavin, determination of its properties, its distribution in natural products, and its differentiation from other vitamins of the B complex. The value of riboflavin in the diet of the hen as related to egg production and the requirements of turkeys for this vitamin are also considered. Sixty-two references are given.

**Beef cattle for breeding purposes**, J. R. DOUGLAS (*U. S. Dept. Agr., Farmers' Bul. 1916* (1942), pp. 11+18, figs. 7).—General directions for selection, management, development, and care of breeding beef cattle.

**Experiments in creep-feeding beef calves**, B. R. TAYLOR, O. S. WILLHAM,

and L. E. HAWKINS (*Oklahoma Sta. Bul.* 262 (1942), pp. 14, figs. 5).—From these and previous experiments (E. S. R., 79, p. 370), it is concluded that creep-fed February, March, April, and May heifer calves produced 35–50 lb. extra weight, as compared with noncreep-fed steer calves. The creep-fed calves were rather light in weight for slaughter, and they made slower and more expensive gains during a subsequent finishing period. During a 48-day feeding period the helpers made average daily gains of 2.15 lb. on ground shelled corn, soybean pellets, silage, and ground limestone. In free-choice feeding on shelled corn, whole oats, and 43 percent cottonseed meal the calves seemed able to properly balance the ration to conform with standard recommendations.

**Cystic pituitary in young cattle with vitamin A deficiency, L. L. MADSEN, S. R. HALL, and H. T. CONVERSE. (U. S. D. A.). (*Jour. Nutr.*, 24 (1942), No. 1, pp. 15–24, pls. 2).**—Continuing the studies of vitamin A deficiencies in cattle (E. S. R., 85, p. 233), 13 of 15 deficient animals varying in age from birth to 787 days had cystic pituitary glands. Although cystic pituitaries were rare in cattle in general, the cystics persisted in spite of adequate carotene intake following the deficiency feeding as long as over 500 days. There was little evidence of regeneration. Histological study showed the cysts to occur either in the residual lumen or within the posterior lobe, and if large enough the glandular parenchyma was replaced or constricted to suggest partial hypophysectomy. It seems probable that the injury to the pituitary glands results from the mechanism responsible for injury to the optic nerve and central nervous system.

**Lucerne for fattening sheep, H. P. D. VAN WYK and W. A. VERBEEK (*Farming in So. Africa*, 17 (1942), No. 197, pp. 501–505, 526, figs. 6).**—The average daily gains of several breeds of sheep grazed for 65 days on alfalfa were 0.24 lb. When one-half were grazed for a further 56 days on soybeans and velvetbeans the average daily gains were 0.198, whereas those continued on alfalfa grazing made gains of only 0.072 lb. The carcasses at the conclusion of the experiment had an attractive appearance, whereas at the commencement there was no fat cover. In the grazing test there were 35 purebred and crossbred sheep. Bloating was observed on the alfalfa pasture, but it was not serious in most cases.

**The endogenous nitrogen metabolism of pigs with special reference to the maintenance protein requirement, B. A. DU TOIT and D. B. SMUTS (*Onderstepoort Jour. Vet. Sci. and Anim. Indus.*, 16 (1941), No. 1–2, pp. 169–179, figs. 5).**—The nitrogen excretion of nine pigs on a nitrogen-free diet showed a sharp drop during the first day, with a slower decrease until the sixth day after which it continued apparently constant. The data showed clearly that the equation  $P = 0.81 W^{0.751}$  indicates the endogenous nitrogen production of the pig as previously shown for sheep (E. S. R., 73, p. 663). In this formula  $P$  represents the protein in grams and  $W$  the weight in kilograms.

**The effect of season on the fattening of swine at various stages of growth, G. DUNLOP and A. WEST (*Empire Jour. Expt. Agr.*, 10 (1942), No. 39, pp. 161–168).**—Analyses of gains and economy of gains of pigs fattened in the modern Scandinavian type of piggery showed that 3 weeks longer were required to reach bacon weight in winter and approximately 100 lb. more feed per unit of gain than were needed by summer-fed pigs. The longer period of light under spring feeding conditions with increased metabolism and its effects on the pituitary are noted. The studies were conducted with individually fed pigs in the summer and winter of 1932–34, with group feedings of 202 animals in the summers of 1926–31 and 261 in the winters of these years. It was noted that pigs required more feed per unit of gain as they increased in weight. There seemed to be a need for controlling environment during long-term nutritional experiments and in genetical studies.

**Cacao by-products in pig feeding—cocoa-cake meal and de-theobrominized cocoa-cake meal as feeding-stuffs for pigs**, R. BRAUDE and A. S. FOOT (*Empire Jour. Expt. Agr.*, 10 (1942), No. 39, pp. 182-188, figs. 2).—In a group feeding experiment cocoa cake meal fed at a level of 8 percent to six 65-lb. pigs per lot for 126 days produced average daily gains of 0.99 lb., but caused digestive disturbances and even death. Other similar lots made average daily gains of 1.068 and 1.003 lb. with 8 and 16 percent cocoa meal treated to remove the theobromine. In a second experiment untreated cocoa meal was successfully introduced at a 10-percent level for 50 days to pigs averaging 130 lb. The average daily gains made by this group were 1.41 lb., as compared with 1.60 lb. by a control lot. There was no evidence of liver enlargement, but the coats of the control pigs were smoother and cleaner.

**Fütterungsversuche mit Birnentreckentrestern an Schweinen** [Feeding experiments with dried pear residue for swine], E. CRASEMANN and A. TSOHERNIAK (*Landw. Jahrb. Schweiz*, 56 (1942), No. 4, pp. 387-412; *Fr. abs.*, pp. 411-412).—The results of three experiments with 35 kg. pigs showed that dried pear residue waste might replace ground barley when proteins were supplied from meat meal, peanut meal, or skim milk, but the gains made were to a large extent ill because of the poor digestibility and large water content of the dried pear residue. In general this feed seemed effective to reduce the amount of roughages fed to the pigs, but a poor feed utilization may result. The pear residue feeding had no influence on the quality of the pork.

**Pig-feeding experiment using dried *Clostridium* residue**, R. BRAUDE and A. S. FOOT (*Jour. Agr. Sci. [England]*, 32 (1942), No. 3, pp. 324-329, fig. 1).—The spent liquor after distillation and drying from acetone and butyl alcohol manufacture by fermenting cane molasses with a pure culture of *Clostridium* was found to be an efficient protein for pigs. In these tests three lots of eight pigs on the control ration of cereals, meat meal, and minerals made average daily gains of 1.30 lb., whereas a comparable ration in which 9 percent dried *Clostridium* residue replaced the 10 percent meat meal in the ration made average daily gains of 1.35 lb. Another group which received 5 percent meat meal and 5 percent *Clostridium* made average daily gains of 1.24 lb. The feed required per unit of gain on the different rations was similar.

[Abstracts of papers on poultry production and breeding] (*Poultry Sci.*, 21 (1942), No. 5, pp. 465-466, 467-470, 470-479).—Abstracts of papers prepared for presentation at the 1942 cancelled meeting of the Poultry Science Association, dealing with the results of experimental work, are presented as follows: Whey Solubles as a Source of Growth Factors in Chick Rations, by E. P. Berry, C. W. Carrick, R. E. Roberts, and S. M. Hauge (p. 465), Influence of Starting Rations Upon Subsequent Growth, by R. E. Roberts and C. W. Carrick (p. 477), Distillers' Dried Solubles as a Vitamin Supplement for Chick Rations, by R. E. Synold, C. W. Carrick, R. E. Roberts, and S. M. Hauge (p. 478), and Utilization of Fat by Chickens—A Method for Determining the Absorption of Nutrients, by D. Whitson, C. W. Carrick, R. E. Roberts, and S. M. Hauge (p. 479) (all Purdue Univ.); Relation of Diet to Hatchability of Eggs Produced in Batteries and in Open-Front Houses, by H. R. Bird and J. A. Marvel (p. 465) (Univ. Md.); Crossbred Broilers and Layers Compared With Related Purebreds, by C. H. Bostian and R. S. Dearstyne (p. 465), and Improvement of General Viability in Single-Comb White Leghorns Through Breeding, by C. H. Bostian and R. S. Dearstyne (pp. 465-466) (both Univ. N. C.); The Riboflavin Requirement of Turkeys for Hatchability and Growth, by R. V. Boucher, H. Patrick, and H. C. Knandel (p. 466), Inheritance of Egg Shape, by D. R. Marble (p. 473), Inheritance in the Domestic Fowl of a Lethal Condition Affecting Both Mandibles, by D. R. Marble, E. V. Hammers, and J. A. Harper (p. 474), and The Nutritional Significance of Biotin in Chick

and Poultry Nutrition, by H. Patrick, R. V. Boucher, R. A. Dutcher, and H. C. Kandel (n. 476) (all Pa. State Col.); Nutritional and Economic Values of a Bluegrass Pasture for Laying Hens, by G. D. Buckner, W. M. Insko, Jr., and A. Harms (p. 466) (Ky. Expt. Sta.); A Study of Modified Expressions of Sex-Linked Early Feathering, by M. I. Darrow (p. 468) (Kans. State Col.); The Effect of Soybean Meal on Hatchability, by L. E. Card (p. 467), Results of Hypophysectomy in Growing Chickens, by A. Nalbandov and L. E. Card (p. 474) (Univ. Ill.); The Importance of Livability to Wartime Egg Production, by C. D. Carpenter (p. 467); The Influence of Processing by Oiling on the Interior Quality of Shell Eggs After Storage, by J. S. Carver and R. J. Evans (pp. 467-468), and The Calcium and Phosphorus Requirements of Single-Comb White Leghorn Pullets, by R. J. Evans and J. S. Carver (p. 469) (Wash. Expt. Sta.); Egg Production and Mortality of White Leghorns Fed High and Low Protein Rations, by T. B. Clark, T. D. Runnels, J. H. Rietz, and C. E. Weekley, Jr. (p. 468) (W. Va. Sta.); Sexual Activity in Guineaes Subjected to All-Night Light, by G. T. Davis and R. Penquite (pp. 468-469) (Okla. A. and M. Col.); The Experimental Induction of Ovulation in the Domestic Fowl, by R. M. Fraps and T. C. Byerly (p. 469), Growth Rate of Pullets in Relation to Production Characteristics and Viability, by C. D. Gordon (p. 470), Cow Manure as a Source of Certain Vitamins for Growing Chickens, by J. C. Hammond (p. 471), and The Composition of Turkeys of Different Breeds, by H. M. Harshaw, W. L. Kellogg, and R. R. Rector (p. 471) (all U. S. D. A.); Miscellaneous Observations on the A. O. A. C. Vitamin D Assay, by J. C. Fritz and H. R. Halloran (p. 469); Quantitative Requirement of the Hen for Pantothenic Acid, by M. B. Gillis, G. F. Heuser, and L. C. Norris (p. 470), The Comparative Viability of Unselected Leghorns and Strains Bred for Resistance or Susceptibility to the Avian-Leukosis Complex, by F. B. Hutt, J. H. Bruckner, and R. K. Cole (p. 472), The Influence of Different Daily Periods of Illumination Upon the Body Weight of White Leghorn Males, by W. F. Lamoreux (p. 473), Factors Other Than Manganese Required To Prevent Perosis in Chicks, by J. McGinnis, L. C. Norris, and G. F. Heuser (p. 474), X-Ray Radiation in Detection of Fertility in Fresh Eggs, by A. L. Romanoff (p. 477), and The Relationship Between Body Temperature and Genetic Resistance to *Salmonella pullorum* in the Fowl, by J. C. Scholes and F. B. Hutt (p. 477) (all Cornell Univ.); Study of Vitamin D From Different Sources and Its Effect on the Bone Ash Curve, by H. R. Halloran, E. V. Minasian, R. W. Collins, J. H. Hooper, and J. C. Fritz (p. 471); Further Observations on Vitamin D Stability, by J. L. Halpin, J. H. Hooper, E. H. Kramke, and J. C. Fritz (p. 471); Observations on the Shank Pigmentation of Chicks, by V. Heiman and L. W. Tighe (pp. 471-472); The Feeding of Single Massive Doses of Vitamin D to Birds, by J. H. Hooper, J. L. Halpin, and J. C. Fritz (p. 472); Strains of White Plymouth Rocks for Specific Economic Purposes, by R. G. Jaap (pp. 472-473) (Okla. Sta.); Acorns of the Willow Oak (*Quercus phellos*), A Source of Vitamin A Activity, by T. R. King and H. W. Titus (p. 473) (Va. A. and M. Col. and U. S. D. A.); Effect of Season and Heredity on the Incidence of Blood Spots, by I. M. Lerner and W. R. Smith (p. 473) (Univ. Calif.); Hormonal Induction of "Broodiness" in Roosters, by A. Nalbandov and L. E. Card (pp. 474-475); Pastures for Developing Pullets and for Laying Hens, by J. E. Parker and B. J. McSpadden (p. 475), and Seasonal Variation in Semen Production in Male Fowls, by J. E. Parker and B. J. McSpadden (p. 475) (both Univ. Tenn.); Corn Dried Distillers' By-Products in Laying Rations, by R. T. Parkhurst, C. R. Fellers, and J. W. Kuzmeski (p. 475), and The Nutritive Properties and Use of Crab Meal, by R. T. Parkhurst, J. A. Lubitz, M. S. Gutowska, and C. R. Fellers (pp. 475-476) (both Mass. State Col.); The Value of B-Y Riboflavin Supplement for Replacing Dried Skimmilk in an All-Mash Laying Ration, by P. R. Record,

R. M. Bethke, D. C. Kennard, and V. D. Chamberlin (pp. 476-477) (Ohio Sta.); Incubation Studies With Duck Eggs, by C. W. Upp and T. G. Culton (pp. 478-479) (La. Sta.); and Some Physiological and Morphological Comparisons Between Standard Bronze, Broadbreasted Bronze, and U. S. D. A. Small-Type Turkeys, by A. G. Williams (p. 479) (Ohio State Univ.).

**Nutritional experiments with chickens**, A. J. MacDONALD (*Indian Jour. Vet. Sci. and Anim. Husb.*, 11 (1941), No. 3, pp. 207-238).—A mixed cereal ration supplemented with green feed and calcium fed to White Leghorn, Rhode Island Red, and desi chicks to 24 weeks of age gave poor growth, excessive mortality, and poor feed utilization. When this ration was supplemented with skim milk as a drink it proved satisfactory. The best results were obtained when milk alone instead of milk and water were both provided up to 6 weeks of age. Soybean meal as a supplement to the cereal ration improved growth and egg production, but the results were not as good as when skim milk was supplied. This substance was especially important up to 6 weeks of age. The conclusions are based on the results of five experiments with about 100-200 chicks in each.

**Soybean meal in poultry feed**, C. W. CARRICK. (*Ind. Expt. Sta.*). (*Flour & Feed*, 43 (1942), No. 6, pp. 14-15).—In studies with young chicks (E. S. R., 87, p. 697) soybean meal properly processed was found to supply a high quality of protein for supplementing corn, but it and corn were deficient in several mineral and vitamin factors which may be corrected by other common products or pasture.

**Observations on the value of whale-meat meal as a constituent of chick diets, with a note on the influence of added protein on the efficiency of utilization of the gross energy of a ration**, E. T. HATMAN (*Jour. Agr. Sci. [England]*, 32 (1942), No. 2, pp. 179-193).—Whale meat vacuum-dried at 80° C. and a sample dried at 145° were shown, when added to a cereal ration for chicks, to have high biological values as ascertained by slaughter tests. The nutritive values of the whale meat were less affected by the lower temperature of drying, since the average weights of 26 chicks fed for 5 weeks with the vacuum-dried meal on a ration with a 17-percent protein level were 466.8 gm. as contrasted with 406.2 gm. for a group in which whale meal dried at 145° was substituted. Outbreaks of feather picking occurred in the whale meal groups for the same reasons as previously noted for gizzard erosion (E. S. R., 87, p. 262). The details and weights of the individual birds at 5-week intervals and the composition of the carcasses of individual birds are presented.

**The value of dairy products in nutrition, I, II** (*Poultry Sci.*, 21 (1942), No. 5, pp. 387-406).—Two papers are presented.

**I. Basal rations for chick assays**, R. A. Sullivan, E. Reeves, E. Bloom, and W. Rateike (pp. 387-395).—A basal ration of cereal products with casein and lactose was found to promote growth to an average weight of 232 gm. in Single-Comb White Leghorn cockerels at 8 weeks of age. When supplemented with filtrate factors, liver residue, factor W, and riboflavin, growth to 8 weeks was improved. With the combination of all these supplements the average 8 weeks' weight was 678 gm. A mixture of dairy products consisting of dried buttermilk, dried skim milk, and dried whey gave equal results, but this was further improved by alfalfa meal, liver extracts, and liver residue to produce 8 weeks' weights of over 700 gm. In a 6-week experiment 5 and 10 percent peanut meal as a supplement produced increased growth. In a further experiment a basal ration including 10 percent peanut meal was used in testing supplements of dried whey, yeast, and buttermilk. Each of these showed a definite improvement, but the birds did not feather as rapidly or smoothly. Both yeast and buttermilk appeared to contain factors in addition to riboflavin. Several combinations in basal rations were compared with chicks to 8 weeks of age.

In these tests more than 10 percent peanut meal without reducing the oat products and including alfalfa extract was tested. As a result a ration consisting of 20 percent oatmeal, corn meal 10, wheat bran 10, wheat middlings 10, ground oats 10, peanut meal 15, purified casein 10, lactose 5, salt mix 5, and oils (soybean oil, alfalfa extract, and cod-liver oil) 5 percent, was employed. Markedly subnormal growth was produced on the basal ration alone, but when supplemented with whey growth equal to that on a practical ration was attained.

II. *Growth factors for chicks*, R. A. SULLIVAN, E. BLOOM, E. REEVES, and W. RATELKE (pp. 396-406).—In experiments on growth of Single-Comb White Leghorn day-old chicks to 5-8 weeks of age, it was shown that dairy products contained in addition to riboflavin growth factors similar to a crude preparation of the W factor needed in poultry mash. The presence in dairy products of a factor in yeast was noted as a possible explanation of the extra growth obtained with the dairy products. Other experiments indicated that milk may contain an as yet unidentified member of the filtrate fraction. Dairy products seemed to be deficient in choline. The studies were conducted with chicks receiving heated and unheated rations compounded as in the previous investigation, and with various supplements of dairy products, pantothenic acid, the W factor, and yeast and liver extracts and residues.

The effects of feed supplements in the economy and efficiency of poultry feeding (*Rhode Island Sta. Rpt.* [1941], pp. 31-32).—Results are briefly reported with six pens of pullets of the effects of buttermilk, cereal grasses, and grass juice on the hatchability, percentage of thick albumin, and yolk color of the eggs produced.

A liver concentrate as a source of unrecognized vitamins required by the chick, L. R. RICHARDSON, A. G. HOGAN, and R. J. KARRASCH. (Mo. Expt. Sta.). (*Jour. Nutr.*, 24 (1942), No. 1, pp. 65-72, fig. 1).—Chicks on a basal ration containing the known vitamins grew slowly and developed perosis (E. S. R., 85, p. 674), but in further studies it was found that fuller's earth at a pH of 1.0 adsorbed unrecognized substances from a water extraction of liver and normal growth was promoted. Additions of water extract of the liver plus 0.1 percent biotin or 1 percent fuller's earth eluate furnished the needed supplement to the basal ration for groups of 10-22 chicks of each sex up to 6 weeks of age.

Sunlight lamps for laying hens, F. E. MUSSFHL and F. D. YUNG (*Nebraska Sta. Bul.* 344 (1942), pp. 8, figs. 3).—Single-Comb White Leghorn hens were kept in good condition with comparable hatchability and egg production by furnishing daily 100 A. O. A. C. units of vitamin D per hen from fish oil or 2 hours' daily exposure of lots of 125 hens to S-1 or S-4 lamps placed 60 in. from the floor during the interval October 15 to March 15.

Black rot in fresh shell eggs, A. R. WINTER. (Ohio State Univ.). (*U. S. Egg and Poultry Mag.*, 48 (1942), No. 9, pp. 506-509, 520).—Bacterial cultures of black rot eggs incubated at room temperature showed bacteria to be present in 103 of 109 eggs cultured, while molds were present in the other 6 eggs. It was thought likely that these organisms had come from fecal material, soil, and water. It was assumed that the source of infection was dirt on the shell or water used in cleaning the eggs, and the black rot condition was prevented by producing clean eggs. The genera and species of the bacteria found and the success in reculturing in fresh eggs are indicated.

Squab raising, A. R. LEE and S. K. HAYNES (*U. S. Dept. Agr., Farmers' Bul.* 684, rev. (1942), pp. [2]+20, figs. 19).—A revision of the publication previously noted (E. S. R., 33, p. 872).

## DAIRY FARMING—DAIRYING

[Investigations with dairy cattle and milk products by the Ohio Station] (*Ohio Sta. Bul.* 617 (1940), pp. 45-47, 47-49, 50, 70, fig. 1).—Results of investigations are briefly reported on feeds needed per unit of milk produced up to 350 lb. of fat per year; lowering the grain requirements of dairy cattle by hay and pasture feeding; ensiling carrots for milk production; wheat and alfalfa silage compared with alfalfa hay for milk production; ground corn as a preservative for legume silage; irradiation of cows did not increase milk production but increased vitamin D in the milk; no difference in effectiveness on rickets of vitamin D from soft curd and homogenized milk; loss of vitamin C in milk prevented by cold temperature; carotene content of roughages reflected in milk; damage to reproductive organs from vitamin A deficiency; vitamin D content of milks; and increased use of roughages for milk production.

[Pastures and feeding for dairy cattle by the Georgia Coastal Plain Station]. (Partly coop. U. S. D. A.). (*Georgia Coastal Plain Sta. Bul.* 32 (1941), pp. 67-69).—Permanent and annual pasture tests and grain feeding for dairy cattle are briefly presented.

Korean lespedeza seed as a protein supplement for milk production, H. A. HERMAN and A. C. RAGSDALE (*Missouri Sta. Bul.* 451 (1942), pp. 7).—In two reversal feeding trials of 40 days' duration each with 2 groups of 10 dairy cows, 188 lb. of Korean lespedeza seed satisfactorily replaced 75 lb. each of cottonseed meal and soybean meal for milk production and the maintenance of weight. The lespedeza-fed groups produced an average of 29.39 lb. of fat-corrected milk per day, while those on the normal ration produced an average of 29.48 lb. Approximately equal amounts of grain, silage, and hay were consumed by the 2 groups. Digestion trials with 2 Holstein-Friesian heifers indicated that the proteins of ground Korean lespedeza seed were equal to those of cottonseed meal and soybean meal.

War emergency plans for raising calves and heifers, W. E. KRAUSS (*Ohio Sta. Bimo. Bul.* 218 (1942), pp. 149-155).—The nutritive requirements of calves are reviewed, with suggestions as to how essentials may be supplied with emergency feeds.

The cow's udder, W. E. PETERSEN (*Minnesota Sta. Bul.* 361 (1942), pp. 16, figs. 10).—The cow's udder is considered as to its growth, development, evolution, external and internal structure, and circulation, and physiological functioning of milk secretion and milking.

[Investigations of dairy bacteriology] (*Jour. Bact.*, 44 (1942), No. 2, pp. 255-256).—The results of the following papers are abstracted: Observations on Bacteriological Condition of Creamery Water Supplies, by H. F. Long and R. T. Corley (Iowa State Col.), and Influence of Growth at Low Temperature on Heat Resistance of *Lactobacillus bulgaricus*, by J. G. Voss and W. C. Frazier (Univ. Wis.).

Bacteriological control of milk quality, L. LITTLE (*Jour. Milk Technol.*, 5 (1942), No. 4, pp. 221-226).—Three samples of 10 cc. each were taken from 1,200 samples of milk collected at monthly intervals and tested by the methylene blue reductase test in comparison with the oval tube counts of Myers and Pence (*E. S. R.*, 85, p. 661). When testing the milk with 5,000-20,000 and over 20,000 bacteria per cubic centimeter approximately the same results were obtained, but there was an unbelievable difference between the grades of milk. The careless handling of utensils and milking machines was considered responsible for the higher counts after pasteurization, but in many cases raw milk with low bacterial counts was responsible for high counts after pasteurization because of the presence of thermoduric organisms. Heat-resisting bacteria

were poor reducers for the methylene blue and resazurin tests, and therefore their presence with other bacteria may assist in their identification with unsanitary production. The oval tube technic has proven its worth for replacing the standard plate count in routine control studies.

**The plate count and methylene-blue reduction test applied to milk, H. BARKWORTH, J. O. IRWIN, and A. T. R. MATTICK** (*Jour. Dairy Res. [London]*, 12 (1941), No. 3, pp. 265-314, fig. 1).—Comparison of the plate counts of samples of milk showed this method to be slightly less discriminatory than the methylene-blue reduction test observed every 5 min. but more sensitive than the methylene-blue test observed every half hour. Miscellaneous, special, and inspected milk samples were investigated singly and in duplicate after different periods of treatment and when the plate counts were made on different kinds of media and for samples collected and stored for different intervals. The agreement between the methylene-blue test and the plate count was better than 80 percent. Reduction time for a given plate count was affected by season (winter or summer), time of milking (morning or evening), and by age of the sample. Comparable results were obtained from the plate count, the methylene-blue test, and the fat test (Gerber) when the standard technic was rigorously adhered to. Comparable results of keeping quality as ascertained by the methylene-blue test at 15.5° C. were obtained between specific laboratories but not for general application. Minor changes in production did not affect plate count or reduction time, but higher correlations were found in summer than in winter milk. Addenda including statistical analyses of the different methods are included. Because of the ease of conducting and repeating, the methylene-blue reduction test is preferred. The studies were based on results obtained at four different laboratories.

**Dye reduction in milk related to Eh, pH and dissolved gases, J. M. FRAYER** (*Vermont Sta. Bul.* 498 (1942), pp. 34, figs. 15).—Further study of dye reduction in milk (E. S. R., 83, p. 816) led to the tentative conclusion that the high sensitivity of the resazurin dye reaction and the possible occurrence of color changes resulting from factors other than those attributable to a high bacterial content and physiological abnormalities indicated that the methylene-blue test for milk quality is likely to give better results for the average milk plant operator than known modifications of the resazurin test, especially without complete microscopic confirmation. Low count milk in bright sunlight acted the same to resazurin additions as poor quality milk. There was no relation between the moment of dye reduction and the pH. The Eh level at the resazurin pink stage was more variable than that occurring when the dye was fully reduced. In the interpretation of dye reduction tests it cannot be assumed that (1) all cell types in milk have the same influence on dye reduction and dissolved gas depletion; (2) that oxygen is the only gas involved in the resazurin reduction; and (3) that all resazurin color modifications result from abnormalities deleterious to quality. The bacterial growth phase at the moment of the test had much to do with the shape of the curve produced, and temperature was also a factor. Studies were made on divided samples of milk having different acidities, gas contents, cultures present, etc., in establishing the comparative time: potential curves. The studies made included colostrum, reconstituted milk, and milk from animals with mastitis.

**The freezing-point of milk.—I, The freezing-point and solids-not-fat content of the milk of individual cows throughout a period of lactation, R. ASCHAFFENBURG and P. L. TEMPLE** (*Jour. Dairy Res. [London]*, 12 (1941), No. 3, pp. 315-321, figs. 2).—The relative constancy of the freezing point and solids-not-fat content of the milk from three Shorthorn cows over a period of 6 mo. was confirmed. No influence of state of lactation on the freezing point depres-

sion was observed, but ample supplies of spring pasture lowered the freezing point. Extremes were not associated with different stages of the oestrous cycle.

**Thermoduric organisms in relation to high-temperature short-time pasteurization,** F. W. FABIAN. (Mich. State Col.). (*Jour. Milk Technol.*, 5 (1942), No. 4, pp. 237-242).—Four groups of thermoduric bacteria were commonly found in milk which has survived pasteurization, namely, micrococci, streptococci, sarcinae, and bacilli. The cow's udder and improperly cleaned utensils were the principal sources of thermoduric bacteria. The control of thermoduric bacteria is considered to be a producers' problem, while the control of thermophilic bacteria is a dealers' problem. There is included a bibliography of 31 references on thermoduric bacteria and milk pasteurization.

**The influence of ammonia on the development of rancidity in milk,** C. H. CASTELL (*Jour. Milk Technol.*, 5 (1942), No. 4, pp. 195-201, fig. 1).—Small amounts of ammonia were found to lower the surface tension of milk and accelerate the development of rancid flavors at 5° C. It seems doubtful if the concentration of ammonia in the atmosphere of the barn where cows are being milked would ever be a major factor causing rancidity to develop in milk or cream.

**The "cream top" type bottle for laboratory sampling of homogenized milk,** J. LEVINE and R. H. FEINGOLD (*Jour. Milk Technol.*, 5 (1942), No. 4, pp. 202-203, figs. 2).—Methods for sampling homogenized milk to comply with the regulations are presented.

**Problems incident to the production and use of homogenized milk,** G. M. TROUT (Mich. Expt. Sta.). (*Jour. Milk Technol.*, 5 (1942), No. 4, pp. 233-236).—A general discussion of problems arising from and the control of homogenization of milk.

**The rheology of butter, I-III,** R. M. DOLBY (*Jour. Dairy Res. [London]*, 12 (1941), No. 3, pp. 329-349, figs. 7).—Three studies in this series are briefly presented.

I. *Methods of measuring the hardness of butter* (pp. 329-336).—The splitting or crumbling of butter samples caused a lack of reproducibility in the measures of hardness of butter by the Scott-Blair apparatus (E. S. R., 81, p. 102). An improved method has been developed, based on resistance to different sized wires drawn through butter at different temperatures.

II. *The relation between rate of shear and shearing stress. The effect of temperature and of reworking on hardness and on structural viscosity* (pp. 337-343).—A practical measure for hardness of butter was furnished by the ratio of the rate of shear to the load. The viscosity of the butter decreased rapidly as the rate of shear increased at temperatures of 6°-18° C.

III. *The effect of variation in buttermaking conditions on the hardness of the butter* (pp. 344-349).—Cream rapidly cooled after pasteurization made a harder butter than cream cooled less rapidly. The hardness of the butter was not influenced by the type of pasteurizer, temperature of cream during holding and churning, temperature of the wash water, and amount of working.

**A simplification of the Scott Blair-Coppen test for the pitching consistency of cheese curd,** G. W. and M. F. SCOTT BLAIR (*Jour. Dairy Res. [London]*, 12 (1941), No. 3, pp. 322-328, fig. 1).—Extensive study of the pitching test (E. S. R., 85, p. 813) showed that much less accuracy in timing is required to give satisfactory results in Cheddar cheese manufacture than was formerly thought necessary.

**The effect of dextrose and sucrose sugars upon the properties of ice cream,** W. H. E. REID, K. R. MINERT, and C. W. DECKER. (Univ. Mo.). (*Ice Cream Rev.*, 16 (1942), No. 2, pp. 18-21, 46, 50, figs. 5).—Batches of ice cream made up with 10-15 percent sucrose and 5-0 percent dextrose, respectively, showed that the

replacement of sucrose had no significant effect on the acidity, pH, viscosity, or specific gravity of the mix, but ice cream frozen in batch freezers gave a somewhat colder sensation than ice cream frozen in continuous freezers. Macroscopic study of the crystals showed ice cream from the continuous freezer to have a finer and closer texture than ice cream from batch freezers. Ice creams containing dextrose were slightly less sweet than samples made up entirely of sucrose. The resistance of samples of the ice cream melting-down temperatures was related to the dextrose present. Differences in the freezing point would in part explain the differences in the stability of ice creams containing dextrose and sucrose. Smaller ice crystals were present in samples drawn from the continuous freezer at 22° F. which contained sucrose than were present in dextrose samples. The crystalline structure was affected by the temperature at which ice cream was drawn from the freezer. The properties of the ice creams were not appreciably affected by variations in the freezing procedure in different types of freezers.

A method for saving sugar in ice cream manufacture, A. LEIGHTON and O. E. WILLIAMS. (U. S. D. S.). (*Ice Cream Rev.*, 26 (1942), No. 2, pp. 14-15, 40, 42, 44, fig. 1).—Study of methods of saving sugar in ice cream manufacture showed that less than 13 percent did not produce a sufficiently sweet product. Four mixes containing 13 percent with varying quantities of fat and solids-not-fat showed the importance of considering higher overruns to offset increased costs and employing high concentrations of sugar in the water of the mix. This allows the substitution of milk solids for sugar economically feasible. The substitution of other sweetening products for the sucrose is also proposed.

Manual for dairy manufacturing short courses (*Ann Arbor, Mich.: Edwards Bros., 1940, pp. V+266, figs. 3*).—This manual, prepared by the department of dairy manufactures of the Pennsylvania State College, contains much useful information on the testing, manufacturing, and control of dairy products.

## VETERINARY MEDICINE

Approved laboratory technic: Clinical pathological, bacteriological, mycological, parasitological, serological, biochemical, and histological, J. A. KOLMER and F. BOERNER (*New York and London: D. Appleton-Century Co., [1941], 3. ed., pp. XXVII+921, pls. 12, figs. [381]*).—This work, prepared in collaboration with 28 specialists and including laboratory methods to be used by veterinarians, is presented in five sections. Section 1 (pp. 1-51), which consists of 3 chapters, relates to general laboratory methods; section 2 (pp. 52-315), of 11 chapters, to clinical pathological methods; section 3 (pp. 316-579), of 11 chapters, to bacteriological methods; section 4 (pp. 580-688), of 6 chapters, to serological methods; and section 5 (pp. 689-841), of 7 chapters, to chemical methods. Additional methods are given in an appendix (pp. 843-870).

Veterinary surgery notes, E. R. FRANK (*Minneapolis, Minn.: Burgess Pub. Co., 1942, rev., pp. [2]+258, figs. 183*).

[Work in animal pathology and parasitology by the Ohio Station] (*Ohio Sta. Bul. 617* (1940), pp. 47, 58-59, 71-72).—The work of the year reported (*E. S. R.*, 83, p. 540) relates to the failure of artificial sunlight to control Bang's disease, the shedding of mastitis germs by apparently normal cows, tetrachloroethylene or a combination copper sulfate-nicotine sulfate the best control for gastrointestinal parasites of sheep, and the rotation of sheep and cattle on pasture as an aid in parasite control.

[Work with animal diseases by the Rhode Island Station] (*Rhode Island Sta. Rpt. [1941], pp. 32-34*).—The work of the year (*E. S. R.*, 85, p. 815) reported

upon relates again to infectious coryza (*H[emophilus] gallinarum*) infection, infectious bronchitis, and autopsy examinations of fowl and small animals.

**Agricultural research in Great Britain—animal diseases** (In *Agricultural Research in Great Britain*. London: Agr. Res. Council, 1942, pp. 64-74).—A brief presentation of investigational work under way with diseases and parasites of livestock in Great Britain.

[Contributions on endoparasites] (*Helminthol. Soc. Wash. Proc.*, 9 (1942), No. 2, pp. 56-63, 65-74, figs. 3).—Contributions presented include the following: Early Natural Infections of Suckling Pigs With Helminth Parasites, by J. S. Andrews and J. W. Connelly (pp. 56-57), Observations on Fatalities in Sheep Caused Primarily by Heavy Natural Infections With the Stomach Worm *Haemonchus contortus*, by K. C. Kates (pp. 57-60), On the Survival of the Preparasitic Stages of the Cattle Lungworm on Pastures, by D. A. Porter (pp. 60-62), Death of Pigs Associated With the Presence in the Heart Tissue of Larvae of *Strongyloides ransomi*, by L. A. Spindler and C. H. Hill (pp. 62-63), New Host-Parasite Records (p. 65) and A New Nematode, *Skrjabinema parva* (Nematoda: Oxyuroidea), From Deer (pp. 66-68), both by G. Dikmans, The Occurrence of *Bartonella* in Cases of Anaplasmosis and in Apparently Normal Cattle, by J. C. Lotze and G. W. Bowman (pp. 71-72), Earthworms as Possible Intermediate Hosts of *Capillaria caudinflata* of the Chicken and Turkey, by R. W. Allen and E. E. Wehr (pp. 72-73), and The Occurrence in the United States of the Turkey Ascarid *Ascaridia dissimilis* and Observations on Its Life History, by E. Wehr (pp. 73-74) (all U. S. D. A.); and Inoculations With *Trichomonas foetus* (Protozoa) in White Rats and Mice, by B. B. Morgan (pp. 68-71) (Univ. Wis.).

**Studies on brucellosis in Mexico: Comparative study of various diagnostic tests and classification of the isolated bacteria**, M. RUIZ CASTANEDA, R. TOVAR, and R. VELEZ (*Jour. Infect. Diseases*, 70 (1942), No. 2, pp. 97-102, figs. 2).—The classification of 150 strains of *Brucella* in 200 patients in Mexico revealed 143 as *B. melitensis*, 5 *B. abortus*, and 2 *B. suis*.

**The Brucella complement fixation reaction**, B. WISE and H. W. CRAIG (*Jour. Infect. Diseases*, 70 (1942), No. 2, pp. 147-151).—It is concluded that in general the *Brucella* complement fixation reaction possesses no advantage over the more easily performed agglutination test. However, because the appearance of complement-fixing antibodies frequently precedes that of agglutinins, complement fixation may be occasionally useful for the diagnosis of acute brucellosis. *Brucella* polysaccharide, brucellin, and brucellergin have been found to provoke the appearance of complement-fixing antibodies when injected intravenously into rabbits and intracutaneously into humans.

**Studies on the transmission of lymphocytic choriomeningitis virus by arthropods**, A. MILZER (*Jour. Infect. Diseases*, 70 (1942), No. 2, pp. 152-172, figs. 3).—In work with the guinea pig the transmission of lymphocytic choriomeningitis by the yellow-fever mosquito occurred by bite when the mosquitoes were incubated at various constant temperatures ranging from 26° to 34° C., while no virus was detected in mosquitoes incubated at 25° and lower or at 37°. Best results in transmission were obtained with mosquitoes kept at 28°, 30°, and 32°. Successful transmission occurred at periods of time varying from 7 to 38 days following the infective blood meal. Six attempts to transmit lymphocytic choriomeningitis from infected to normal guinea pigs by the northern house mosquito and *Aedes albopictus* incubated at room temperature (22°-25°) at intervals ranging from 5 to 15 days were unsuccessful. Successful transmission of lymphocytic choriomeningitis from infected to normal guinea pigs by means of bedbugs incubated at 22°-25° was obtained in 11 of 18 attempts at intervals of time ranging from 10 min. to 85 days. In one instance transmission of the virus from an infected mouse to a normal guinea pig by bedbugs after 16 days

had clapsed was demonstrated. Both male and female bedbugs as well as first-stage larvae were able to transmit the virus. Evidence was presented showing that bedbugs are unable to transmit infection by bite alone and that transmission usually occurs only when the bugs are allowed to defecate on the bitten area. Virus was detected in dried feces collected from infected bedbugs as long as 85 days from the time of infection. Infection was also transmitted by rubbing infected bug feces on the lightly scarified skin of normal guinea pigs. One experiment was made showing that virus may persist through molting from first to second larval stages, but not when the same bedbug lot molted to the third and fourth larval stages. Transovarial transmission of the virus to subsequent larvae was demonstrated in one instance, but two attempts to repeat this experiment were unsuccessful. Attempts to transmit infection by forcing mice and guinea pigs to swallow living, infected bedbugs in gelatin capsules failed. One successful transmission experiment was done under conditions which approximated those occurring in nature.

One attempt to transmit lymphocytic choriomeningitis from an infected to a normal rhesus monkey by uncontrolled feeding of rhesus monkey lice (*Eupodiscinus longiceps* (Paiget)) failed. The virus, however, was shown to survive for at least 24 hr. in infected monkey lice incubated at 22°-25°. Four attempts to transmit lymphocytic choriomeningitis by uncontrolled feeding of infected mites (*Atricholaelaps glasgowi* (Ewing)) incubated at room temperature on normal mice at intervals ranging from a few minutes to 25 days gave negative results. The virus, however, was shown to survive for at least 25 days in infected mites. Successful transmission was obtained by forcing mice and guinea pigs to swallow living infected mites in gelatin capsules.

**Encephalomyelitis in Saskatchewan, 1941 (preliminary report),** R. O. DAVISON (*Canad. Pub. Health Jour.*, 33 (1942), No. 8, pp. 388-398, figs. 2).—An account of an epidemic of this disease in man in the summer of 1941 due to the western type.

**Western equine encephalitis,** G. D. W. CAMERON (*Canad. Pub. Health Jour.* 33 (1942), No. 8, pp. 383-387).—A discussion of this disease, particularly as it applies to Canada.

**Mosquitoes and encephalitis in the Yakima Valley, Washington, I-V** (*Jour. Infect. Diseases*, 70 (1942), No. 3, pp. 263-283, figs. 4).—This contribution appears in five parts.

I. *Arthropods tested and recovery of western equine and St. Louis viruses from Culex tarsalis Coquillett*, W. M. HAMMON, W. C. REEVES, B. BROOKMAN, and E. M. IZUMI (pp. 263-266) (Univ. Calif., Wash. State Col., U. S. D. A., et al.).—During a 4-mo. period in the summer of 1941, 15,610 living arthropods, of which 12,466 were mosquitoes, were collected, frozen, and inoculated into laboratory animals for the purpose of virus isolation. From *C. tarsalis* three strains of St. Louis encephalitis virus and five strains of western equine encephalomyelitis virus were isolated. No virus was isolated from other species of mosquitoes, though the samples of *Aedes*, *Theobaldia*, and *Anopheles* were of such order that, had infection rates been equal to those of *Culex*, isolations would have been probable. During the period of 41 days when all infected mosquitoes were caught at least 1 of every 386 *C. tarsalis* was infected and at least 1 of every 813 of all mosquitoes caught. Final identification of viruses was by neutralization tests with specific hyperimmune serums.

II. *Methods for collecting arthropods and for isolating western equine and St. Louis viruses*, W. M. HAMMON, W. C. REEVES, and E. M. IZUMI (pp. 267-272) (Univ. Calif., Wash. State Col., U. S. D. A., et al.).—Methods for obtaining

suitable live specimens of certain arthropods for virus isolation, together with methods of handling for identification, are described.

**III. Feeding habits of *Culex tarsalis* Coq., a mosquito host of the viruses of western equine and St. Louis encephalitis.** F. B. Bang and W. C. Reeves (pp. 273-274) (Univ. Calif., Wash. State Col., U. S. D. A., et al.).—Through precipitin tests it was demonstrated that *C. tarsalis* feeds in nature on cows, horses, man, pigs, dogs, chickens (other birds?), and sheep. It is pointed out that if this species is demonstrated to be an efficient vector of western equine and St. Louis viruses of encephalitis this widespread feeding makes it possible for it to spread the infection among many mammals and birds.

**IV. A trap for collecting live mosquitoes.** W. C. Reeves and W. M. Hammon (pp. 275-277) (Univ. Calif.).—Description and illustrations are given of a trap that was designed for the collection of live mosquitoes during an extensive field survey.

**V. Summary of case against *Culex tarsalis* Coquillett as a vector of the St. Louis and western equine viruses.** W. M. Hammon, W. C. Reeves, B. Brookman, and C. M. Gjullin (pp. 278-283) (Univ. Calif., Wash. State Col., U. S. D. A., et al.).—The evidence here reviewed indicates that *C. tarsalis* is the most important vector of western equine and St. Louis encephalitis viruses in the Yakima Valley. Its possible role elsewhere will have to be judged on the basis of local observations. A summary of experimental arthropod transmission of the western type of the equine encephalomyelitis virus given in tabular form reveals (1) its transmission by nine species of mosquitoes (*Aedes* spp.), the bloodsucking conenose, and a tick (*Dermacentor andersoni*) and (2) nontransmission by six other mosquitoes (*Aedes* three, *Anopheles* two, *Culex* one), a reduviid bug (*Triatoma rubida* Uhler), three flies (*Lyperosia*, *Tabanus*, *Stomoxys*), the cat flea, and *Diphanus montanus*.

**Studies on eastern equine encephalomyelitis.—VI. Facilitation of infection in the mouse.** L. S. KING (*Jour. Expt. Med.*, 76 (1942), No. 4, pp. 325-334, figs. 2).—In continuation of these studies (*E. S. R.*, 82, p. 683) 50 percent glycerine injected intraperitoneally, intramuscularly, or intravenously was found to enhance greatly the activity of equine encephalomyelitis virus injected intramuscularly, increasing its virulence up to a hundredfold. The same effect is produced by very concentrated sodium chloride. The result appears due to dehydration of the nervous system, suddenly produced. Gradual withdrawal of body fluids, produced by depriving animals of drinking water, results in sharp concentration of the blood, equal to that produced by glycerine or salt, but such deprivation of water alone does not result in significant dehydration of the brain nor does it have any effect on virus action. The facilitation effect is not produced by drastic procedures involving shifts of electrolytes without loss of total water from the brain. Glycerine has no facilitating action when the virus is administered intranasally or intraocularly, suggesting a fundamental difference in pathogenesis between these routes and the intramuscular.

**Search for sources and carriers of equine encephalomyelitis virus.** R. GWATKIN and I. W. MOYNIHAN (*Canad. Jour. Res.*, 20 (1942), No. 11, Sect. D, pp. 321-337).—Examinations were made of the brains of many fowl and mammals and the spleens of several others, also many insects and ticks, but only two ground squirrels were found infected with the equine encephalomyelitis virus. This is said to be the second occasion on which results have suggested the presence of virus in a very small amount in ground squirrel brains (*E. S. R.*, 85, p. 824).

**Induced resistance of the central nervous system to experimental infection with equine encephalomyelitis virus.—I. Neutralizing antibody in the central nervous system in relation to cerebral resistance.** I. M. MORGAN, R. W.

SOHLESINGER, and P. K. OLITSKY (*Jour. Expt. Med.*, 76 (1942), No. 4, pp. 357-369, figs. 2).—Neutralizing antibody to equine encephalomyelitis virus was found in the spinal fluid of rabbits sufficiently vaccinated with active or formalin-inactivated virus. Antibody was specific for the western or for the eastern virus. Neutralizing capacity of spinal fluid was equivalent to that of a 1:300 dilution of serum of the same animal and was of the same order of magnitude as that of perfused brain of a vaccinated animal. Vaccinated rabbits which showed antibody in the spinal fluid resisted intracerebral or intracisternal injection of active virus. This immunity was specific, i. e., there was no cross-reaction between the eastern and western virus after vaccination with formalin-inactivated virus. On the other hand, lack of antibody in the spinal fluid, even when antibody was demonstrable in the undiluted serum, was associated with lack of cerebral resistance.

**The starling (*Sturnus vulgaris* L.) and foot-and-mouth disease**, W. S. BULLOUGH (*Roy. Soc. [London], Proc., Ser. B*, 131 (1942), No. 862, pp. 1-12, figs. 9).—Circumstantial evidence is presented which suggests the possibility of a connection between the starling and the occurrence of unexplained outbreaks of foot-and-mouth disease. The starling is singled out as the one common species of bird in the British Isles which is intimately connected with cattle, and it is shown that striking correlations exist between the migrations, movements, and distribution of this species and the geographical and monthly incidence of the disease. An attempt is also made to analyze the position of foot-and-mouth disease in Finland, Sweden, and Denmark. In the case of Sweden, where the starling is absent in autumn and winter, a graph is obtained which is the reverse of that for the British Isles where, in autumn and winter, the starling is most numerous.

**Starling movements and the spread of foot-and-mouth disease**, W. S. BULLOUGH (*Nature [London]*, 149 (1942), No. 3790, pp. 683-685, figs. 3).—This contribution is based upon the study above noted.

**Experimental infection of the chick embryo with the virus of pseudo-rabies**, F. B. BANG (*Jour. Expt. Med.*, 76 (1942), No. 3, pp. 263-270, pls. 2).—The chick embryo responds to experimental infection with the virus of pseudo-rabies with a disease pattern simulating the natural infection. Virus lesions of the membrane are followed by infection of all tissues of the central nervous system.

**Studies on the *Salmonella* group: Methods of isolation and pathogenicity of strains occurring in the intestines of chickens**, W. L. MAILMAN, J. F. RYFF, and E. MATTHEWS. (Mich. Expt. Sta.). (*Jour. Infect. Diseases*, 70 (1942), No. 3, pp. 253-262).—Methods used for the isolation of *Salmonella* from man were found by the authors to be applicable to avian intestinal contents. A combined method using tetrathionate broth as an enrichment medium and either MacConkey's agar or bismuth sulfite agar as differential media is described. The need of a selective medium to isolate *Salmonella* from intestinal contents and feces is apparent from the results obtained where organisms of the *Salmonella* and *Escherichia* groups were mixed. The latter obscures or overgrows the *Salmonella* organisms when no inhibitory agent is present. The following organisms were isolated from the intestinal contents or feces of chickens: *S. aberdeen*, *S. give*, *S. californica*, *S. worthington*, *S. oranienburg*, *S. paratyphi* B, *S. new brunswick*, *S. urbana*, *S. hvittingfoss*, *S. muenchen*, and *S. pullorum*. Of the species isolated, *S. californica*, *S. urbana*, *S. aberdeen*, *S. give*, and *S. hvittingfoss* have not previously been reported from chickens. A total of 204 birds were examined in this study using the recommended technic and media for isolation of *Salmonella*. From the intestinal tracts of 48 of these, 72 strains of organisms were isolated which were found to belong to the *Salmonella* group. Twenty-two birds carried

*Salmonella* other than *S. pullorum*; 35 of the strains were *S. pullorum*. None of the salmonellas isolated from chicken intestinal contents or feces showed any pathogenicity for monkeys (*Macacus rhesus*) when fed in excessive doses.

**A group of coliform bacilli serologically related to the genus *Salmonella*, C. A. PELUFFO, P. R. EDWARDS, and D. W. BRUNER.** (Ky. Expt. Sta.). (*Jour. Infect. Diseases*, 70 (1942), No. 2, pp. 185-192).—Description is given of a group of seven paracolou strains which possess flagellar antigens closely related to those of *S. dusseldorf* and *S. cerro*. The seven strains, the majority of which were isolated from diseased animals, composed five serologic types whose antigenic composition was determined. All the bacilli fermented lactose slowly and liquefied gelatin. They are Enterobacteriaceae whose biochemical properties do not coincide with those of any of the genera now recognized.

**New epidemiological aspect of spotted fever in the Gulf coast of Texas, L. ANIGSTEIN and M. N. BADER** (*Science*, 96 (1942), No. 2494, pp. 357-358).—Report is made of several cases of spotted fever in an area of the Gulf coast of Texas, apparently transmitted by the lone star tick.

**On penicillin, K. MEYER, E. CHAFFEE, G. L. HOBBY, M. H. DAWSON, E. SCHWENK, and G. FLEISHER** (*Science*, 96 (1942), No. 2479, pp. 20-21).—Description is given of a method for the extraction from *Penicillium notatum* of penicillin, a powerful antibacterial substance discovered by Fleming<sup>7</sup> in 1929. Compared to other naturally occurring bactericidal substances like pyocyanine, gliotoxin, gramicidin, or actinomycin, the isolation of penicillin proved rather difficult. This is due to the great instability of the agent and to the simultaneous production by the mold of many yellow pigments of similar chemical properties which are practically inactive as bactericidal agents. Reference is made to the remarkable chemotherapeutic effect of purified penicillin, coupled with a low toxicity, as reported by Chain and his associates in 1940.<sup>8</sup>

**Activity of penicillin in vitro, G. L. HOBBY, K. MEYER, and E. CHAFFEE** (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 277-280).—The findings here reported confirm the observations of H. W. Florey et al.<sup>9</sup> on the antibacterial activity of penicillin against gram-positive organisms. Preparations have been obtained of such activity that 0.03γ inhibits the growth of 2 to 4 million hemolytic streptococci. This represents an equivalent of 240-250 Oxford units per milligram.

**Observations on the mechanism of action of penicillin, G. L. HOBBY, K. MEYER, and E. CHAFFEE** (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 281-285, figs. 3).—In continuation of earlier work (see above), it was shown that penicillin acts either as a bacteriostatic or bactericidal agent depending on the experimental conditions. The number of organisms decreases at a constant rate until 99 percent of the organisms have been destroyed. The rate of killing varies with different organisms. The action of penicillin on hemolytic streptococci is not accompanied by lysis of the organisms. No detectable amount of penicillin is destroyed or absorbed from solution by the organisms. It appears to be effective only when active multiplication takes place.

**Chemotherapeutic activity of penicillin, G. L. HOBBY, K. MEYER, and E. CHAFFEE** (*Soc. Expt. Biol. and Med. Proc.*, 50 (1942), No. 2, pp. 285-288).—Penicillin has been shown to be highly effective against hemolytic streptococcus and pneumococcus infections in mice when given subcutaneously, intravenously, or intraperitoneally. When given in the form of oil suspensions or dry pellets, a single subcutaneous injection confers a high degree of protection. Penicillin is apparently nontoxic within the range of therapeutic dosage.

<sup>7</sup> Brit. Jour. Expt. Pathol. 10 (1929), No. 3, pp. 226-236, figs. 4.

<sup>8</sup> Lancet [London], 1940, II, No. 8, pp. 226-228.

<sup>9</sup> Lancet [London], 1941, II, No. 7, pp. 177-188, 189, figs. 8.

**Chronic toxicity of diphenylene sulfide to the albino rat,** J. O. THOMAS, F. DEEDS, and A. J. COX. (U. S. D. A. et al.). (*Food Res.*, 7 (1942), No. 2, pp. 161-169, fig. 1).—The continued feeding of diphenylene sulfide to young male albino rats for 165 days resulted in lessened growth rates on concentrations of 0.10 and 0.05 percent, but not on 0.025 percent, in the diet. Food consumption decreased as the slopes of the growth curves decreased and varied inversely with the concentration of diphenylene sulfide in the diet. Retardation of growth on the 0.05-percent dosage level was due to the decrease in food intake. Even on the diet containing 0.10 percent diphenylene sulfide inanition was chiefly responsible for the inhibition of growth. The spleens of the experimental animals decreased in weight as the dose of the sulfide increased. The histology of the organ, however, remained normal. A light brown pigmentation of the epithelial cells of the proximal convoluted tubules of the kidneys was seen. There was no evidence of cell destruction or of blood injury.

**Control of sheep diseases,** R. R. DYKSTRA, L. M. RODERICK, J. W. LUMB, H. FARLEY, and J. H. WHITLOCK (*Kansas Sta. Cir.* 212 (1942), pp. 19).—A practical account of the diseases of sheep and their control.

**The occurrence of uncomplicated cobalt deficiency of sheep in South Australia,** I. W. McDONALD (*Austral. Vet. Jour.*, 18 (1942), No. 3, pp. 107-115, figs. 5).—Evidence is presented of the occurrence of a simple dietary deficiency of cobalt in sheep in South Australia. There was no evidence that a deficiency in copper was involved.

**The efficacy of cobaltized salt for the prevention of cobalt deficiency symptoms in sheep,** J. E. BOWSTEAD, J. P. SACKVILLE, and R. D. SINCLAIR (*Sci. Agr.*, 22 (1942), No. 8, pp. 479-481, fig. 1).—The feeding of cobaltized salt was as satisfactory as the feeding of cobalt chloride in solution to thrifty sheep on a low cobalt ration, as evidenced by the similarity in average growth, reproduction, and fleece weights of the two groups. Under the conditions of the trial the use of a cobaltized salt mixture containing 4 oz. of cobalt chloride per ton of salt provided 64 percent as much cobalt as when 8 mg. of cobalt in solution was fed weekly. This lower cobalt intake was sufficient to maintain the ewes in as satisfactory a condition as when larger amounts were administered in solution.

**Enzootic ataxia and copper deficiency of sheep in Western Australia,** H. W. BENNETTS and A. B. BECK (*Austral. Council Sci. and Indus. Res. Bul.* 147 (1942), pp. 52).—This summary of enzootic ataxia, a disease of the unweaned lamb characterized clinically by a failure of coordination of muscles of the hind limbs and pathologically by demyelination of the nervous system, a typical degeneration of the spinal cord being pathognomonic, is followed by a discussion of the effect of copper deficiency in adult sheep. A low copper status of the mothers (liver, blood, and milk) and of the affected progeny (liver and blood) has been constantly demonstrated in all cases investigated. The disease is prevented by administration of copper supplements to the mother, and in the lamb the course of the disease is arrested by copper treatment. Copper promotes optimal growth in lambs and has a marked beneficial effect on the adult members of the flock, anemia and other signs of ill health being absent in the breeding ewe and wool growth being normal throughout. A list is given of 53 references.

**Urinary calculi in sheep: A short review of relevant literature,** W. I. B. BEVERIDGE (*Austral. Vet. Jour.*, 18 (1942), No. 3, pp. 127-132).—This review is presented with 19 references to the literature.

**The parasitic worms of sheep in Scotland and their control,** D. ROBERTSON (*Highland and Agr. Soc. Scot. Trans.*, 5. ser., 54 (1942), pp. 54-79, figs. 8).

**Survival of sheep nematodes in pastures,** D. A. SHORB. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 7, pp. 329-337).—The importance of pasture rota-

tion for the control of gastrointestinal parasites of sheep led to the experimental work with their more important nematode parasites conducted at the Beltsville Research Center in 1938-39 here reported. In the first experiments on summer pastures it was shown that the time necessary for the pastures to become free from preparasitic stages of the nematodes originally present was less than 3.5 mo. The second experiment reduced this period to less than 2.5 mo. The third experiment showed that the time may be only 2 mo., and that even the presence of an abundance of shade and a heavy growth of grass may not protect the early stages of the nematodes. In the winter or late fall there was no development to infectivity of preparasitic stages of ovine nematodes, but a small number of *Ostertagia* and *Trichostrongylus* in the egg or preinfective larval stage survived and developed to the infective stage the following spring. There was evidence that preinfective stages of *Nematodirus* and *Ostertagia* survived the cold weather of early spring but did not become infective until late in the spring. Eggs of *Trichuris ovis* survived on the pasture for as long as 3.5 mo. in summer.

**Listerellosis in a goat**, R. GIFFORD and D. F. EVELETH. (Ark. Expt. Sta.). *Jour. Amer. Vet. Med. Assoc.*, 101 (1942), No. 788, pp. 413-417, figs. 3).—Description is given of a case of listeriosis, or "circling disease," in a goat from northwestern Arkansas. *Listeria monocytogenes* was isolated from the brain of this animal. Its morphology, motility, cultural characteristics, biochemical behavior, pathogenicity, and agglutination reactions are outlined in detail.

**Diseases of swine**, C. G. GREY and C. N. DALE (*U. S. Dept. Agr., Farmers' Bul.* 1914 (1942), pp. 32, figs. 7).—This practical account supersedes *Farmers' Bulletin* 1244 (E. S. R., 49, p. 787).

**A study of hemolytic streptococci from a horse treated with sulfanilamide after streptococcal bacteriemia developed during immunization**, J. L. HENDRY (*Jour. Infect. Diseases*, 70 (1942), No. 2, pp. 112-118, figs. 4).—"Hemolytic streptococci isolated from the blood taken the day before death from a horse under treatment for 10 days with sulfanilamide for streptococcal bacteriemia were found to be considerably more resistant in vitro to the action of sulfanilamide than the standard culture with which the horse was being immunized. Those recovered from one of the heart valves at autopsy appeared to be definitely less resistant than those from the blood but more resistant than the standard strain. The hemolytic streptococci from the spleen were found to be markedly susceptible to the action of the drug. Evidence was obtained that the resistance of the micro-organisms in the blood to sulfanilamide increased progressively during therapy. There was apparently no decrease after 14 mouse passages in the resistance to the drug of the one culture tested. Sulfanilamide-inhibiting activity was demonstrated in broth filtrates of the standard strain as well as of the streptococci from the blood, heart, and spleen. The inhibiting activity was produced sooner by the drug-resistant micro-organisms. The presence of a primary aromatic amine in the filtrates was not detectable."

**Rabies**, L. T. WEBSTER (*New York: Macmillan Co.*, 1942, pp. VI+168, figs. 8).—In part 1 of this work the diagnosis of rabies is presented in six chapters and in part 2 the prevention of rabies in four chapters. A 13-page list of references is included, and additional data, including tables on the immunizing potency of antirabies vaccine, are given in appendixes.

**Estudios inmunológicos sobre la pluralidad de los virus rábicos en Venezuela (Immunological studies on the plurality of rabies viruses in Venezuela)**, V. KUBES and F. GALLIA (*Bol. Inst. Invest. Vet. [Venezuela]*, 1 (1942), No. 1, pp. 45; *Eng. abs.*, pp. 43-45).

**Experimental nicotinic acid deficiency in the adult silver fox**, A. Z. HODSON and J. K. LOOSLI. (U. S. D. A., Cornell Univ., et al.). (*Vet. Med.*, 37 (1942),

No. 11, pp. 470-473, figs. 3).—"Nicotinic acid deficiency was produced experimentally in 10 adult silver foxes. The symptoms of the deficiency are inflamed and pus-filled areas in the cheek and around the teeth—more rarely on the tongue, refusal of food, gastrointestinal hemorrhage, and finally a collapse condition in which the animal has become completely relaxed and at least partially unconscious. Five animals which received oral administration of nicotinic acid before the collapse stage of the deficiency was reached recovered completely. Five animals which reached the collapse stage, even though nicotinic acid was given to 3 of them, died. Other than the collapse of the animal, there is no clear line of demarcation between the mild and severe deficiency, as the degree of mouth inflammation varies from animal to animal and often recedes slightly in the collapse stage."

**Spontaneous coccidioid al granuloma in the lungs of wild rodents**, L. L. ASHBURN and C. W. EMMONS (*Arch. Pathol.*, 34 (1942), No. 5, pp. 791-800, figs. 3).—A further report of findings in rodents trapped in the desert around San Carlos, Ariz. (E. S. R., 86, p. 828).

**A serological study of some avian relationships**, R. J. DEFALCO. (Rutgers Univ.). (*Biol. Bul.*, 83 (1942), No. 2, pp. 205-218, fig. 1).

**The immunization of fowls against mosquito-borne Plasmodium gallinaceum by injections of serum and of inactivated homologous sporozoites**, P. F. RUSSELL and B. N. MOHAN (*Jour. Expt. Med.*, 76 (1942), No. 5, pp. 477-495, fig. 1).—Report is made of attempts to immunize domestic fowls against mosquito-borne infections of *P. gallinaceum* by means of (1) vaccination with inactivated homologous sporozoites, (2) injections of serums, both normal sheep serum and serum from fowls chronically infected with homologous *Plasmodium*, and (3) combinations of both sporozoite vaccine and serum. "It was possible to reduce the normal malaria death rate (55.4 percent) in these fowls by each of the above methods but most markedly by the combined prophylactic treatment. Mortality rates were 21.1 percent in vaccinated fowls, 16.7 percent in serum-treated fowls, and 7.3 in those having the combined treatment. Intensity of infection was measured by counting the percentage of red cells infected each day. It was found that in each group of fowls having prophylactic treatment the average of highest percentages of red cells infected was less than in untreated malarious fowls (30.1 percent). The average figure was 20.5 percent in vaccinated fowls, 17.9 percent in those having serum injections, and 15.0 percent in those having combined treatment. The prepatent period was not markedly affected by any of the prophylactic procedures. It averaged 9.1 days in the untreated group, 8.9 days in both the vaccinated and serum-treated groups, and 9.7 days in the group having combined treatment."

**Reciprocal transmission tests with infectious catarrh of chickens, mice, and rats**, J. B. NELSON (*Jour. Expt. Med.*, 76 (1942), No. 3, pp. 253-262).—In observations conducted over a period of 5 yr. infectious catarrh of chickens (fowl coryza of slow onset) was not transmissible to mice or rats by nasal instillation of the specific coccobacilliform bodies. Exudates were also inactive in both rodents on foot pad injection. The infectious catarrhs of the mouse and the rat were reciprocally transmissible by the nasal injection of exudates or tissue cultures of the respective coccobacilliform bodies and by direct contact. Exudates and cultures also produced an arthritic reaction in both hosts on foot pad injection. The coccobacilliform bodies of mouse catarrh were innocuous in chickens on nasal instillation, whereas those of rat catarrh were established locally but were maintained for only two passages. In the opposite host each of the two rodent forms of infectious catarrh reproduced the typical features of the naturally acquired disease, a highly fatal pneumonia being characteristic of the mouse but not of the rat.

## AGRICULTURAL ENGINEERING

[Agricultural engineering investigations by the Ohio Station] (*Ohio Sta. Bul.* 617 (1940), pp. 67-68).—These included work on corn storage, showing, among other results, that corn dried to less than 14 percent moisture content should be placed in tight bins to prevent reabsorption of moisture, although ample ventilation is necessary to prevent molding of green corn (coop. U. S. D. A.); and barn curing experiments, showing that alfalfa hay will undergo about three-fourths of the necessary moisture reduction in about 4 hr. of good field drying, after which the remainder of the necessary drying can be done by means of air driven by a pressure fan through suitable air flues in the barn, with improvement in the nutritional quality of the hay.

Surface water supply of the United States, 1940, parts 1, 2, 3, 5, 8; 1941, parts 7, 9, 10, 12-14 (*U. S. Geol. Survey, Water-Supply Papers* 891 (1942), pp. IX+567, pl. 1; 892 (1942), pp. VIII+441, pl. 1; 893 (1942), pp. IX+662, pl. 1; 895 (1942), pp. VII+340, pl. 1; 898 (1942), pp. VIII+426, pl. 1; 927 (1942), pp. VI+355, pl. 1; 929 (1942), pp. VI+311, pl. 1; 930 (1942), pp. IV+123, pl. 1; 932 (1942), pp. V+214, pl. 1; 933 (1942), pp. VI+246, pl. 1; 934 (1942), pp. V+229, pl. 1).—These papers record measurements of stream flow, No. 891 covering the North Atlantic slope basins, No. 892 the South Atlantic slope and eastern Gulf of Mexico basins, No. 893 the Ohio River Basin, No. 895 the Hudson Bay and upper Mississippi River basins, and No. 898 the western Gulf of Mexico basins for the year ended September 30, 1940; and No. 927 the lower Mississippi River Basin, No. 929 the Colorado River Basin, No. 930 the Great Basin, No. 932 the Pacific slope basins in Washington and upper Columbia River Basin, No. 933 the Snake River Basin, and No. 934 the Pacific slope basins in Oregon and lower Columbia River Basin for the year ended September 30, 1941.

Surface water supply of Hawaii, July 1, 1939, to June 30, 1940 (*U. S. Geol. Survey, Water-Supply Paper* 905 (1942), pp. IV+136).—This report presents measurements of stream and ditch flow in the Territory.

The effect of wall-friction on gravity-waves, M. P. O'BRIEN and A. D. CHAFFIN, JR. (Univ. Calif.). (*Amer. Geophys. Union Trans.*, [23] (1942), pt. 1, pp. 84-87).—The authors show the development of a formula to predict the width of channel necessary to obtain inappreciable energy losses through wall friction for a particular combination of depth and period and length of wave, together with experiments showing that the theory is sufficiently accurate for the purpose.

The expression arrived at is given in the form  $P_1 - P_2 = \int_0^l (N/T) dx$ , in which  $P_1$  is the power transported into the reach at  $x=0$  and  $P_2$  is the power leaving at  $x=l$ ,  $N$  is the dissipation of energy per cycle per unit-length of channel, and  $N/T$  is the average rate of dissipation. Since the power loss is intended to be small, the equation may be rewritten as  $\Delta P/P_1 = (N_1/TP_1) l$ , in which  $(\Delta P/P_1)$  is the fractional permissible power loss and  $N_1$  is the loss per cycle per unit-length of channel at the first station.

Canal lining cured by sprayed coats of white-pigmented compound, O. G. BODEN (*Jour. Amer. Concrete Inst.*, 13 (1942), No. 5, pp. 449-451, fig. 1).—The heat-reflecting characteristics of a white-pigmented compound kept concrete temperatures as low as when the clear-coated concrete was burlap shaded.

Fuel consumed and work performed by farm tractors, A. P. BRODELL and M. R. COOPER (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1942, F. M. 32, pp. [2]+29).—This report summarizes the findings on fuel consumption, acreage plowed, width of plows used, and total time of tractor use in 1940 in the study previously noted (*E. S. R.*, 88, p. 108).

Simple control system for cooling potato storages, T. E. LONG (*North*

*Dakota Sta. Bmo. Bul.*, 5 (1942), No. 1, pp. 8-12, figs. 5).—The author describes a set-up including a differential thermostat of which the elements are placed one in the ceiling inside the storage space, the other outside the building with setting of the thermostat such that the fan is operated whenever the outside temperature is lower by 2° or 3° than that inside the building. A frost-prevention thermostat with sensitive elements in the air intake stops the fan motor when the incoming air reaches a temperature low enough to cause freezing. The wiring arrangements are shown.

**Farm buildings**, D. G. CARTER and W. A. FOSTER (*New York: John Wiley & Sons; London: Chapman & Hall*, 1941, 3. ed., rewritten, pp. IX+404, figs. 222). The third edition of this book has been, like the second (E. S. R., 59, p. 883), very fully revised and rewritten. A series of problems for further study has been added. The contents of the new edition are: Economics and costs of farm buildings; building materials—lumber and logs; concrete—other masonry; miscellaneous building materials; structural requirements; the structure of farm buildings; cost and quantity calculation; arrangement and location of farm buildings; environmental conditions in farm buildings; farm barns—general purpose barns; dairy barns; special purpose barns; poultry housing; swine housing; silos; grain and hay storage; storage and service buildings; farm housing conditions and needs; farmhouse planning; kitchens and storage equipment; house construction—general problems; specifications—details of house construction; and house remodeling.

## AGRICULTURAL ECONOMICS

[Papers and notes on agricultural economics] (*Jour. Farm Econ.*, 24 (1942), Nos. 2, pp. 369-529, figs. 2; 3, pp. 557-703, figs. 8).—No. 2 includes papers on: Legislative and Administrative Reasoning in Economics, by J. R. Commons (pp. 369-391) (Univ. Wis.); Forty Years of Farm Management Research, by J. A. Hodges (pp. 392-401) (Kans. Expt. Sta.); Proposal for Revision of *Agricultural Statistics*, by N. Jasny (pp. 402-419); The Scale of Operations in Agriculture, by R. W. Ruid and D. L. MacFarlane (pp. 420-433) (Univ. Ky.); The Disposal of Agricultural Surpluses, by J. B. Condliffe (pp. 434-446) (Univ. Calif.); Obstacles to Agricultural Production Expansion by R. Schickele (pp. 447-462) (Iowa Sta.); and Schisms in Agricultural Policy—The Shift in Agricultural Policy Toward Human Welfare, by M. Ezekiel (pp. 463-476) (U. S. D. A.), Agriculture as a Commercial Industry Comparable to Other Branches of the Economy, by M. R. Benedict (pp. 476-496) (Univ. Calif.); and Rescue Programs and Managed Agricultural Progress, by J. B. Canning (pp. 496-511), with a discussion by T. W. Schultz (Iowa State Col.) and A. B. Wolfe (Ohio State Univ.). Notes are included on An Economic Analysis of Length of Feeding Period in the Production of Hogs, by R. E. Menze (pp. 518-523) (Iowa State Col.); Relation of Income to Farm Capital, by A. B. Lewis (pp. 523-528) (U. S. D. A.); and An Investigation on Complementarity Relations Between Fresh Fruits—A Rejoinder, by S. Hoos (pp. 528-529).

No. 3 includes papers on: Agricultural Price Policies in War Time, by H. Working (pp. 557-570); New Frontiers of the Great Plains, by C. F. Kraenzel (pp. 571-588) (Mont. Expt. Sta.); Stabilization Operations of the Commodity Credit Corporation, by G. Shepherd (p. 589-610) (Iowa Sta.); Conservation Expenditures on Federal Lands, by A. Z. Nelson (pp. 611-620) (U. S. D. A.); An Ancient Experience With Price Control, by H. Kirchberger (pp. 621-636); A Method of Determining Feasible Irrigation Payments, by H. E. Selby (pp. 637-646) (U. S. D. A.); and Rationing Objectives and Allotments, Illustrated With Sugar Data, by J. J. Kaplan (pp. 647-664) (Iowa Sta.). Notes are included on:

**Economic Aspects of Artificial Insemination of Commercial Dairy Cows**, by A. A. Dowell and L. M. Winters (pp. 665-676) (Minn. Sta.); **The Iowa Statutory Provisions for Automatic Lease Renewal**, by V. B. Sullam (pp. 677-684); **Peasant Farming in India**, by I. W. Moomaw (pp. 685-694); **Determination of Relative Risks Involved in Growing Truck Crops**, by W. K'ing (pp. 694-698) (U. S. D. A.); and **What We Eat**, by L. and P. Williamson (pp. 708-703) (Cornell Univ.).

[**Investigations in agricultural economics by the North Dakota Station**] (*North Dakota Sta. Bimo. Bul.*, 5 (1942), No. 1, pp. 15-20, 32-33).—Included are articles, **Land Values and Transfers in North Dakota**, by M. H. Taylor (pp. 15-18), making analysis of the land transfers in Traill and Ward Counties during the second quarter of 1942 and briefly discussing the factors affecting land values in North Dakota (coop. U. S. D. A.); and **Efficient Transportation Now a Necessity**, by P. V. Hemphill (pp. 18-20), briefly discussing the present transportation conditions in the State and outlining means by which transportation facilities can be conserved. The usual tables of North Dakota farm prices are brought down through August 1942 by Hemphill.

[**Investigations in agricultural economics by the Ohio Station, 1939**]. (Partly coop. U. S. D. A.). (*Ohio Sta. Bul.* 617 (1940), pp. 62-66).—Brief general findings are reported on studies of methods of renting farm lands in the State, the legal aspects of landlord-tenant relationships, the relation of retail prices to quality of fresh and canned fruits and vegetables, and the principal types of egg and poultry handling by cooperative associations. Also included are tables showing the percentage by months of the annual farm income received from different products and the average rates charged for the transportation of hogs to Cleveland by mile zones, 1937-39, by motortrucks and by railroads.

[**Investigations in agricultural economics by the Ohio Station**] (*Ohio Sta. Bimo. Bul.* 218 (1942), pp. 160-162).—An article by C. W. Hauck and J. K. Samuels based on data for 87 independent retail grocery stores in Cincinnati includes and discusses tables showing the relation of percentage of margin to sales of fruits and vegetables and between attractiveness of display and sales. The table of index numbers of production, prices, and income by J. I. Falconer is brought down through July 1942.

[**Investigations in agricultural economics by the Rhode Island Station**] (*Rhode Island Sta. Rpt.* [1941], pp. 3-10).—General findings are reported for studies of (1) the Rhode Island receipts of canned milk in 1940 as compared with 1933-38 and 1921-25; (2) the receipt of fluid milk and consumption in Newport in 1940 as compared with the period 1935-39; (3) the trucking of milk to Providence, which includes receipts, sources of supplies, average number of producers per truck, quantity per producer, hauling charges, possible savings in mileage and costs under a proposed reorganization of the trucking system, etc. (coop. U. S. D. A. et al.); (4) the trends of agriculture in Providence and Bristol Counties; and (5) the production and marketing of potatoes in the State.

**An economic analysis of farming in the Cedar Creek Soil Conservation Demonstration Area, Franklin County, North Carolina, 1935**, R. E. L. GREENE. (Coop. U. S. D. A.). (*North Carolina Sta. Tech. Bul.* 70 (1942), pp. 32, figs. 7).—This report is based on data for the crop year 1935 for 172 farms in the west central part of Franklin County. The area is included in the eastern two-thirds of the Cedar Creek Soil Conservation Demonstration Area established in 1935. The physical, economic, and social characteristics of the county are described, and analysis is made of various factors.

The average size of farm in 1935 was 134 acres, with 43 acres in crops, 14 in idle cropland, 5 in open pastures, and 73 in woods and waste. No definite cropping rotation was followed. In 1935 about 70 percent of the land in corn and tobacco and 90 percent of that in cotton had been in row crops in 1934.

Livestock production in the area was small. The average labor income in 1935 was \$554 per farm. Of the farms, 14 percent had a minus labor income, 37 a labor income of less than \$250, and only 19 percent an income of over \$1,000. The average labor income increased from \$209 for farms using less than 200 man-work units to \$1,181 for those using 600 or more work units. As the acreage in crops increased from less than 25 to 100 or over, the labor income increased from \$304 to \$1,286. The farms with a crop index of less than 85 had an average labor income of \$176 as compared with \$895 for those with a crop index of 100 to 114. With less than 150 work units per man, the labor income was \$305 as compared with \$1,013 with 300 or more units per man. Sixty-six percent of the operators, including croppers, were tenants. Tenants had only about one-half as many acres in crops as owners and part owners. They had lower labor efficiency, lower crop yields, and a slightly higher percentage of the crop area in row crops and a smaller percentage in soil-improving crops.

**Economics of soil conservation in West Virginia, E. C. WETZELL.** (Coop. U. S. D. A.). (*West Virginia Sta. Bul. 305 (1942), pp. 59, fig. 1.*)—"This study concerns the economic feasibility of a definitely planned program of soil conservation on privately owned farm lands which has been demonstrated by the Soil Conservation Service. Data for five successive years (1935-39) covering approximately 900 farms in six areas of West Virginia have been studied to determine (1) changes in land use, cropping practices, and livestock programs as a result of the conservation plans; (2) some problems of management associated with conservation on farms of various types; and (3) the economic feasibility of the adoption of indicated soil conservation plans by self-sufficing and by commercial farmers." The demonstration program, the movement for soil conservation districts, and the general factors affecting conservation are discussed. In the analysis of the changes in agriculture during the 5 yr. of the conservation effort, the farms are divided into cooperating and noncooperating and beef cattle, dairy, general, and small subsistence farms. An analysis is made for the years 1935, 1937, and 1939 of the types of farming, land use, crop production, fertility practices, crop yields, livestock production, and farm receipts and income. In appraising the feasibility of conservation, three farms in each of the four types of farms were selected for case analysis. Planning for conservation is discussed.

In general, the program of the Conservation Service did not greatly alter the agriculture of the various areas, although some noteworthy changes took place. Both cooperating and noncooperating farms reduced their cropland, particularly the corn and wheat acreages. The reduction was greater for the cooperating farms. Cooperating dairy, beef cattle, and general farms increased their acreages of alfalfa. Cooperating farms appeared to be increasing the quality of cropping systems somewhat more than noncooperating farms. The acreages of both crop and pasture lands treated with lime and fertilizer were greatly increased. Small self-sufficing farms did not cooperate in any of the public programs to any appreciable extent. The numbers of livestock on both cooperating and noncooperating farms were increased, the increase being greater on the cooperating farms. "The greatest problem of soil conservation in West Virginia is the small size of farm units and poor management. Low incomes as a result of small farms, and lack of intensity in business organization, discourage and prohibit conservation. Consumption requirements are greater than net income; hence resources are exploited."

The author suggests that the following major conclusions might be derived from the study: "(1) The various agencies seeking to aid conservation should adapt their programs to fulfill the most urgent needs of the several types of

farming; let them differentiate between self-sufficing and commercial units in particular. The causes for depletion and exploitation must be removed before subsidies for fertility practices and similar programs will give permanent improvement. (2) Many farm units are too small and of such low quality that exploitation is inevitable as a result of subsistence pressure. Such units need to be enlarged or relocated; and the production program of many units, both large and small, must be more intensively organized so as to produce a volume of income sufficient to satisfy family, capital, and conservation needs. (3) Less attempt to make conservation a type of public works and direct subsidies, and more effort toward teaching farmers the nature of their resources and how to manage them without burdensome cash outlays, would probably result in greater understanding and appreciation of the land and in more permanent soil conservation. (4) It would be unreasonable to compel the application of land-use measures under the police power authorized by the soil conservation district law unless the measures are economically feasible in terms of the farm business to which they are applied."

**More food through conservation farming.** A. T. SEMPLE ET AL. (*U. S. Dept. Agr., Farmers' Bul. 1009 (1942), pp. [2]+54, figs. 47*).—"This bulletin discusses in general the ways in which conservation measures increase crop production, improve pasture and range, and maintain the productivity of the soil."

**Farm income and expenses of Farm Security Administration borrowers:** Summary report, all regions, 1940, C. A. STOKSTAD (*U. S. Dept. Agr., Bur. Agr. Econ., 1942, F. M. 33, pp. [1]+10, fig. 1*).—Tables show by Farm Security Administration regions and by States in each region the averages per farm per crop, livestock and livestock product sales, other farm income, other income not from the farm, total farm and family operating expenses, cash value of living from farm, capital expenditures, and debt payments for 16,191 Farm Security Administration borrowers.

**Mountain farming in the Ozark area of western Arkansas, with particular reference to goat dairying as a use for low-grade land.** G. TOWNSEND (*U. S. Dept. Agr., Bur. Agr. Econ., 1942, F. M. 31, pp. [2]+31, figs. 2*).—"This study was made "to ascertain the sources and the level of income obtained by a representative group of 'mountain farmers'; and to develop and analyze data describing the production requirements and returns for each of the more important farm enterprises common to the locality." The data were obtained by interviewing 30 farmers in the northwestern part of Newton County. "The first section describes various aspects of farm organization, operation, and earnings in 1940. The second section presents the usual, or typical, handling practices, production requirements, and production rates for milk goats and the three other livestock enterprises [dairying, hogs, and sheep] from which the income of most of the farms is derived. The third section compares the four livestock enterprises in terms of their suitability as major farm enterprises. The final section is devoted to an over-all consideration of opportunities for expanding goat dairying and some facts bearing upon the feasibility of cheese manufacturing as a possible means of improving market outlets for goat's milk."

**Farm-adjustment opportunities in Washington Parish, Louisiana.** K. L. BACHMAN and R. J. SAVILLE. (*Coop. La. Expt. Sta.*). (*U. S. Dept. Agr., Bur. Agr. Econ., 1942, F. M. 34, pp. [2]+73, figs. 7*).—"The present agricultural situation in the parish—the historical development, climatic conditions, soil resources, the farming, types of farm organization, and income from different types of farm organizations; and the farm adjustment opportunities—long-time adjustments in size of farms, alternatives for present farm organizations, the possibility of added income from farm forestry, and of tung production—are discussed. A pattern for better farm living is outlined.

**Farmer experience with the beef cattle enterprise in Louisiana,** F. MERRICK and J. N. EFFERSON (*Louisiana Sta. Bul. 353 (1942), pp. 31, fig. 1*).—Detailed records for the year ended August 1940 were obtained by interviews for 197 farms having at least 20 head of breeding stock. The farms were located in the eastern general farming, the central mixed farming, the Mississippi Delta cotton farming, the rice farming, and the southwestern cut-over areas. Analysis is made of the operating costs, the overhead costs, gross returns, net operating returns, and the relations of size of herd, calving percentage, hours of man labor per head, mortality rate, capital turn-over, and quality of cattle to costs and returns.

The net operating returns per farm and per head of cattle were: Eastern area \$528 and \$5.17, central area \$677 and \$4.36, Delta area \$603 and \$4.05, rice area \$676 and \$4.41, cut-over area \$208 and \$2.50, and all farms \$576 and \$4.18. Overhead costs per head were \$5.19, \$6.26, \$6.26, \$5.00, and \$1.79 in the respective areas. For all farms the net operating returns less overhead costs resulted in a net loss of \$146 per farm or \$1.06 per head of grown stock. Net operating returns per head on farms above and below the average for different factors were: Small herds (average 79 head) \$3.49 and large herds (average 238 head) \$4.57; low calving percentage (average 47) \$2.72 and high percentage (average 74) \$5.76; low amounts of man labor per cow (average 4.1 hr.) \$4.54 and high amount (average 12.3 hr.) \$3.70; low mortality rate (average 2 percent) \$5.35 and high rate (14 percent) \$2.51; low capital turn-over (average 12 percent) \$3.65 and high turn-over (33 percent) \$4.79; and low value per head (\$26) \$2.91 and high value (\$39) \$5.22. "The most favorable net returns per farm and per head were found for farms with larger-than-average-sized herds; calving percentage of more than 60 percent; more efficient use of labor, horses, and pasture; low mortality rates; a relatively high capital turn-over; and high-quality cows."

**Area analysis and agricultural adjustments in Nemaha County, Kansas,** W. H. PINE. (Coop. U. S. D. A.). (*Kansas Sta. Bul. 305 (1942), pp. 47, figs. 6*).—"The primary purpose of this study was to determine desirable agricultural adjustments for Nemaha County, Kansas. Secondly, methods of analyzing an area and determining adjustments were tested. This publication emphasizes the adjustments, but a brief description of the method adopted is presented for the benefit of those who may be interested in applying the general method to other counties.

"In this study it was attempted to relate a number of variables which affect the success of individual farms and an area as a whole. A number of factors were also studied which indicate the success of the agricultural economy in the area. Included among these factors were items such as condition of farmsteads and tax delinquency. An exhaustive analysis of the influence of any one factor was not attempted.

"The analysis began with an inventory of (1) the physical resources, (2) present land utilization, and (3) the indicators of the degree of success of the agriculture of the county. Based upon the data in the inventory, the county was divided into 25 agricultural areas. While all factors were considered, five were used principally in the delineation process: (1) Land type (soil), (2) physical land use (crop or pasture), (3) size of farm, (4) condition of farm finance, and (5) condition of the farmstead.

"Suggested adjustments for an area were determined by (1) comparing the area with the other areas in the county with respect to resources, the uses of the resources, and the relative success of the agriculture; and (2) preparing budgets for various systems of farming and sizes of farms."

**Trends in agriculture, Providence and Bristol Counties, Rhode Island,**

**1850-1940, J. L. TENNANT** (*Rhode Island Sta. Misc. Pub. 10* [1942], pp. [2]+35, figs. 17).—Tables and graphs are included with brief discussions showing for the State, Providence County, and Bristol County by the U. S. Census of Agriculture periods the changes in population (1800-1940) and in acreage, numbers, or production of hay, corn, potatoes, dairy cows, milk, butter, chickens, eggs, hogs, sheep, beef cattle, pear, peach, and apple trees, grapevines, and vegetable crops. The beginning dates for the tables, other than that for population, vary from 1850 to 1900.

**A study of land use in thirty-one towns in Aroostook County, Maine, A. E. WATSON** (*Maine Sta. Bul. 413* (1942), pp. [3]+53-106, figs. 11).—The purpose of this study is to provide some fundamental data which may be used as a basis for developing an adequate and feasible land-use program within the area studied. The agricultural development and agricultural trends of the area, the soils and topography, roads, and present land use, etc., are described. The land in the area was classified into five classes "according to its present intensity of use, and the probable future use or uses, after consideration of its physical characteristics and various economic factors." A map shows the location of the various land classes. The farms were classified as good, fair, poor, or abandoned, largely on the basis of size and conditions of the buildings; size, shape, and topography of the fields; and the general state of cultivation of crops being grown. The situation in a problem area is described, and policies appearing to have potentialities of practical application in the area are discussed.

Land class V (the best agricultural land) included 12.8 percent of the land; class IV (areas under good cultivation, but the agriculture not so intensive as in class V) 26; class III (agriculture in state of decline or nearly defunct) 3.4; class II (practically abandoned for agriculture) 0.2; class I (permanent forests) 53.9; and nonagricultural uses 3.7 percent. "The better land classes had a larger percentage of road mileage improved, more farms located on Caribou loam, a wider distribution of electricity and telephone services, and larger farm units than was found in the poorer areas. The average general property tax per farm was highest in land class V. The highest tax delinquency occurred in the better agricultural areas. Overassessment, size of the farm, and a heavy debt load undoubtedly have contributed to this situation." The program suggested for handling the marginal and submarginal areas is development of resources within the area, relocation of isolated families, and the development of town forest areas.

**Egg production in Maine, G. F. DOW** (*Maine Sta. Bul. 412* (1942), pp. [3]+51, figs. 10).—This is the first report of a series planned on the economics of the production and marketing of poultry and eggs in Maine. The information contained includes "the general set-up of poultry production in the State, care and handling of eggs, breeds of layers, size of flocks, seasonal variation in egg production, date of hatching pullets, mortality and disease problems, and the utilization of eggs." The marketing of hatching eggs and baby chicks, the sale of market eggs, and the marketing of live and dressed poultry are to be included in the later reports. Most of the detailed information was obtained through interviews obtained from 86 poultrymen in different sections of the State for the year ended June 30, 1941. The size of flocks studied varied from about 200 to 4,833 layers. Of the 86 farms studied, 51 received at least 90 percent of their total farm income from their poultry flocks.

**Thirty years of farming in Tompkins County, New York, E. G. MISNER** ([*New York*] *Cornell Sta. Bul. 782* (1942), pp. 59, figs. 3).—This bulletin brings together and compares some of the results obtained in a farm-management study for the crop year 1907 (E. S. R., 25, p. 594), a study of 250 farms in Dryden Township for the crop year 1917, a study (in cooperation with the U. S. Depart-

ment of Agriculture) of labor-income records of 916 farms in six townships for the year 1927 (E. S. R., 71, p. 867), and a study of the crop year 1937 of 544 farms in five townships (E. S. R., 83, p. 690). The comparisons include weather, prices, tenure, classification of the land, operator's history, types of farming, size of farms, capital, assets and liabilities, receipts, expenses, labor income, farm privileges, and cost of living. The factors affecting labor income are analyzed and discussed. The business-analysis factors for a well-organized and successful dairy farm, a dairy and poultry farm, a dairy and cash-crop farm, a cash-crop farm, and a specialized farm are given and discussed.

**The production and marketing of cabbage in New York**, R. W. HOCKER ([*New York*] *Cornell Sta. Bul.* 780 (1942), pp. 51, figs. 26).—"The purpose of this bulletin is to assist growers, dealers, kraut manufacturers, wholesalers, and others in determining effective methods of cabbage production and marketing. It is based on data from various sources, and on information obtained in a special study of cabbage production and marketing."

The section on cabbage production describes and discusses the types of farming, acreages, yields, and cultural practices in the different cabbage areas of the State, the factors affecting production, prices received by New York growers, and factors affecting such prices. Marketing by New York producers—methods of disposal, returns per ton in 1940, storage, and types of buyers—and the marketing of New York cabbage by shippers—types of transportation, seasonality of sales, storage, cost of handling stored cabbage, destination of shipments, and freight rates—are discussed. Wholesale prices in New York City and retail prices are also briefly discussed. A section on cabbage for sauerkraut manufacture discusses the production, prices received by growers, the manufacture of kraut, and the f. o. b. factory and retail prices of sauerkraut.

**Trends of muskmelon production and prices by areas, with particular reference to Northeastern States**, W. KLING (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1942, *F. M.* 36, pp. [2]+35, figs. 9).—"The muskmelon-producing areas of the United States are described. The past and prospective trends and price factors in the different areas, and the competition in the northeastern area are discussed. Suggestions are made for improving the quality of the melons.

**Farm tenure law in Kansas**, H. A. HOCKLEY and H. HOWE (*Kansas Sta. Bul.* 303 (1942), pp. 27).—"The objectives of this study were threefold: (1) To learn of the problems of farm tenancy that are related to, or affected by, landlord-tenant law, (2) to analyze and interpret the present status of the law, and (3) to suggest possible improvements." The material is presented in sections on security of tenure, conservation and improvements, collection of rents, and settlement of disputes. An appendix lists the Kansas statutes dealing with landlord-tenant relationships.

**The stock-share lease**, J. H. MCCOY and W. E. GRIMES (*Kansas Sta. Cir.* 213 (1942), pp. 39).—"This revision of Circular 155 (E. S. R., 63, p. 483) includes new sections on factors affecting the contributions of the landlord and tenant, equitability of the stock-share lease, and customary arrangements of the stock-share lease and test of fairness. Some of the sections have been enlarged.

**Standards and procedure for classification and valuation of land for assessment purposes in Montana**, H. H. LORD, S. W. VOELKER, and L. F. GIESEKER (Coop. U. S. D. A.). (*Montana Sta. Bul.* 404 (1942), pp. 28).—"The purpose of this bulletin is to set forth standards and procedure for the systematic assessment of agricultural land by which assessments can be made to reflect the productivity value of the land. The proposed method consists of grading land according to productivity within use classes and the determining of relative values of these grades." The determination of use classification of land and the grading of land according to productivity, yield histories, soil surveys, and other

sources of productivity information are discussed. The requirements for classification and grading of land for assessment are described, with statements of land classification grades used by the station for farming, grazing, and irrigated lands. The factors affecting land assessment valuations and methods of arriving at such valuations are discussed. A program for reassessment in a county—organization for reclassification, classifying and grading land, and determination of revaluation schedule—is discussed.

**New Hampshire rural towns' comparative road burdens and road services.** W. R. PARKS and J. C. HOLMES. (Coop. U. S. D. A.). (*New Hampshire Sta. Bul.* 339 (1942), pp. 31+ [19]).—This study "was undertaken at the request, and under the auspices, of the State Agricultural Planning Committee." It describes briefly the rural road system of the State and its impact on the rural part of the State. The inadequacy of the rural road system is analyzed and discussed in sections on (1) unequal town burdens in construction and maintenance of town (class V) roads, dealing with the comparative ability of towns to maintain town roads, State aid to class V roads, and the extent to which town road aid and Duncan aid (State aid for maintenance of class V roads) equalize class V road burden; (2) maintenance of uneconomic roads and misclassification of town roads; and (3) unequal town burdens in the completion of secondary (SAO) mileage, dealing with the construction aids to the State secondary highways and problems of completing SAO mileage in low-valuation towns. A program of action is outlined and discussed under sections on revision of Duncan aid formula, State supervision of Duncan aid expenditures, reclassification of town roads, alleviation of low-valuation towns' burdens in SAO construction, utilization of rural resources data in projecting secondary highways, and town developments of priorities in local road improvement and maintenance. "Now that through routes are nearly completed, the planning for future construction should be based on a thorough study of its relation to restoring, conserving, and improving the agricultural and timber resources of the State and also its recreational advantages."

**Price administration, priorities, and conservation of supplies affecting agriculture in the United States in 1917-18.** A. G. PETERSON (*U. S. Dept. Agr., Agr. Hist. Ser. No. 3* (1941), pp. [2]+16).—The 1917-18 wartime activities of the Department, the regulation of prices, priorities, and conservation measures pertaining to farm machinery and equipment, fertilizers, insecticides and fungicides, leather goods, and foods are described and discussed.

**Variations in flue-cured tobacco prices.** S. L. CLEMENT (*North Carolina Sta. Tech. Bul.* 69 (1942), pp. 38, figs. 11).—The main purposes of this study were "to determine the extent of daily variations in prices paid for the same quality of tobacco on the same market; and to measure, or indicate, the influence of some of the factors responsible for these variations." The tobacco auction procedure, the Federal inspection and market news service, and the company grading systems are described. Most of the analyses are based on data regarding 66,344 lots of tobacco sold on the Farmville, N. C., market during the 1938-39 season, and records of farmers' rejections and resales of 908 lots in the 1939-40 season. Analysis is made of the daily variations in prices for individual lots of a given grade in relation to U. S. grades and selected company grades, the factors associated with price variations, the day-to-day and seasonal variations, and the financial results of resales by growers. A study was also made of the grades of tobacco purchased by the "Big Three" cigarette companies.

"The average of daily spreads between high and low prices paid for 14 representative U. S. grades in 1938 amounted to \$15.33 for 100 lb., or 63.5 percent of the season average prices of these grades. Even when the effect of

extreme chance variations had been removed by the elimination of 10 percent of the poundage at each extreme of the price range, there remained an average spread of \$8.07 per 100 lb., or 33.4 percent of the season average price. . . . For the 16 company grades selected the weighted average of daily spreads was \$7.72, or 28.89 percent of the season average price, and the average of daily spreads between the tenth and ninetieth percentiles was \$3.53, or 13.21 percent of the season average price." "The analysis of 15 representative company grades bought in 1938 on one market indicated that on the average 24.4 percent of each company grade consisted of tobacco classified in one U. S. grade, 38.6 percent in two U. S. grades, and 48.4 percent in three." In the U. S. grades of average or better quality, prices tended to increase as size of lot increased up to at least 400 lb. Interviews with growers suggested strongly that personal relationship between growers and buyers influenced prices to a considerable extent. When a number of grades were considered it did not appear that any day of the week had an advantage over other days as to prices. The studies showed that the three cigarette companies were purchasing the same grades of tobacco at the same time in 1938 on the Farmville market.

**Twelve years of farm accounts in Illinois**, P. E. JOHNSON and H. C. M. CASE (*Illinois Sta. Bul.* 491 (1942), pp. 185-271, figs. 36).—"The reactions of progressive farm operators to a wide variety of physical and economic conditions is shown by an analysis of nearly 18,000 records kept in cooperation with the Extension Service of the University of Illinois from 1926 to 1937. These records show the land use on the accounting farms during these years, and how investments, incomes, expenditures, and earnings differed from year to year and between farming-type areas. The records were also grouped to show differences in farm organization and income resulting from differences in size of farm and in sources of income. The farms from which these records were taken were better-than-average farms. They were larger than the average farm in their locality and had better managers." The data are presented and discussed under the following headings: Prices for the period 1926-37; changes in investments, incomes, and expenditures; investments, income, and expenditures by farming-type areas; land use on accounting farms; influence of size of farm on farm organization and income; and variations in farms due to source of income.

**Inspection and control of weights and measures in the United States**, G. W. HERVEY and R. S. HADSELL (*U. S. Dept. Agr., Consum. Counsel Ser. Pub.* 7 (1942), pp. [2]+VII+86, figs. 6).—"The subject matter of this report deals largely with the results of a survey of systems of weights and measures administration, conducted by the Consumers' Counsel Division in the spring of 1938 in various States, cities, and counties. Due consideration is given to existing differences between a model law prepared by the National Conference on Weights and Measures (association of weights and measures enforcement officials) and the corresponding laws of each class of jurisdiction." "In addition to the information acquired through the survey, this report contains a discussion of the historical background of the subject of weights and measures, and a brief review of relevant details of an inquiry into chain-store marketing and distribution, begun in 1928 by the Federal Trade Commission. A tabular summary of Federal laws and regulations pertaining to weights and measures and a selected, annotated bibliography are also included." Appendixes include an outline of the essentials of the model law recommended by the National Conference on Weights and Measures and the National Bureau of Standards and the two survey schedules used.

**The Hoch-Smith Resolution: A study of a congressional mandate on transportation.** E. O. MALOTT (*U. S. Dept. Agr., Agr. Hist. Ser. No. 4 (1942), pp. VI+117*).—"This research aimed to study the effectiveness of a legislative direction on rate making to a regulatory commission. In the course of the study many attitudes and opinions bearing upon the subject were noted and these are given as quotations to avoid, if possible, an incomplete statement of views." The Hoch-Smith Resolution (43 Stat. 801) was passed by the Congress and signed by the President in January 1925 and is still on the statutes, without amendment. This report, in addition to an introductory chapter, includes chapters on the legislative history of the resolution, Interstate Commerce Commission activity under the resolution, interpretations and accomplishments of the resolution, reasons for its failure to accomplish stated objectives, and lessons for the future. The text of the resolution is included in the appendix.

**A preliminary study of cotton ginning costs in North Carolina.** S. L. CLEMENT (*North Carolina Sta. Tech. Bul. 71 (1942), pp. 23, figs. 6*).—The ginning industry—number of gins, volume of cotton ginned, number of gin saws, gin capacity, kinds of power, gin ownership, and present value of gins—is described. Data for 63 gins obtained for the 1940-41 season are analyzed to show the average cost per bale for different items of ginning expense, the frequency distribution of gins on the basis of average cost per bale, and the relationship of volume of ginning and number of gin stands to ginning costs.

The number of active gins in the State declined from 2,625 in 1914 to 824 in 1940, but the number of bales per active gin practically doubled. The average number of saws per gin increased from 80 in 1906 to 211 in 1940. The cost of ginning per bale in the 63 gins studied ranged from \$2.42 to \$6.54, averaging \$3.16. The average costs for different items were: Administration 42 ct., ginning labor 55, repairs and upkeep 18, power and fuel 38, bagging and ties 81, and depreciation 46 ct. Average costs per bale declined as the number of bales increased up to 1,501-2,000 bales. Some relationship was found between ginning costs and the fee charged the grower for ginning. The estimated average receipts per bale from ginning fees, assuming fees were collected for all bales ginned, were \$3.37, being 21 ct. in excess of the average costs of ginning. The costs were in excess of the estimated receipts for approximately 43 percent of the gins.

**Some factors affecting the quality of ginning services in South Carolina.** J. M. STEPP and H. A. WHITE. (Coop. U. S. D. A.). (*South Carolina Sta. Bul. 344 (1942), pp. 15, fig. 1*).—"This study was undertaken in an attempt to discover, if possible, what factors affect the quality of ginning services in South Carolina. Its purpose was to assist farmers in choosing a ginner who can and will do a good job of ginning, and to aid gimmers in discovering what to do to improve their ginning services."

Data for 1941 were obtained by a survey of 49 gins located in 20 counties of the State. Some of the findings were: Of 29,392 bales ginned by the 49 gins 8.4 percent was reduced one or more grades because of gin damage. Ten percent of the gins accounted for 47 percent of the gin-damaged cotton, and one-fifth of the gins for two-thirds of the damaged cotton. A high percentage of rough ginning was done in gins operated by merchants and a low percentage in those operated by oil mills. There was no consistent relationship between experience of gin managers and quality of ginning. Experience of the ginner and quality of ginning were related. The gins with the highest and lowest volumes of output had the lowest percentage of gin damage. In general, there was a relationship between age of gin stands and quality of ginning. Gins with driers usually did the better ginning. The relationship between cleaning equipment and quality of ginning was not so obvious.

**American tobacco types, uses, and markets**, C. E. GAGE (*U. S. Dept. Agr. Cir. 249, rev. (1942), pp. 129, pl. 1, figs. 45*).—This revision (E. S. R., 68, p. 843) brings the tables, charts, and other data up to 1940 in most cases. Some sections are somewhat enlarged and new data added.

**Market classes and grades of livestock**, L. B. BURK and C. V. WHALIN (*U. S. Dept. Agr. Bul. 1360, rev. (1942), pp. 30, figs. 13*).—This completely revised bulletin (E. S. R., 55, p. 562) outlines and briefly explains the United States standards for market classes and grades of cattle, calves, swine, and sheep and lambs, and defines or discusses the standard market terms associated with such classes and grades.

**Trucking milk to Providence, Rhode Island**, A. MACLEOD, J. L. TENNANT, and W. J. CORR, JR. (*U. S. Dept. Agr., Bur. Agr. Econ., 1942, pp. 131+31, figs. 3; also [Rhode Island Sta. Misc. Pub. 11 (1942), pp. 131+31, figs. 3]*).—This contribution to the regional program of research in milk marketing sponsored by the New England Research Council on Marketing and Food Supply describes the trucking of milk to Providence as of May 1941 and discusses the problems affecting milk hauling and charges in the Providence milkshed. Data are presented as to the number of truck routes, size of trucks, mileage traveled per day, charges, estimated costs of operations, etc. A reorganized system of truck routes is outlined, and estimates made of the number and size of trucks needed, mileage that would be traveled, costs, etc. An appendix contains data as to the cost of operating motortrucks, published by the [Connecticut] Storrs Experiment Station (E. S. R., 87, p. 873).

In May 1941 there were 50 commercial milk routes, the trucks traveling 4,017 miles and the rate charged averaging 34.4 ct. per hundredweight of milk. Under the reorganized system the number of trucks would be reduced to 25 large and 6 smaller trucks. It would reduce the total distance traveled to 2,258 miles and the estimated average cost per 100 lb. of milk to 20.7 ct. Of the reduction in cost, truck operation accounted for less than one-third and the balance would result from the elimination of unnecessary profits, reduction of "services" other than hauling milk, etc.

**The grain milling industry in Knoxville trade area**, C. E. ALLRED, B. H. LUEBKE, and M. B. JOHNSON (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 142 (1942), pp. IV+29, figs. 9*).—"This report deals with the functions, buying problems, operating problems, and efficiency of mills, in relation to possible greater service to farm communities." It is based on data secured in the summer and fall of 1941 by visits to 45 mills in 23 counties. It describes and discusses the types, location, and milling capacity of the mills, the grain storage facilities, the competition for grain supplies and the problems of procurement, the mill equipment, and the mill efficiency and possibilities.

**Marketing the Illinois peach crop**, V. A. EKSTROM (*Illinois Sta. Bul. 492 (1942), pp. 273-320, figs. 16*).—The peach industry of the United States and of Illinois is described. The competition of Illinois peaches with those of other States and the outlook for the peach industry in Illinois are discussed. The harvesting, preparation for market, and methods of transporting the Illinois crop to market are also described and discussed. Some analysis is made of the proportion of the crop shipped by truck, kinds of truckers, kinds of markets to which the crop is trucked, and length of truck hauls.

Surveys of 126 growers in 1938 and 192 growers in 1939 showed that 63 and 80 percent, respectively, of the crops were shipped by truck. Of 361 truckloads included in the 1939 survey, 60 percent moved 201 to 450 miles. A special survey in August 1942 showed for the 240 trucks included that the estimated period before replacement of the poorest tire was under 3 mo. for 33.8 percent of the trucks, from 3 to 6 mo. for 25.4 percent, and that "only 18 percent of the trucks

will probably be in condition for hauling Illinois peaches in 1943 if the fires are used meanwhile at the same rate as in 1941 and are not replaced."

**An economic study of commercial fruit and vegetable canneries in South Carolina, J. M. STEPP** (*South Carolina Sta. Bul. 342 (1942), pp. 55, figs. 15*).—This is a companion bulletin to the one on community canneries in the State (E. S. R., 87, p. 441.) All (20) of the commercial canneries were visited, and records were obtained regarding the facilities and operation of each cannery. Vegetable and peach production in the State is described. The types, locations, organization and ownership, capital investment, indebtedness, etc., of the canneries; the quantities of different fruits and vegetables canned; the length of the canning season and the quantity of different products canned in 1940; the sources of, prices paid for, and methods of purchasing raw materials; labor utilization; and the marketing of canned goods, including sales outlets, destination of shipments, and transportation are among the topics discussed.

The 20 canneries were located in 14 counties and were operated by 13 firms. The 18 canneries for which data were available canned 339,356 No. 2-equivalent cases in 1940, but had a total capacity of 1,473,629 cases. The total volume of raw materials processed was approximately 8,000 tons, and the total value was about \$112,000. "With every cannery of fruits and vegetables in the State operating at its normal level of output, employment in 1940 would have been somewhere between 941 and 1,272 workers." The average value of products was \$1.453 per case, and the cost per case was \$1.383, consisting of raw products 31.9 ct., cans and cases 53.6, labor 20, miscellaneous variable costs 15.5, and fixed costs 17.3 ct.

**Selling fresh fruits and vegetables cooperatively, J. H. HECKMAN** (*U. S. Dept. Agr., Farm Credit Admin. Bul. 49 (1941), pp. VII+78, figs. 16*).—"The purpose of this study is to present a general picture of the selling methods used by cooperative associations handling fresh fruits and vegetables during the period 1928 to 1938. It will discuss the variations among associations in marketing practices for different classes of commodities and for different types of buyers. It also will deal with the many changes that have occurred in the distribution of fresh fruits and vegetables within the last few years. These changes include developments in transportation, refrigeration, mass-buying, and other important factors which have brought about modifications in the sales programs of cooperative associations marketing perishable products." The data, which cover 100,737 car equivalents for the years 1928, 1933, and 1938, were obtained from 55 cooperative associations in 26 States. The sales practices—methods of sale, types of sales, types of buyers, etc., are described and discussed for fruit and vegetable, fruit, vegetable and potato, potato, vegetable, western fruit, peach, and strawberry associations. Another section deals with sales policies—working relations with buyers, future sales, time of sale, pricing, pooling, billing and collecting, development of trade territory, etc. Buyer practices when purchasing from cooperatives—purchase methods, purchase types, and methods of transportation—are also described.

**Dehydration of fruits and vegetables by farmers' cooperative associations, H. C. HENSLEY** (*U. S. Dept. Agr., Farm Credit Admin., 1942, WC 1, pp. [2]+54, figs. 54*).—The activity of cooperatives in the production of dried fruits and vegetables is briefly discussed. Desirable location and size and type of dehydration plants are discussed. The equipment for and procedures of cabinet, tunnel, drum, spray, and rotary types of dehydrators and vegetable preparation are illustrated with photographs. The prospects for post-war demand for dehydrated foods are briefly discussed. Maps are included showing the major vegetable areas in the United States. Copies are included of (1) Information

Sheet on Dehydrated White or Irish Potatoes and (2) Tentative FSCC Specifications for White (or Irish) Potatoes, Dehydrated.

**Foreign Agriculture, [October 1942]** (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Foreign Agr., 6 (1942), No. 10, pp. [2]+343-364, fig. 1*).—Included are articles on The Agricultural Resources of Mozambique, by B. Merdian (pp. 343-358), describing the climate, vegetation, population, and economy of the Colony and discussing the factors affecting agricultural development, the present and potential agriculture, and the foreign trade; and Britain Creates Central Planning Authority, by M. Ogdon (pp. 359-364), describing the Ministry of Works and Planning Bill passed by the House of Commons on June 2, 1942, and the functions of the new Ministry.

**The agricultural resources of Madagascar**, B. MERDIAN (*U. S. Dept. Agr., Off. Foreign Agr. Relat., Foreign Agr. Rpt. 7 (1942), pp. [2]+21, figs. 6*).—The people, the physical factors affecting the agricultural development, and the foreign trade are discussed, as are also the extent of the agricultural industry, the surplus food produced, the crops grown for export, and the forest products.

**The International Wheat Agreement** (*U. S. Dept. Agr., Off. Foreign Agr. Relat., 1942, pp. [1]+32*).—This report was prepared by the Washington Wheat Meeting, July 1941-June 1942. It includes the announcement, July 2, 1942, by the Governments of Argentina, Australia, Canada, the United Kingdom, and the United States of the memorandum of agreement, the memorandum, the draft convention, the minutes of the final session of the meeting, notes of approval by the Governments, lists of all delegates and aides, and the organization of the International Wheat Council. A statement prepared by G. P. Boals (pp. 21-31) on the significance of the agreement is also included.

## RURAL SOCIOLOGY

**The social economics of agriculture**, W. GEE (*New York: Macmillan Co., 1942, rev. ed., pp. XII+720, figs. 10*).—This is a revision of the first edition (E. S. R., 68, p. 633).

**[Investigations in rural sociology by the Rhode Island Station]** (*Rhode Island Sta. Rpt. [1941], pp. 55-57*).—Topics discussed include the European immigrant in rural Rhode Island and land use and rural living on the urban margin (coop. U. S. D. A.).

**The physical status and health of Farm Security clients in southeast Missouri.—Preliminary Report No. 1, Results of blood tests for hemoglobin**, C. E. LIVELY. (Coop. U. S. D. A. et al.). (*Missouri Sta., 1942, pp. [1]+9, fig. 1*).—One in 3 of the 1,667 whites examined showed less than 80 percent hemoglobin and more than 3 in 5 of the 992 Negroes examined fell below 80 percent. The whites had a definitely smaller proportion under 60 percent and under 70 percent than the Negroes. On the other hand, the whites placed  $2\frac{1}{3}$  times as many as the Negroes at 90 percent or above.

A smaller proportion of males than females were suffering from secondary anemia. "With respect to age, it may be said that those persons aged 45 or over were in better physical condition with respect to blood hemoglobin than either of the groups aged 10-24 or 25-44. The youth group, those aged 10-24, showed the poorest record in this respect."

**The physical status and health of farm tenants and farm laborers in southeast Missouri.—Preliminary Report No. 2, The physical defects of adult males**, C. E. LIVELY and H. F. LIONBERGER. (Coop. U. S. D. A. et al.). (*Missouri Sta., 1942, pp. [1]+21, figs. 11*).—Diseases of the digestive system accounted for 44.6 percent of all defects found among the 1,115 males examined. This study revealed that the male population examined possessed relatively good

teeth, but there was evidence that dental care was inadequate. More than a third (35.2 percent) were in possession of a full set of teeth. The corresponding percentages were 34.7 for whites and 36.1 for Negroes. Of all the males examined, 34.8 percent had either gingivitis or pyorrhea; 14.6 were found to possess hernias, so defined as to include enlarged rings. Fourteen cases of ulcers of the stomach and intestines were found among males aged 25 yr. or over. Ten of these cases were among whites. Diseases and defects of the respiratory system accounted for 21.2 percent of all physical defects. Defective tonsils were found in 54 percent of both whites and Negroes. Of all white and Negro males between the ages of 15 and 24 yr., 71 percent had defective tonsils, as compared with approximately 40 percent of those aged 45 or over. Defects of the nasal fossae, most of which were deviations of the nasal septum, were found in 47 percent of the whites and 23 percent of the Negroes. Less than 3 percent of the total group of males examined had adenoids. Approximately 2 percent of the white and Negro males had sinusitis. All of the 17 cases of pulmonary emphysema were found among males above the age of 25 yr., with 14 cases occurring after the age of 45. Sixteen of the cases occurred in the white population.

For every 100 males examined, 18 cases of diseases of the eyes were found. Negroes placed fewer cases at all ages than did the whites, although the difference after age 44 was slight. Defective hearing was found to be three times as prevalent among the white males examined as among Negro males, with 2.3 percent of the whites and 0.7 percent of the Negroes so classified. Twenty cases of anemia, obesity, goiter, and diabetes per 100 white males examined and 51 cases per 100 Negro males examined were found to occur. It was found that 41.8 percent of the Negroes and 14.4 percent of the whites were suffering from secondary anemia. The status of numerous other relatively minor ailments is also presented.

**The physical status and health of farm tenants and farm laborers in southeast Missouri.—Preliminary Report No. 3, The physical defects of adult females, C. E. LIVELY and H. F. LIONBERGER.** (Coop. U. S. D. A. et al.). (*Missouri Sta.*, 1942, pp. [1]+28, figs. 10).—This report dealt with the physical defects found among 1,064 females (670 white and 394 Negro) aged 15 yr. and older. Of these 32 percent were attributed to diseases and defects of the digestive system, with 84 percent of these accounted for by defective conditions of the teeth. Both whites and Negroes showed 210 such defects per 100 persons. Of other diseases and defects, the relative proportions for whites and Negroes were respectively as follows: Urogenital 21.3 and 19.8; respiratory 14.7 and 11.5; nutrition and endocrine gland 10.8 and 14.8; circulatory 9.3 and 9.5; organs of perception 13.5 and 7.5; and others 3.1 and 4.6 percent.

**Culture of a contemporary rural community: Sublette, Kansas, E. H. BELL** (U. S. Dept. Agr., Bur. Agr. Econ., *Rural Life Studies* No. 2 (1942), pp. [4]+113, figs. 10).—This is a report on another of the six communities studied contemporaneously as to community stability during 1940 (E. S. R., 88, p. 271). Many of the data are presented on a county basis for Haskell County, southwestern Kansas.

**Community organization for war and for peace, D. SANDERSON.** (Cornell Univ.). (*Social Forces*, 21 (1942), No. 1, pp. 1-7).—The author concludes that community planning must be the foundation of any sound system of planning for larger units. Community organization will become increasingly necessary if we are to prosecute this war successfully, and it will be equally necessary after the war if we are to win the peace.

## FOODS—HUMAN NUTRITION

**Food and beverage analyses, M. A. BRIDGES and M. R. MATTICE** (Philadelphia: Lea F. Febiger, 1942, 2 ed., rev., pp. 344).—These tables, now in the second edi-

tion, bring together data from many sources bearing on the proximate, mineral, and vitamin content of foods and beverages, including not only natural foods but also special food products, designated by trade names, and certain prepared foods. The data are presented to indicate the percentage composition of the foods as well as the amounts of the specific nutrients in average serving portions. Various classifications of foods, for example, according to carbohydrate, protein, or fat content, and brief discussions concerning the minerals and vitamins in foods are included. New data in this edition include "tables on the acidity of foods, their fiber content, the occurrence of sulfur, bromine, calcium, oxalate, phytins, purines, available carbohydrates, and ionizable iron. The reaction of foods is covered by a table of pH values which embodies all the common and many uncommon foods. There is a table of organic acids in fruits, vegetables, and a few miscellaneous items. Extensive information is given on the acid-ash and alkaline-ash factors." It is pointed out that this book is not intended as a source of material for the scientist in the field of nutrition, but as material for convenient reference of dietitians, nurses, etc. An extensive bibliography to the source material used is appended.

**The nation's food. IV, Cereals as food. III, The chemical composition and nutritive value of oats and oatmeal, II. C. MOIR** (*Chem. and Indus.*, 61 (1942), No. 2, pp. 17-21).—This summary presents data from many sources on the proximate composition of oats and oat products. A few data on mineral content, on the constitution of the protein, on the physical and chemical constants of oat oil, on enzyme activity, and on thiamin content are also given. The nutritive value of oats is discussed in the light of these data.

**Cereal cellulose, a roughage material suitable for experimental animal diets, E. R. HARDING** (*Science*, 95 (1942), No. 2461, p. 234).—A cereal cellulose, derived from rice hulls by a high-pressure chemical process of treatment together with extensive washing, is reported to have been satisfactorily used at a 5-percent level for roughage in animal diets. The product contains no protein (0.043 percent N) or fat, is devoid of thiamin, riboflavin, and P and contains only 0.022 percent Ca, an amount so low as to permit of use in ordinary studies of this element. The material is unsuitable, however, for use in diets designed to study Fe availability, since the Fe content amounts to 0.001 percent, due to the material being dried in a steel rotary drier. The cellulosic ingredients include 70 percent  $\alpha$ -cellulose, with the rest made up of simpler celluloses and hydrocelluloses. It is noted that the cereal cellulose is to be made available through one of the larger scientific supply houses.

**Modern bread from the viewpoint of nutrition, II. C. SHEERMAN and C. S. PEARSON** (*New York: Macmillan Co.*, 1942, pp. VI+[2]+118).—It is pointed out that the developments within the past century in wheat production, milling, and baking have resulted in a highly developed technologically standardized staple white bread which is not much different from the breads of a decade or a century ago in the matter of energy value (about 1,200 calories per pound), but which is an impoverished product from the standpoint of protein, mineral, and vitamin values. Whole-wheat bread, bread made with skim milk powder, and bread which contains a significant proportion of wheat germ have a more satisfactory protein value than a bread made from white flour and water. The calcium value is raised by the milk now commonly used in bread making or by calcium enrichment of the white flour. Improvement in the iron value of bread may be attained by iron enrichment of the white flour, by the use of whole-wheat flour, or by the use of flours specially milled so as to be freed from the very coarse portion of the wheat, a roughage portion that might be irritating to some people, and yet to retain practically all of the nutrients rejected in the making of white flour. Vitamins of the B group may be re-

tained by the use of whole-wheat flour or of long extraction flours, or may be replaced by the incorporation of wheat germ or by the use of milk solids and vitamin-rich yeast. Breads nutritionally modernized in any of these ways justify larger use in the diet than nutritionally impoverished bread. It is believed that the nutritionally improved breads can now safely be utilized to supply as much as 40 percent of the calories of the normal diet, and that this more prominent place will frequently be physiologically, as well as economically, advantageous.

**Use milk, an essential food** (*Nebraska Sta. Cir.* 71 (1942), pp. 15, figs. 4).—This publication, pointing to the value of milk in reinforcing the diet with many excellent food nutrients, furnishes information on ways to utilize more milk in the home and especially the farm home. Consideration is given to the handling of milk in the home; to the use of milk for drinking and cooking and in frozen desserts (for which several recipes are given); to the use of cream; the use, making, and storing of butter; and the making of various cheeses.

**Is there need for the fortification of milk?** E. V. McCOLLUM (*Amer. Jour. Pub. Health*, 32 (1942), No. 1, pp. 80-84).—Because there is no advantage in making any single food a complete food; because it is more advantageous for a family to buy more ordinary milk than to buy a lesser volume of so-called "improved" premium milk; because publicity necessary to create demand for a fortified milk would do a disservice to the consumer by creating the impression that ordinary milk may not be after all the superior food, the economical purchase, and the best single supplementary article of diet among the protective foods; and because fortification of milk other than with vitamin D would impose the burden of added official supervision and inspection—because of all these considerations, it is concluded that it is unwise to permit fortification of milk other than with vitamin D.

**Staphylococci and Salmonella control in foods, I-IV** (*Food Res.*, 7 (1942), Nos. 1, pp. 1-15, figs. 2; 2, pp. 96-103).—Four papers are presented.

**I. Effect of ultra-violet radiation and ozone on bakery custard and cream fillings**, W. H. Cathcart, R. E. Ryberg, and A. Merz (pp. 1-9).—When custard products were exposed for various intervals to an atmosphere of the test organism, both with and without simultaneous exposure to ultraviolet radiation or to an atmosphere of ozone, the ultraviolet rays (2,000-2,950 a. u.) served only as an aid in maintaining a sterile atmosphere and were of no value in sterilizing products contaminated before the bacteria were killed. Ozone in the concentration in which it could be used had a low rate of killing and was ineffective in helping to control the staphylococci and the *Salmonella* bacteria in custard and cream fillings. An off-aroma developed in samples exposed to ultraviolet radiation for 2 hr. or more or to the atmosphere of ozone.

**II. Effect of pure fruit fillings**, R. E. Ryberg and W. H. Cathcart (pp. 10-15).—Custard fillings with additions of ground fruit thoroughly mixed and cooked with the rest of the mixture were inoculated with known numbers of the test organisms and incubated 24 hr. at 98°-99° F. The growth of the organisms in this period was found to be effectively inhibited in lemon, orange, pineapple, apricot, and strawberry fillings of the type described. This inhibitory action appeared to be greater on the *Salmonella* organisms than on the staphylococci, the amount of inhibition being at least partially controlled by the pH of the filling but also determined in part by a relationship between the pH and the types of acids or other substances present. The addition of milk reduced the inhibitory action, probably because of the buffering effect. The concentration of lemon juice required to exert an inhibitory effect was so high as to make the flavor of the resultant custard unsatisfactory.

**III. Effect of chocolate and cocoa fillings on inhibiting growth of staphylococci**,

W. H. Cathcart and A. Merz (pp. 96-99).—The growth of *Staphylococcus aureus* in chocolate and cocoa fillings inoculated with the organism was observed. Water rather than milk was used in the formula of the mix, which was varied by the use of different kinds and quantities of chocolate or cocoa and by the use or omission of egg yolks. The fillings made with the natural chocolate or cocoa were found effective in inhibiting growth of *S. aureus* in comparison with a standard custard. The effectiveness of the chocolate and cocoa was greatly increased by eliminating eggs from the formula. The inhibitory action was assumed to be due in part to the pH of the filling, but the main inhibitory action appeared to be due to the nonfat portion of the chocolate or cocoa.

IV. *Effect of cooking bakery custards*, W. H. Cathcart, A. Merz, and R. E. Ryberg (pp. 100-103).—A bulk custard made by a standard formula was inoculated with the test organism (*Staphylococcus aureus* or *Salmonella enteritidis*) by adding the prepared culture of known bacterial content to the thickening mix and bringing the batch to a second boil, where it was held for the desired length of time. In other tests the uncooked inoculated custard mixture was filled into raw pie shells, the pies then being baked for 25-35 min. at 246° C. Bacteriological examination of the cooked custards showed that they were rendered sterile of the test organisms in the one case by merely bringing to the second boil and in the other case by the baking. Since the experiments were conducted under commercial conditions with aseptic precautions, it is expected that properly prepared custards in normal practice will be essentially sterile with respect to these two organisms.

**Production of staphylococcus enterotoxin in canned corn, salmon, and oysters**, E. DAVISON and G. M. DACK (*Food Res.*, 7 (1942), No. 1, pp. 80-84).—From the studies described, it is concluded that "certain staphylococci can elaborate enterotoxin in experimentally inoculated cans of corn and of oysters. This was demonstrated by intravenous injection of monkeys and feeding of human volunteers. We were unable to demonstrate staphylococcus enterotoxin in inoculated canned salmon. The salmon was assayed by intravenous injection into monkeys and by feeding of human volunteers. Concentration of enterotoxin from foods by precipitation from saturated  $(\text{NH}_4)_2\text{SO}_4$  solution can be accomplished, but it does not give a high enough percentage of positive results to be used as a practical routine method of assay."

**Home canning**, W. V. CRUESS and A. W. CHRISTIE, revised by W. V. CRUESS (*California Sta. Cir.* 276, rev. (1942), pp. 48, figs. 15).—This revision of an earlier publication (E. S. R., 51, p. 808) describes and summarizes approved canning methods for fruits, vegetables, and meat, and gives general information on the principles of canning and vitamins in canned foods. A section on food poisoning, by K. F. Meyer and J. C. Geiger, is also included.

[**Food preparation and vegetable studies**], D. DICKINS (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 10, p. 2).—Progress is reported on a survey of methods of food preparation among owner and cropper white and Negro families in two counties of the State, and on laboratory studies of losses of vitamin C in various methods of storing and cooking turnip greens.

[**Studies in foods and nutrition by the Ohio Station**] (*Ohio Sta. Bul.* 617 (1940), pp. 40, 55, 60).—Progress reports (for 1938-39) are given on a study of the vitamin C content of muskmelons (p. 40), the antigraying factor for rats (p. 55), and the food needs of young adults (p. 60) (E. S. R., 83, p. 562).

[**Nutrition studies by the Rhode Island Station**] (*Rhode Island Sta. Rpt.* [1941], pp. 49-51).—Progress is reported on a continuation of studies (E. S. R., 85, p. 853) on vitamin A metabolism of human subjects and nutritional status with respect to vitamin C.

**Annual review of physiology, IV**, edited by J. M. LUCK and V. E. HALL

(Stanford University, Calif.: *Amer. Physiol. Soc. and Ann. Rev., Inc.*, 1942, vol. 4, pp. VIII+709, figs. 2).—Among the 23 reviews comprising this publication (E. S. R., 86, p. 856), the following deal with topics of nutritional significance: Developmental Physiology, by H. L. Hamilton and B. H. Willier (pp. 67-88); Water Metabolism, by J. P. Peters (pp. 89-114); Growth, by G. S. Avery, Jr. (pp. 115-138); Energy Metabolism, by W. H. Chambers, E. Shorr, and S. B. Barker (pp. 139-170) (Cornell Univ., Univ. Texn., et al.); Blood, by H. P. Smith (pp. 245-272); The Digestive System, by E. J. Van Liere (pp. 273-296) (W. Va. Univ.); and Metabolic Functions of the Endocrine Glands, by C. N. H. Long (pp. 465-502).

**The evaluation of nutritional status**, E. N. TODHUNTER (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 2, pp. 79-82).—A summary, with 20 references to the literature, of recent progress in the development of methods for evaluating nutritional status, particularly with reference to individual nutrients.

**Nutrition for national defense (a summary)**, V. PHILLIPS. (Wash. State Col.). (*Wash. State Col., Inst. Dairying Proc.*, 13 (1941), pp. 67-69).—This brief discussion of the problem of insuring adequate nutrition stresses the fact that the first requirement toward attaining higher nutritional standards is a better distribution of income. The second is a better distribution of food money among different types of food, in other words more intelligent selection of food.

**Nutrition and national defense**, R. M. WILDER (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 1, pp. 1-8).—In this address, delivered at the 1941 convention of the American Dietetic Association, the author summarizes evidence in the literature of the extent of precritical malnutrition in this country, including among others reports from the State agricultural experiment stations of Florida (E. S. R., 83, p. 274), Maine (E. S. R., 84, p. 696), Minnesota (E. S. R., 86, p. 555), Oregon and three other western stations cooperating in an investigation of ascorbic acid metabolism (E. S. R., 84, p. 424), and Pennsylvania (E. S. R., 86, p. 858).

**Research in Army subsistence**, R. A. ISKER (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 1, pp. 20-22).—In this address the author describes the work of the subsistence research laboratory of the Quartermaster Corps, U. S. Army, with special reference to the development of a field ration for the use of highly mobile units such as mechanized or parachute troops. The ingredients of the three units of the daily ration, having a net weight of 32.86 oz. and providing 3,726 calories, are listed, with individual weights and calories furnished.

**The importance of nutrition in the prenatal clinic**, J. H. EBBS and W. J. MOYLE (*Jour. Amer. Dietet. Assoc.*, 18 (1942), No. 1, pp. 12-15).—Essentially noted from another source (E. S. R., 87, p. 593).

**Infant nutrition: A textbook of infant feeding for students and practitioners of medicine**, W. M. MARRIOTT, revised by P. C. JEANS (*St. Louis, Mo.: C. V. Mosby Co.*, 1941, 3. ed., rev., pp. 475, figs. [32]).—This book, originally written by W. M. Marriott, has been brought up to date in the present revision by P. C. Jeans, who points out that the purpose of the book remains the same, namely, to bring together such facts and ideas as have a practical bearing on infant nutrition and to present them in such a way as to make them useful to the practitioner and student.

**Influence of diet on the uric acid excretion of young children**, J. E. HAWKS and G. EVERSON. (Mich. Expt. Sta.). (*Amer. Jour. Diseases Children*, 62 (1941), No. 5, pp. 955-966).—In three long-time balance studies conducted with preschool children by the method noted previously (E. S. R., 77, p. 725), data were obtained on the urinary uric acid excretion. In the first two experiments the children were placed on a diet furnishing 3 gm. of protein per kilogram of body weight; later the protein was increased to 4 gm. per kilogram. In the third experiment the change in the diet involved a calorie increase of about

20 percent. The change from the 3- to the 4-gm. protein level increased the uric acid elimination in all cases, although purine-free protein (egg white and gelatin) caused a smaller increase than meat protein. There was a better correlation between the values of uric acid and ammonia than between uric acid and other urinary nitrogenous substances, suggesting that there was a relation between the production of uric acid and that of ammonia.

**The iron requirement of children of the early school age,** F. A. JOHNSTON and L. J. ROBERTS (*Jour. Nutr.*, 23 (1942), No. 2, pp. 181-193).—The procedure employed to determine the iron requirement of the children was that of finding the lowest iron intake required to produce and maintain a good hemoglobin level, namely, 13-14 gm. With this method in view, the plan of the present study involved the selection of subjects, 12 boys and 9 girls from 8 to 11 yr. of age, who had been living for at least 2 yr. in an institution where the diet was fairly uniform in order that their hemoglobin levels could be considered a product of that diet. On this institutional diet, which was good in all diet essentials, the total daily intake of iron averaged 12.6 mg. in the 2-week period at the beginning of the study in which aliquots of the food were analyzed. In general the intakes of the boys were higher than those of the girls. The hemoglobin levels and red cell counts were determined at the beginning of the study; the hemoglobin level of the 21 children then averaged 12.9 gm., with 19 of them between 12 and 14 gm., and the red cell counts averaged 4,160,000, with no significant differences between the sexes. At the end of the 2-week preliminary period, the children were matched in groups of 3, one child of each group being given a daily supplement of 4 mg. of iron, another 2 mg., and the third none. After iron supplementation had been continued for 7 mo., hemoglobin levels were again determined and the data examined to find the lowest intake that gave good hemoglobin levels. Such examination indicated that 11.4 mg. of iron per day, or 0.35 mg. per kilogram, sufficed to maintain good hemoglobin levels when the rest of the diet was adequate. The hemoglobins of children given the 2- or 4-mg. supplements over the 7-mo. period did not rise, indicating that the higher intake of iron was not needed. "It is possible also that lower intakes, had they been tried, might have been found to serve just as well."

**Successful rearing of a second generation of mice on an artificial diet,** L. K. ROGERS, L. W. McELROY, and G. R. COWGILL (*Science*, 95 (1942), No. 2460, pp. 203-204).—In this preliminary report the basal ration on which success was achieved is described qualitatively as consisting of "Labco casein, cornulose, Crisco, Osborne and Mendel salt mixture with added zinc carbonate, agar, wheat germ oil, and 3 percent rice polish filtrate factor II. This basal mixture was supplemented with cod-liver oil concentrate, thiamin, riboflavin, pyridoxin, nicotinic acid, calcium pantothenate, choline, *p*-aminobenzoic acid, and inositol. During the past month linoleic acid has been added."

**Rate of hemoglobin regeneration in blood donors,** W. M. FOWLER and A. P. BARER (*Jour. Amer. Med. Assoc.*, 118 (1942), No. 6, pp. 431-437, figs. 6).—Two hundred normal male subjects donating from 500 to 600 cc. of blood showed a drop in blood hemoglobin content varying from 1.2 to 4.4 and averaging 2.3 gm. per 100 cc. In 105 of these men in whom hemoglobin recovery was followed, the recovery periods ranged from 18 to 98 days, and the average time required for the blood hemoglobin to return to its original level was 49.6 days. The longer recovery periods were associated with a greater drop in hemoglobin and could not be correlated with the initial blood hemoglobin values. With a smaller donation there was a smaller drop in blood hemoglobin, and the recovery period was shorter. Hemoglobin was regenerated in the men at the rate of 0.049 gm. per 100 cc. In a group of 13 women donors the average drop in hemoglobin

was 2.2 gm. and the average daily increase in hemoglobin amounted to 0.04 gm. per 100 cc. Observations following subsequent donations suggested that these may be given with safety as soon as the blood hemoglobin has returned to its original level, but that an interval of 3 mo. should be allowed if the hemoglobin of the donor is not determined regularly. The rate of hemoglobin regeneration after subsequent blood donations did not seem to be slower than after the first donation.

"The administration of 1 gm. of iron and ammonium citrates per day increased the daily hemoglobin regeneration by 49 percent and shortened the recovery period from 49.6 to 35.2 days during the first period of its administration. It had progressively less effect after subsequent blood donations."

**The concentration of the substance in blood which is stimulatory for *Lactobacillus casei*  $\epsilon$ , R. E. FEENEY and F. M. STRONG. (Univ. Wis.). (*Jour. Biol. Chem.*, 142 (1942), No. 2, pp. 961-962).**—Fat-soluble preparations which simulate the stimulatory action of blood, as observed in the recovery of riboflavin added to blood by the method of Snell and Strong (*E. S. R.*, 82, p. 587), were obtained from beef and dog bloods by continuous ether extraction. Further purification, accomplished by partitioning between ether and water and between dilute alcohol and petroleum ether, gave preparations showing marked stimulation at a level of approximately 75 $\gamma$  per 10 cc. of medium. This stimulatory effect indicated that the active material had been concentrated from 500 to 1,000 times.

**The use of radioactive copper in studies on nutritional anemia of rats, M. O. SCHULTZE and S. J. SIMMONS (*Jour. Biol. Chem.*, 142 (1942), No. 1, pp. 97-106, fig. 1).**—Radioactive copper,  $^{64}\text{Cu}$ , with a half life of 12.8 hr., was prepared, extracted, and concentrated, and the radioactivity counted, all by methods noted. This isotope, having properties suitable for physiological studies, was fed, in amounts of from 100 to 150 mg. per rat, in a small amount of milk to young rats made severely deficient in iron or copper on a milk diet. After from 24 to 48 hr. of copper therapy, the animals, which had been kept in metabolism cages, were sacrificed, and the distribution of the copper in the tissues was determined. The copper-deficient rats retained more of the single therapeutic dose of copper than did iron-deficient rats. In both types of animals only a small fraction of the copper fed was retained. The kidney, the liver, and the bone marrow showed the highest relative retention of copper. The entrance of therapeutic copper into the bone marrow of the copper-deficient rats was demonstrated.

**The influence of nutritional supervision on dental caries, P. R. HOWE, R. L. WHITE, and M. D. ELLIOTT (*Jour. Amer. Dent. Assoc.*, 29 (1942), No. 1, pp. 38-43, fig. 1).**—This investigation was concerned with the incidence of new caries in a group of 189 children from 3 to 12 yr. of age under the supervision of the medical-nutrition department of the Forsyth Dental Infirmary for Children for an average period of 3.3 yr. as compared with the incidence in controls, children who were also dental patients at the infirmary but who received no dietary advice. "A significant reduction was found to have occurred in the average number of new cavities per child per year in each age group of the supervised children as compared with the controls. The average decrease in new cavities for all age groups was 56 percent. These findings indicate that the progress of dental caries in children can be substantially reduced by an intensive educational program in nutrition."

**Graying of hair produced by ingestion of phenylthiocarbamide, C. P. RICHTER and K. H. CLISBY (*Soc. Expt. Biol. and Med. Proc.*, 48 (1941), No. 3, pp. 684-687, figs. 2).**—Of 23 black rats given as their sole drinking water a solution of phenylthiocarbamide in increasing concentrations from 0.001 per-

cent at the beginning to 0.1 percent, representing daily doses increasing from 1.3 to 14.1 mg., all but one showed definite graying of the fur, beginning as early as 27 days and becoming very distinct after 58 days. In most cases the graying took place in essentially the same pattern, which is described and illustrated by photographs. In all instances the top of the head remained black. In 5 of the grayed rats which were given tap water in place of the phenylthiocarbamide solution, the hair turned black again over the entire body in the reverse order of the graying, the return of the color being complete in 83 days.

These findings are considered of particular significance as showing that graying may result from a positive factor in the diet, as well as from a deficiency of some factor, although the possibility is suggested that the phenylthiocarbamide may combine in the body with pantothenic acid or some other factor and thus produce an actual deficiency.

**Recent advances in vitamin knowledge: Vitamins and microorganisms,** E. N. TODD HUNTER (*Jour. Home Econ.*, 34 (1942), No. 2, pp. 109-112).—This review of the literature is presented under the headings microbiological assays, synthesis of vitamins by micro-organisms, and vitamin C and micro-organisms. A list of 16 references to the literature is appended.

**Absorption, metabolism, and storage of vitamin A and carotene, with some remarks on the vitamin A requirement,** T. K. WITH (*Köbenhavn (Copenhagen): Einar Munksgaard; London: Humphrey Milford, 1940, pp. VIII+263*).—This work, translated from the Danish by H. Andersen, presents details of studies carried out in the State Vitamin Laboratory, Köbenhavn (Copenhagen), in 1937-39. The scope of the work is indicated by the chapter headings as follows: Chemistry of vitamin A and the carotenoids, structure of vitamin A and the carotenoids—its connection with their biological activity, comparison between biological estimation and chemical measurements of vitamin A—conversion of measured results and older vitamin A units to International Units, Carr-Price reaction of the carotenoids and its significance to chemical measurement of Vitamin A, technic of analysis, studies on the carotenoid and vitamin A contents of serum, studies on the excretion of vitamin A and carotenoids with feces, studies on the vitamin A content of the liver in man, studies on the absorption and conditions for depositing of vitamin A in the rat, studies on the vitamin A consumption of chicken embryos, and on the vitamin A requirement of man and warm-blooded animals. An extensive bibliography and protocols of the experiments are presented in separate chapters.

**Vitamin-A and the biologically active carotenoids,** R. F. HUNTER (*Chem. and Indus.*, 61 (1942), No. 8, pp. 89-94).—This review is concerned with the chemistry and the physiological activity of vitamin A and the members of the carotenoid group with which it is actively associated.

**Changes of vitamin A distribution in choline deficiency,** H. POPPER and H. CHINN (*Soc. Expt. Biol. and Med. Proc.*, 49 (1942), No. 2, pp. 202-204).—Young rats placed on a low-choline, low-methionine, high-cystine diet supplemented with carotene and the crystalline vitamins developed fatty livers of varying degrees within from 2 to 10 days. Examination of the tissues for vitamin A under the fluorescence microscope or by chemical analysis showed the livers to be poor in vitamin A. The kidneys, showing characteristic hemorrhagic changes on about the sixth day, were extremely rich in vitamin A. In control animals, receiving 25 mg. of choline chloride daily, the livers were rich in vitamin A and the kidneys did not contain the excessive amounts of the vitamin.

**An investigation of simple methods for diagnosing vitamin A deficiency**

by measurements of dark adaptation, D. J. DOW and D. M. STEVEN (*Jour. Physiol.*, 100 (1941), No. 3, pp. 256-262, fig. 1).—This study, conducted on two well-nourished subjects in good health, was concerned chiefly with the relation between recovery times (the time required to perceive a field of constant brightness during dark adaptation following a period of light adaptation) and the final threshold of rod vision, as determined with the adaptometer and technique described by Steven and Wald (*E. S. R.*, 87, p. 313). The final rod thresholds did not vary with the individual tests and were identical for the two subjects, but the recovery times were less constant and unlike for the two. As the level of vitamin A nutrition was optimal for both, it is emphasized that there is no ground for stating that the longer recovery time indicates a poorer state of vitamin A nutrition, and it is concluded that although tests of the recovery time type will probably detect a severe case of night blindness, they are not sufficiently sensitive to give unequivocal data on the course of dark adaptation.

"In certain circumstances a 'recovery time' test may be of use. It may be important to measure the initial speed of dark adaptation of aviators, seamen, or other nocturnal workers. Such tests may be of value in these cases, especially when the complete course of dark adaptation is recorded also by an accurate method, but they must be considered ad hoc tests of the speed of dark adaptation and not a method of diagnosing vitamin A deficiency."

**Vitamin B<sub>1</sub> (thiamine hydrochloride).**—Annotated bibliography supplement (*Rahway, N. J.: Merck & Co., 1942*, pp. [2]+62).—A second supplement (*E. S. R.*, 86, p. 708), dated August 1942, to this bibliography (*E. S. R.*, 86, p. 423).

**Studies of the average American diet.**—1, **Thiamine content**, R. L. LANE, E. JOHNSON, and R. R. WILLIAMS (*Jour. Nutr.*, 23 (1942), No. 6, pp. 613-624).—This paper deals with the thiamin content of a series of diets formulated to contain all the more important foodstuffs of the American dietary, as indicated primarily by the compilation of Stiebeling and Phipard (*E. S. R.*, 81, p. 142), and in proportions corresponding to the annual per capita consumption of each. Representative samples of these foods, including cereal products, dairy products, meats, fats and oils, and vegetables and fruits, were analyzed for thiamin by the thiochrome method of Schultz, Atkin, and Frey noted on page 223. The figures for individual foods were used in calculating the thiamin content, per 2,500 calories, of the various diets formulated; these calculated values were checked by actual analyses of the various diet mixtures. The results showed that the thiamin content of the average American diet is about 0.8 mg. per 2,500 calories, and that the principal contributors of thiamin to the prevailing diets are lean pork, bread, and milk. It is estimated that universal substitution of enriched flour and bread for the corresponding unenriched products would increase the average thiamin intake about 64 percent to about 1.3 mg. per 2,500 calories.

Preliminary trials of the thiochrome method in comparison with the rat curative method indicated that the former tended to give low thiamin values for cooked flesh foods on account of incomplete extraction. This error was probably of significance, however, only in estimating the contribution of lean pork to mixed diets. It was also shown that flesh foods desiccated at low temperature by boiling with xylene gave thiochrome assay values that were much too low. The data presented on the thiamin content of foods as purchased would permit approximate calculation of thiamin yields of other diets as cooked and served.

**Thiamin content of various milks**, N. KENDALL (*Jour. Ped.*, 20 (1942), No. 1, pp. 65-73, figs. 3).—The method described for determining thiamin in milk involved incubation of the milk with takadiastase; oxidation of the thiamin to thiochrome by the addition of potassium ferricyanide, followed by sodium hydroxide; extraction of the thiochrome with isobutyl alcohol; and measurement

of the fluorescence of this solution in the fluorimeter. A blank, run with each specimen of milk, was treated similarly, except that the reagent was omitted, and the fluorescence, representing that of the reagents and of nonthiochrome substances in the milk, subtracted from that of the sample. The raw cow's milk tested contained from 41 to 48  $\mu\text{g.}$  of thiamin per 100 cc.; from 10 to 20 percent of the thiamin content was lost in pasteurization. The several samples of market milks tested contained from 35 to 40  $\mu\text{g.}$  of thiamin per 100 cc. Evaporation of milk appeared to destroy from 25 to 50 percent of the thiamin, since the 3 brands of evaporated milk tested contained but from 18 to 27  $\mu\text{g.}$  of thiamin per 100 cc. after reconstruction to simulate fresh milk. Most of the reconstructed dried milks assayed contained from 30 to 60 percent less thiamin than fresh cow's milk. Thiamin values for 63 specimens of human milk obtained from 32 women from 1 to 10 days post partum varied from 0 to 9  $\mu\text{g.}$  per 100 cc., the gradual rise occurring during the first few days of lactation.

**The variability in the thiamin content of western Canadian hard red spring wheat of the 1940 crop,** H. JOHANSSON and C. E. RICH (*Cereal Chem.*, 19 (1942), No. 2, pp. 308-313, figs. 3).—When 265 samples of hard red spring wheats taken from commercial car lots from shipping points in Manitoba, Saskatchewan, and Alberta were assayed for thiamin content by the modified thiochrome method of the authors (E. S. R., 87, p. 8), the values, expressed as micrograms per gram on a 13.5-percent moisture basis, averaged 3.93, with a range from 2.2 to 8.0. The means for each province were not significantly different, but the western part of the area showed a greater range in values. A map showing areas with wheats of similar thiamin content (at four different levels) indicated a random arrangement, with no relation to soil type. Areas according to thiamin distribution were found also to be unrelated to areas based on the ash and protein content of the wheat each produced.

**The measurement and metabolism of thiamin and of a pyrimidine stimulating yeast fermentation found in the blood cells and urine of normal individuals,** A. T. GORHAM, J. C. ABELS, A. L. ROBINS, and C. P. RHODES (*Jour. Clin. Invest.*, 21 (1942), No. 2, pp. 161-176, figs. 4).—The techniques used, which are described in detail, were adaptations of the fermentation method of Atkin, Schultz, and Frey (E. S. R., 83, p. 444). The average thiamin levels of the normal white cells was found to be about 10 times that of normal erythrocytes, a distribution similar to that of riboflavin and of ascorbic acid, as recently reported. It is suggested that this higher concentration may be explained by the fact that, of the several blood constituents, the white cells most closely resemble actively metabolizing tissue.

The intravenous administration of 5 mg. of thiamin to three female and two male adult subjects was followed within 3 hr. by increases in the levels of true thiamin in the cells, ranging from 80 to 132 and averaging 100 percent above their original values, and also by increases in PAYF (pyrimidines accelerating yeast fermentation), ranging from 41 to 180 and averaging 143 percent of the original level. With one exception, the values tended to return to base levels within 24 hr. The 24-hr. urinary excretion of both compounds was significantly increased by the test dose of thiamin. Similar injections of PAYF were followed within 3 hr. by a marked increase in the white cell level of PAYF, while there was an increase in thiamin in only one case within that time. The urinary excretion of PAYF after its intravenous administration was considerably less than after injection of the thiamin. That the excretion of PAYF cannot be explained by spontaneous decomposition of thiamin was shown by the demonstration that the administration of thiamin to a leukemia patient is not followed by any increase in the content of PAYF in the urine. It is concluded that in the course of its metabolic activity thiamin is probably broken down to the

pyrimidine compound. This is in line with the observations of Wertz and Mitchell (E. S. R., 87, p. 314).

**Pathological variations in blood and spinal fluid pyruvic acid**, E. BUEDIG, H. WORTIS, and M. STERN (*Jour. Clin. Invest.*, 21 (1942), No. 1, pp. 85-89, figs. 2).—In an effort to determine the clinical significance of pyruvic acid levels in blood and cerebrospinal fluid, determinations of both by methods previously described (E. S. R., 87, p. 603) were made on a group of 41 normal individuals and several groups of patients with various disorders.

Blood values for the normal subjects ranged from 0.77 to 1.23 mg. percent, with an average of 1.02, or well below the 1.30 mg. percent considered to be the highest normal level (E. S. R., 85, p. 852). In the various clinical groups tested, 45 out of 48 whose condition was classified as acute peripheral neuropathy and 22 of 35 with miscellaneous conditions accompanied by elevated temperature showed an abnormal elevation of both blood and spinal fluid pyruvic acid. Normal fasting levels in both blood and spinal fluid were found in cases of chronic peripheral neuropathy, chronic alcoholism without objective evidence of nutritional deficiency, various psychiatric and medical disorders, and certain cases with fever.

It is emphasized that a normal fasting pyruvic acid may not be an invariable evidence of thiamin adequacy. Occasional cases with normal fasting blood pyruvate have shown an abnormal pyruvate curve following glucose ingestion. "This suggests that the pyruvic acid curve following glucose ingestion may prove to be a more sensitive index of thiamin adequacy than the fasting blood pyruvic acid level."

The authors had the technical assistance of D. Esturonne.

**Nicotinic acid**, R. F. GRIGGS (*Science*, 95 (1942), No. 2459, p. 171).—Acceptance for popular usage of "Niacin" and "Niacin Amide" as synonymous with nicotinic acid and nicotinic acid amide is recommended by the food and nutrition board of the National Research Council. The committee which made the recommendation (C. A. Elvehjem, W. H. Sebrell, and T. D. Spies) also recommends, however, that the terms nicotinic acid and nicotinic acid amide be used in scientific literature, and that the new terms be used only where there may be objection from the public, as, for example, objection to the enrichment of bread with nicotinic acid which in the lay mind is confused with the poisonous alkaloid nicotine.

**Studies on the urinary excretion of pantothenic acid**, R. H. SILBER and K. UNNA (*Jour. Biol. Chem.*, 142 (1942), No. 2, pp. 623-628).—Simultaneous determinations of pantothenic acid and riboflavin in the urine and blood of dogs during diuresis before and after oral and intravenous administration of calcium pantothenate and sodium riboflavin are reported. The 2-hr. excretion of two dogs before the administration of the calcium pantothenate contained an average in four experiments of 7.5  $\mu$ g. of pantothenic acid and 9.2  $\mu$ g. of riboflavin. After an oral dose of 1 mg. of calcium pantothenate per kilogram of body weight there was no significant increase in the excretion of the pantothenic acid, but when the dose was increased to 4 mg. there was a distinct increase which reached a peak at from 60 to 100 min. and amounted in 2 hr. to from 0.9 to 5.0 percent of the dosage. When the same doses were given by intravenous injection, from 22 to 31 percent of the 1-mg. dose was excreted in the urine, with the peak within 40 min., and from 41 to 57 percent of the 4-mg. dose with the peak within 20 min. One of the dogs was finally given 4 mg. per kilogram of calcium pantothenate and in another test the same amount of sodium riboflavin by intravenous injection, and the content of both pantothenic acid and riboflavin determined in the blood and urine at stated intervals for 2 hr. The blood level of pantothenic acid rose within 5 min. from 2.2  $\mu$ g.

to 26  $\mu\text{g.}$ , but returned to normal within the 2 hr. The peak in urinary excretion occurred in 20 min. With riboflavin the blood level of riboflavin reached a peak in 11 min. and returned to nearly the original level in 2 hr. The peak in excretion occurred at 40 min. The administration of calcium pantothenate had no appreciable effect on blood or urinary riboflavin and vice versa. This is contrary to the report of Spies et al. (E. S. R., 85, p. 133) that intravenous injection of pantothenic acid in human subjects is followed by a temporary rise in the riboflavin concentration of the blood, and that similarly the injection of riboflavin produces an increase in the pantothenic acid content of the blood.

**A supplementary growth factor for *Lactobacillus casei*, M. F. CLARKE, M. LECHYCKA, and A. E. LIGHT** (*Jour. Biol. Chem.*, 142 (1942), No. 2, pp. 957-958).—Rice polishings concentrate assayed for pantothenic acid by the method of Pennington et al. (E. S. R., 85, p. 442) promoted acid production by *L. casei* well beyond the amounts formerly considered maximum. The factor involved seemed to be present in two commercial yeast concentrates in much smaller concentration than in the rice polishings concentrate and to be absent from the yeast extract (Difco, Bacto) used as a component of the basal medium. The effect of increased acid production was not removed by one treatment of the rice polishings concentrate with fuller's earth at pH 4, and was only partially destroyed by incubation overnight at 50° [C.] with takadiastase, but was destroyed by autoclaving at 15 lb. for 30 min. in NaOH at pH 12.

**Riboflavin.**—Annotated bibliography supplement (*Rahway, N. J.: Merck & Co.*, 1942, pp. [2]+27).—A second supplement (E. S. R., 87, p. 151), dated September 1942, to this bibliography (E. S. R., 85, p. 703).

**The quantitative relationship of riboflavin to cataract formation in rats, H. M. BAUM, J. F. MICHAELREE, and E. B. BROWN** (*Science*, 95 (1942), No. 2453, pp. 24-25).—The inconsistency in cataract formation in rats fed on riboflavin-deficient diets, as reported by various observers, is explained as being due to differences in the freedom of the basal diet from riboflavin. The Bourquin-Sherman diet was found to contain enough riboflavin so that on the basis of average consumption the rats received 0.57  $\mu\text{g.}$  of riboflavin on the basal diet alone. When the vitamins of the B complex other than riboflavin were fed as the crystalline vitamins in place of the 80 percent alcoholic extract of the Bourquin-Sherman diet, only 14 percent of the animals contracted cataract as compared with 90 percent on the less highly purified Bourquin-Sherman diet. When the more highly purified diet was supplemented with from 1 to 3  $\mu\text{g.}$  of riboflavin, cataract developed. On another modification involving Crisco as a source of fat instead of filtered butterfat, none of the rats developed cataract. It is concluded that rats on a diet completely devoid of riboflavin do not develop cataract, and that minute amounts of riboflavin induce cataract, while rations containing more nearly adequate amounts are noncataractogenic.

**Distribution of biotin and avidin in hen's egg, P. GYÖRGY and C. S. ROSE** (*Soc. Expt. Biol. and Med. Proc.*, 49 (1942), No. 2, pp. 294-298).—Quantitative determinations of biotin and avidin in whole egg in which the white and yolk were thoroughly mixed invariably showed an excess of avidin. This finding was confirmed by separate analyses of the white and yolk for free and bound biotin and for free and bound avidin. Determinations of the content of biotin in egg yolk subjected to various treatments suggested that biotin is present in egg yolk in combination with a larger molecule, probably a globulinlike constituent of the egg yolk. This compound was precipitated by cold distilled water (partly also by acetone), was soluble to a large extent in cold saline, and could be split, with simultaneous liberation of biotin, by steaming for a short time. The high molecular biotin compound was found to be nondialyz-

able. The bound biotin in egg yolk was physiologically available, however, to rats as well as to yeast.

**Preliminary observations on "egg white injury" in man and its cure with a biotin concentrate**, V. P. SYDENSTRICKER, S. A. SINGAL, A. P. BRIGGS, N. M. DEVAUGHN, and H. ISBELL. (Univ. Ga. et al.). (*Science*, 95 (1942), No. 2459, pp. 176-177).—This preliminary report describes briefly the production in four adults of signs and symptoms strikingly similar to those of spontaneous avitaminosis on a diet in which approximately 30 percent of the total calories was supplied by desiccated egg white and which was supplemented with thiamin chloride, riboflavin, nicotinic acid, pyridoxin, calcium pantothenate, ascorbic acid, vitamin A, ferrous sulfate, and calcium lactate. During the third and fourth weeks all of the subjects developed a fine scaly desquamation without pruritus, disappearing in from 7 to 10 days. No other skin disturbances developed until the seventh week, when one subject developed a maculosquamous dermatitis of the neck, hands, arms, and legs. During this and the following week, all of the subjects showed a pronounced gray pallor of the skin and atrophy of the lingual papillae. During the ninth and tenth weeks, the skin of all of the subjects became increasingly dry, with reappearance of the fine scaly desquamation. No ocular or genital lesions were observed. After the fifth week symptoms very similar to those of experimental thiamin deficiency appeared. The blood hemoglobin, erythrocytes, and volume of packed red cells decreased definitely, and there was a slight increase in bile pigments and a striking increase in serum cholesterol.

Treatment with an injectable biotin concentrate in doses of from 75 to 300  $\mu$ g. daily, administered in three aliquots, was successful at a level of 150  $\mu$ g. and above. The symptoms similar to those of thiamin deficiency disappeared in from 3 to 5 days and the ashy pallor of the skin in 4 days, and there was a reduction of serum cholesterol in 4 days. Immediately after the administration of 150  $\mu$ g. of biotin, the urinary excretion of biotin rose to about 55  $\mu$ g. and remained at that level until the dosage was increased to 300  $\mu$ g., when the excretion promptly rose to from 140 to 150  $\mu$ g.

**Pathologic aspect of nutritional deficiencies in rats.—I, Lesions produced by diets free of vitamin B<sub>6</sub> (pyridoxine) and the response to vitamin B<sub>6</sub>**, W. ANTOPOL and K. UNNA (*Arch. Pathol.*, 33 (1942), No. 2, pp. 241-258, figs. 9).—This paper discusses in detail, with numerous photographs and microphotographs, the pathology and histology of the deficiency syndrome occurring in rats on diets free from pyridoxin, differentiating the specific from the nonspecific signs and symptoms, and the changes following administration of pyridoxin and other vitamins of the B complex. "The hyperkeratosis and acanthosis of the ears, paws, and snout, together with the edema of the corium, are considered characteristic of vitamin B<sub>6</sub> deficiency in rats."

**Acido ascorbico (vitamin C) en 26 muestras de jugos de uvas [Ascorbic acid (vitamin C) in 26 samples of grape juice]**, H. P. TOMEIO IBARRA (*Univ. Repub. [Montevideo], Rev. Facult. Agron.*, No. 25 (1941), pp. 109-115).—Twenty-two of the samples were of Uruguayan origin and these contained from 1.3 to 4.7 mg. ascorbic acid per 100 cc.

**Vitamin C content of fresh, canned, and dried guavas**, L. GOLDBERG and L. LEVY (*Nature [London]*, 148 (1941), No. 3749, p. 286).—This is a preliminary report of results obtained with guavas from the Transvaal and Cape Province, Africa, analyzed for ascorbic acid by indophenol titration of a 2-percent metaphosphoric acid extract of the material. Fresh guavas, as whole fruit, at the green and hard, ripe and firm, and overripe and soft stages, contained, respectively, 250-350, 300-450, and 50-100 mg. of ascorbic acid per 100 gm. Varietal and regional variations were not wide, but white-fleshed guavas were

usually slightly richer in ascorbic acid than those with pink flesh. The concentration of the vitamin decreased from skin to outer pulp to inner pulp in the proportion 12:5:1. When firm ripe fruit was canned, the ascorbic acid in the canned product (fruit and juice) reached 200-300 mg. per 100 gm.; the use of soft fruit reduced the content to as low as 18 mg. per 100 gm. Pulping and overcooking also greatly reduced the vitamin content. Drying the fruit at low temperature most successfully preserved the ascorbic acid content. The procedure developed involved removal of stones and central pulp from the quartered unpeeled fruit, blanching of the residue for 2 min., followed by drying at 130° F. for from 10 to 12 hr., and powdering of the dried fruit. The powdered guava thus prepared contained 2,500-3,000 mg. per 100 gm. in the white varieties and 2,000-2,500 mg. in the pink-fleshed varieties. Failure to blanch the fruit resulted in lower values.

**Further analysis of the rôle of ascorbic acid in phenylalanine and tyrosine metabolism,** R. R. SEALOCK, J. D. PERKINSON, JR., and D. H. BASINSKI (*Jour. Biol. Chem.*, 140 (1941), No. 1, pp. 153-160, figs. 2).—Similar effects to those previously reported for *l*-phenylalanine (E. S. R., 85, p. 572) were obtained when phenylpyruvic acid was fed to vitamin C-deficient guinea pigs, but the feeding of the *p*-hydroxy derivative of phenylpyruvic acid under the same conditions resulted in the excretion of metabolites only slightly affected by the administration of ascorbic acid.

**Effect of controlled ascorbic acid ingestion upon urinary excretion and plasma concentration of ascorbic acid in normal adults,** C. A. STORVICK and H. M. HAUCK. (Cornell Univ.). (*Jour. Nutr.*, 23 (1942), No. 2, pp. 111-123, fig. 1).—In continuation of the authors' studies on vitamin C metabolism and requirements (E. S. R., 82, p. 428), two men and four women served as subjects for daily determinations after a preliminary saturation period of ascorbic acid in the blood plasma and in 24-hr. urines during 21 experimental periods of 28 days each on stated levels of ascorbic acid.

The mean daily urinary ascorbic acid excretions differed for the various subjects on the same intake. On 200 mg. the values for the women ranged from 154 to 164 mg., and the values for the two men were 135 and 130 mg. Similar variations occurred on the lower levels. The fasting plasma values were characteristic for each individual, with no characteristic sex differences. The mean values for the six subjects on the 200-mg. level ranged from 1.07 to 1.58 mg. per 100 cc. Although in general higher values were obtained on higher intakes of ascorbic acid than on lower, the range of values on each level was so wide as to indicate that a single plasma determination is of limited value as an index of vitamin C nutrition. Two criteria were used in estimating from the vitamin C content of the urine following test doses the minimum requirement for saturation—(1) the lowest individual response to a 400-mg. dose following a preliminary saturation period and (2) the excretion within 24 hr. of at least 50 percent of the test dose. According to (1), the daily requirements of the two men were 100 and 150 mg. and of three of the women 100+, 75, and 125+ mg. daily; corresponding values by criterion (2) were the same for the men and 90, 65, and 90 mg., respectively, for the women. These quantities were in addition to approximately 10 mg. of ascorbic acid in the basal diet.

**The administration of vitamin C in a large institution and its effect on general health and resistance to infection,** A. J. GLAZEBROOK and S. THOMSON (*Jour. Hyg. [London]*, 42 (1942), No. 1, pp. 1-19, figs. 3).—From observations on the diet and cooking practices at a training school for about 1,500 boys from 15 to 20 yr. of age and from vitamin C determinations on some of the foods eaten, it was estimated that while the diet was liberal in calories (over 4,000)

and contained good sources of vitamin C, prolonged cooking times and delays before serving reduced the total intake of ascorbic acid to from 10 to 15 mg. per student per day.

Following a single dose of 300 mg., none of 75 of the boys tested excreted appreciable amounts of ascorbic acid. The resting levels of excretion of the boys in the absence of a test dose ranged from 5.6 to 1.1 mg., with an average of 2.5 mg. per 24 hr. In attempts to saturate a group of 350 boys by adding sufficient ascorbic acid to the milk and cocoa to furnish a total intake (with that of the regular diet) of 200 mg., 8 days were required to bring the resting level of excretion to that of normal adults and 22 days to complete saturation. By adjusting the levels of intake following saturation, excretion levels considered normal were reached on 25 mg. of ascorbic acid twice daily. The same figure was reached in a group study in which 24-hr. urine samples were pooled.

The incidence of common colds and tonsillitis was the same over a period of several months in two groups of adolescents at the institution, one of which received large supplements of ascorbic acid and the other did not. The average duration of colds was the same in the two groups but of tonsillitis longer in the control than in the test group. Rheumatic fever and pneumonia occurred in the control but not in the test group.

**The ascorbic acid requirements of children,** O. A. BESSEY and R. L. WHITE (*Jour. Nutr.*, 23 (1942), No. 2, pp. 195-204, fig. 1).—The blood plasma ascorbic acid levels of 93 healthy city children receiving various amounts of ascorbic acid in their diet were plotted against the dietary intakes as calculated from dietary histories to locate the minimum intake which would give the average maximum post-absorptive blood plasma level.

Of the children who received 3 oz. or more of orange juice daily or an equivalent amount of ascorbic acid in citrus fruits and tomatoes, 80 percent maintained blood plasma levels of ascorbic acid indicative of a liberal intake. The amount of ascorbic acid available from other sources was considered to be insufficient to influence the blood plasma values. "This finding emphasizes the necessity of a regular consumption of citrus fruits or tomatoes if an optimal postabsorptive plasma value is to be maintained. Furthermore, it suggests that in taking nutritional histories the evaluation of the citrus fruit and tomato intake is a simple, practical, and accurate means of determining ascorbic acid consumption, at least as far as the optimum range is concerned."

**Experimental vitamin P deficiency,** S. RUSZNYÁK and A. BENKÓ (*Science*, 94 (1941), No. 2427, p. 25).—It is noted briefly that rats can be used to study vitamin P deficiency and the effectiveness of citrin preparations, for while rats do not develop signs and symptoms of vitamin C deficiency on an ascorbic acid-free diet, they do show lowered capillary resistance within 5 or 6 weeks, and this responds to treatment with from 3 to 4 mg. of citrin daily administered subcutaneously.

**Dietary requirements for fertility and lactation.**—XXX, **Role of p-aminobenzoic acid and inositol in lactation: Preliminary report,** B. SUBE. (Ark. Expt. Sta.). (*Science*, 94 (1941), No. 2433, p. 167).—In this preliminary report evidence is summarized confirming the suggestion made in the preceding report of the series (E. S. R., 87, p. 592) that p-aminobenzoic acid is essential for reproduction and lactation in the rat. Evidence is still inconclusive concerning inositol.

## TEXTILES AND CLOTHING

**The chemical analysis of fibre mixtures,** F. HOWLETT, M. J. MORLEY, and A. R. URQUHART (*Jour. Textile Inst.*, 33 (1942), No. 6, pp. T75-T104, figs. 2).—Following an introductory review of published work on fiber analysis, it is

pointed out that the methods used, although accurate, have had too limited a field of applicability. "The present paper is an attempt to widen the field of use of a few chosen methods so as to include many more fibers, and to explain how far modern finishes can be dealt with. No one previous method has been accepted and modified, but from the well-known solubility data of the more common fibers a series of suitable treatments has been selected so as to cover most of the known fiber mixtures, the accuracy of the methods being greater than the certainty of accurately spinning the mixtures. The only mixture of possible importance that has not been considered is that of wool and casein." Information is given concerning the general principles of the methods selected, the technic and apparatus, and solutions required, and detailed consideration is given to experimental methods used and results obtained in separating and identifying pairs of fibers and triple mixtures. Fifty-four references are given.

**A comparative study of four methods for the quantitative determination of wool in mixed fabrics,** L. E. WEIDENHAMMER. (U. S. D. A.). (*Amer. Dyestuff Rptr.*, 31 (1942), No. 19, pp. 441-445).—The four methods, described briefly and including the caustic boil, aluminum chloride, sulfuric acid, and flotation methods, were applied to two wool and cotton and two wool and spun viscose rayon fabrics manufactured for experimental purposes and to two commercial blanket fabrics. Known mixtures prepared from all-wool, all-cotton, and all-viscose rayon fabrics, finely cut and intimately mixed, were also analyzed by the four methods. The results of the analyses were tabulated and the data analyzed statistically by the method of analysis of variance. The sulfuric acid method was found in general to give higher results than the other methods, which did not differ greatly among themselves. Except for the flotation method, the various procedures used had a high degree of precision. The caustic boil method was very accurate when the correction factor (necessitated because of the solution of some cellulosic material along with the wool fraction) could be accurately determined; in the present tests a correction allowing for about 1½ percent loss of cotton and 5 percent loss of rayon seemed to be about right. The aluminum chloride method tended to give results that were too low by about the same amount as the sulfuric acid results were too high. Calculations indicated that for routine analysis two samples were probably sufficient for any of the four methods. It is pointed out that the caustic boil method, while quick and convenient, requires the use of a correction factor, and that further work is needed to determine the extent to which various cotton and rayon materials are dissolved under the conditions of the test. The flotation test, although somewhat unreliable, has the advantage of requiring but a small sample and of permitting both components to be recovered. The aluminum chloride method, although precise and reasonably accurate, is tedious, time-consuming, and deleterious to operator and equipment. The sulfuric acid method, also precise and accurate, requires fairly large quantities of 70-percent sulfuric acid that may not be available during wartime.

**An examination of the relation between wool quality and fibre diameter,** J. L. STOVES (*Jour. Textile Inst.*, 32 (1941), No. 12, pp. T221-T226, figs. 3).—This is a review of published studies on fiber fineness and wool quality and on methods of measuring fiber diameter. Nineteen references are given.

**Dependence of the indigestibility of wool protein upon its polymeric structure,** W. B. GEIGER and M. HARRIS (*Jour. Res. Natl. Bur. Standards [U. S.]*, 29 (1942), No. 4, pp. 271-277, fig. 1).—"The resistance of wool to digestion by enzymes is probably due to a unique structure, consisting of peptide chains joined by disulfide cross links to form a three-dimensional polymeric network of extremely high molecular weight. This conclusion is substantiated by a study of a series of derived wool proteins similar in composition but expected

to differ in molecular weight. The proteins were prepared by first 'depolymerizing' wool by reducing its disulfide cross links to sulfhydryl groups, then making a series of solutions of this protein of widely varying concentration, and finally rebuilding the disulfide cross links by reoxidation. An investigation of the rates of digestion by pepsin of a series of such proteins showed that those preparations expected to be of low molecular weight were rapidly digested, whereas those expected to be of greatest molecular weight were almost as resistant to digestion as untreated wool."

**A fiber identification stain**, H. L. DAVIS and H. J. RYNKIEWICZ (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 6, p. 472).—A stain containing acid fuchsin (Color Index No. 692) 6 gm., picric acid 10, tannic acid 10, and National Soluble Blue 2B Extra (Color Index No. 707) 5 gm., dissolved in hot water and made up to 1 l., was found to be a versatile and selective stain. Momentary immersion of the fiber in the hot stain or immersion for something over 2 min. for cold dyeing, followed by thorough rinsing, completes the test. With this stain, vegetable fibers, such as cotton or linen, are colored light blue. Of the synthetic fibers, acetate or Nylon is colored pale greenish yellow; cuprammonium, dark blue; viscose, lavender; and Vinyon, very pale blue. Of the animal fibers, wool is stained yellow; raw silk, black; and degummed silk, brown. Some dyed textiles may be identified without previous bleaching by treating with the stain in the usual way, rinsing, and pressing while wet between absorbent papers. A dye mixture characteristic of the color which would have been shown by the undyed fibers is transferred to the papers. The stain is also useful in the identification of films of cellulose acetate or viscose (Cellophane).

**Cloth strength testing** (*Jour. Textile Inst.*, 33 (1942), No. 6, pp. S7-S39, figs. 2).—Reports by members of the general technical committee A (physical testing) of the standardization section of the Textile Institute [British] are presented as follows: Introductory Review of the Committee's Work (pp. S7-S8) and Note on the Variability of Tensile Strength Tests on Cotton Fabric (pp. S22-S23), both by A. W. Bayes; Comparison of Fabric Tensile Test Results Obtained in Different Laboratories, by B. D. Porritt, J. R. Scott, and W. H. Willott (pp. S9-S21); Some Theoretical Notes on the Constant Rate of Traverse Pendulum Type Cloth Tester, by J. G. Martindale and H. J. Woods (pp. S24-S33); The Measurement of Machine Rate of Load on Constant Rate of Traverse Type Cloth Testing Machines, by J. G. Martindale (pp. S34-S37); Methods of Calibrating Textile Strength Testing Machines, by E. Bowen (p. S38); and Method of Calibration of Horizontal Pendulum Type Fabric Tensile Testing Machine, by N. Goodbrand (p. S39).

**The breaking strength of fabrics**, P. LAROSE (*Jour. Textile Inst.*, 32 (1941), No. 9, pp. T167-T178, figs. 7).—Data showing the relation between the grab test and the strip test are presented, and a new test method possessing the advantages of the strip and grab methods is proposed. This test, designated tentatively as the "half-grab" test, "consists in taking a strip of cloth 2 in. wide and raveling only one side of it by removing a few yarns so as to leave a well-defined edge and protruding cross yarns as in the ordinary strip test. The strip is placed in the test machine fitted with jaws 1 in. wide so that the raveled edge is in line with one side of the jaws, as illustrated. On the other side, the strip will extend beyond the jaws for about 1 in. The advantages claimed for this method are that less material is required than for the grab test, perfect alignment of the yarns in the jaws is possible, thus increasing the reliability and accuracy of the results, and at the same time the preparation of the sample involves less work than for the strip test, since only one side is raveled and no measurement of width is necessary." Results

presented for tests by the three methods show that not only is the strip test more accurate on the whole than the grab test, but that the half-grab test is even more reliable. A correlation is worked out by statistical methods showing that a direct relation exists between the breaking strength results obtained by means of the strip method and those by one of the other two methods.

**A service study of three blanket fabrics made from various blends of wool and mohair.** R. E. ROGERS, M. B. HAYS, and J. I. HARDY. (U. S. D. A.). (*Amer. Dyestuff Rptr.*, 31 (1942), No. 13, pp. 318-324, fig. 1).—"Blankets were manufactured from good-quality new Corriedale wool blended with new Corriedale wool of poor quality, with reworked wool, and with mohair. They were put into use in a Government hospital, and test blankets were withdrawn from service at intervals in order to measure the deterioration due to wear and laundering. As measured by laboratory tests throughout service, the fabrics would rate in general in the following order of decreasing use value: Fabric 1, all new wool; fabric 3, containing new mohair; and fabric 2, containing reworked wool. The differences between fabrics, however, are small, and in heat transmission these differences are not even mathematically significant. An analysis of variance shows that fabric 1, containing poor-quality new wool, differs significantly from fabric 2, containing reworked wool, as measured by filling breaking strength both strip and grab, warp strength as determined by the strip method, air permeability, alkali solubility, and methylene blue absorption. According to these tests, fabric 1, part poor-quality new wool, is superior to fabric 2, part reworked wool. Tests for fiber quality on new blankets rated the two fabrics in the same order. Fabric 3 differs significantly from fabric 1 in strip breaking strength, air permeability, cystine sulfur content, and alkali solubility. Fabric 2 differs from fabric 3 in the warp breaking strength by both strip and grab tests, in filling strength by the strip method, sulfur and methylene blue. Fabric 3 is deteriorated more than fabric 1 but less than fabric 2. Tests for fiber end damage and length of fibers on unlaundered blankets, however, show that fabric 3 is least damaged.

"The breaking strength determined by the strip method showed more significant differences between fabrics than by the grab method. Also there were more significant differences in the filling direction than in the warp. As shown by laboratory analyses, significant changes were produced in blankets by service, but increasing amounts of wear and laundering did not produce progressive changes in the various properties. In this study none of the blankets were worn out after 48 or 60 launderings representing 96 and 120 weeks of wear, respectively."

**A study of four classes of sheets during service.** M. B. HAYS and R. E. ROGERS. (U. S. D. A.). (*Jour. Home Econ.*, 34 (1942), No. 2, pp. 112-117, figs. 3).—"The serviceability of percale, fine-count, two brands of mediumweight muslin, and one construction of heavyweight muslin sheets was studied by determining weight per square yard, thickness, warp and filling count and breaking strength, and shrinkage in length and width of representative sheets from each lot tested when purchased and after various intervals of actual service. The sheets were put into service in a Washington hotel where they were used for about 2 yr., after which they were reissued to homemakers. The data obtained indicated that "as wear progressed, each lot of sheets deteriorated progressively. The amount of service given by these five groups of sheets is closely related to their filling breaking strength. The heavyweight sheets intermediate in price were in general heavier, stronger, and less chemically tendered than the other classes originally and during service. The percale and fine-count sheets which were most expensive of those studied did not last so long as the heavyweight muslin, but they had a finer, softer texture.

Although the percale cost more than the fine count, it wore no longer than the latter. In this study the mediumweight muslin sheets which were lowest in price gave the least service."

**A study of oxygen absorption and catalase production during growth of *Chaetomium globosum* on cotton fiber and yarn, D. E. KLEMMER.** (U. S. D. A.). (*Jour. Bact.* 43 (1942), No. 2, pp. 171-180, figs. 5).—Sea-island cotton fiber and yarn manufactured from it were sterilized and inoculated with a strain of *C. globosum*, isolated from mildewed canvas, and incubated for 28 days in a Warburg apparatus of the seven-manometer, refrigerated type. The modified Warburg technic developed for studying the growth of the micro-organism on cotton is described. The growth of the organism was followed by daily measurements of oxygen consumption and by determination of catalase production as measured by the amount of hydrogen peroxide decomposed. In general the rate of growth of the organism on the fiber and on the yarn increased during the first 11 days, as indicated by the increased daily rate of oxygen consumption, after which it decreased. The amount of oxygen absorbed by the fungus growing on the fiber was significantly greater than that absorbed by the fungus growing on the yarn. Likewise, the amount of catalase produced by the fungus on the fiber was greater than on the yarn. These results indicated that, in general, raw cotton would deteriorate more readily in a moist atmosphere than would yarn or fabric, and more care, therefore, should be taken in storing the fiber. The accumulated amount of oxygen absorbed by the organism was estimated by adding the amount absorbed each day to the amount absorbed on previous days. The total amount absorbed by the fungus growing on 1 gm. of the fiber for 28 days was 0.32 milliequivalent and on 1 gm. of yarn 0.21 m. e. By the method of least squares a fourth degree polynomial equation was found for the accumulated absorption values for the fiber and another for the yarn.

**Clothing supplies of socially participating white farm families of Mississippi, A. BOWIE and D. DICKINS** (*Mississippi Sta. Tech. Bul.* 30 (1942), pp. [2]+51, figs. 6).—This study presents an analysis of the clothing owned by members of socially participating white farm families in 6 poor and 6 better agricultural areas in the State. The socially participating family was considered as one in which all members attended daytime preaching at least once a quarter. Clothing inventories were obtained from such families in all of the 70 churches in the 12 areas involved. "Ratings based on the modes for sex and activity groups were set up and given each individual clothing inventory. Somewhat more of the wardrobes of individuals in the poorer than in the better agricultural areas were classed as minimum supplies, while somewhat more of the wardrobes of those in better areas were rated as average and above. That there was not a greater difference was because more members of the poorer area families had gifts of clothing, or made dress garments at home." The composition of the minimum wardrobes for social participation in either area is noted for various family members in terms of headwear, outer garments, and footwear. These minimum wardrobes, it is pointed out, do not represent the minimum desirable for social participation in these areas. The families whose clothing supplies were ranked as minimum were also the ones who made up the majority of the group with the lowest social participation. These clothing types appeared to lack warmth and social acceptability. Clothing supplies with the characteristics most common to the entire sex and activity group were from the standpoint of comfort and social adequacy the best for the least cost.

**Minimum clothing supplies, D. DICKINS** (*Miss. Farm Res.* [Mississippi

*Sta.*], 5 (1942), No. 10, p. 2).—A list of the minimum clothing supplies discussed in the publication noted above.

**Performance during wear of women's and children's wearing apparel fabrics** (*Rhode Island Sta. Rpt.* [1941], pp. 51-52).—A progress report on a cooperative project of six of the northeastern stations.

**British develop clothing standards as result of rationing program** (*Indus. Standardization*, 13 (1942), No. 7, pp. 207-208).—It is noted that four British war emergency standards for women's clothing have been issued by the British Standards Institution "to provide good coupon value" for rationed garments. The four standards, covering women's dresses, underwear, blouses, and boots and shoes, specify methods of manufacture, including minimum allowance for seams, minimum number of stitches per inch and per button and type of seam to be used, in addition to the series of standard sizes qualified according to hip, bust, and waist measure. The standard provides that a size tag indicating the size specification to which the garment conforms must be attached to the garment. Charts for each series of sizes give more detailed measurements, including cross back, cross chest, armhole circumference, etc. The Board of Trade for which the BSI prepared the standards has authority to make these mandatory for the manufacture of all garments in the classifications covered. This has been done in the case of women's underwear and blouses.

**A comparison of the efficiencies of home and commercial laundry processes**, E. LOVELL, J. ROBERTS, and J. BRODIE (*Amer. Dyestuffs Rptr.*, 31 (1942), No. 13, pp. 301-306, 324, fig. 1).—Standard cotton test bundles consisting of (1) high-grade unsized tarantulle sheeting for the determination of tensile strength and fluidity, (2) a standardly soiled heavy weight drill and a standardly soiled tarantulle sheeting for the determination of detergency efficiency, and (3) a white cotton duck for the determination of whiteness retention were laundered by a controlled commercial process and by home processes involving various combinations of gyrator and vacuum-cup washing machines with wringer or spinner and with drying indoors or outdoors. The home supplies consisted of water containing 9 gr. of hardness per gallon, a pure soap flake, sodium carbonate to soften the water, and a bluing. The commercial process used permutite-softened water and a multiple suds formula approved by the American Institute of Laundering. Five series of 20 bundles each were washed by the domestic and the commercial processes. Five bundles from each series were removed after 10, 25, 50, and 100 washings for determinations of tensile strength and fluidity and of whiteness retention and soil removal.

"By a statistical analysis of the data it was found that in the washing of cotton for soil removal the commercial process is superior to all domestic processes. For tensile strength loss the commercial process compares favorably with the domestic processes in which samples were dried outdoors, but loss in strength is greater in the commercially washed samples than in those washed domestically and dried indoors. Chemical degradation is least when clothes are dried indoors as in the commercial method and in the domestic process using indoor drying. The gyrator and vacuum cup gave similar results for degradation and tensile strength loss. The detergency efficiency of the gyrator in most cases was slightly superior to the vacuum cup. The wringer aids materially in soil removal and is superior in this respect to the spinner extractor. From the standpoint of wear indoor drying is preferable to outdoor, but for whiteness retention outdoor drying is preferable."

**The language of fashion: A dictionary and digest of fabric, sewing, and dress**, M. B. PICKEN ET AL. (*New York and London: Funk & Wagnalls Co.*, [1939], pp. XV+175, figs. 580).—Definitions are given for about 8,000 words associated primarily with wearing apparel and accessories and whatever goes

into the making of them. The words are defined from the fashion point of view and are assembled in groups for comparison and quick reference. Important stitches, laces, embroideries, and weaves are described; fabrics and leather are defined and their suitability for garments and other articles specified; furs, real and imitation, are noted; and hundreds of types of garments are given, with important identifying silhouette features and often notes regarding origin. Fashion names and terms from past eras, as well as those in current usage, are given, and trade terms, important trade marks, and copyrighted names are included. For the most part only the preferred spelling and pronunciations are given, but alternates are noted occasionally.

**Glass curtain fabrics studied** (*Ohio Sta. Bul. 617 (1940), p. 61*).—A progress report for the year 1938–39.

## HOME MANAGEMENT AND EQUIPMENT

**Rural family living with supplemental farm incomes** (*Rhode Island Sta. Rpt. [1941], p. 52*).—This progress report on a study of family living under a combined rural-urban situation (residence in the country and employment in the city) deals with food consumption habits as determined by records covering 2 weeks obtained from over 1,000 families.

<sup>10</sup> The experimental work reported is for the most part referred to elsewhere in this issue.

## NOTES

---

**Tuskegee Institute.**—Dr. George Washington Carver, associated with the agricultural research work of the institute since 1896, died January 7. The following extracts from an editorial in *The [Washington] News* summarize his remarkable career:

"Dr. Carver was born about 79 years ago—he never knew the date—in a primitive Missouri cabin. He was a slave and the son of slaves. . . . A war gave him freedom of body, but he freed his own intellect, overcoming almost insuperable obstacles of poverty and prejudice to gain learning and understanding. He devoted his life to the education and advancement of his race and to creative science. His discoveries of new uses for familiar substances, especially for the products of southern agriculture, are a rich legacy to his country and the world."

**Arkansas University and Station.**—Dr. S. B. Locke, assistant professor of plant pathology, has resigned. Dr. M. A. Sprague and L. B. Schweiger, instructors in agronomy and bacteriology, respectively, have entered military service. E. D. Matthews has been appointed associate professor of agronomy.

**California University and Station.**—According to a note in *California Fruit News*, the campus of the School of Agriculture at Davis and most of the facilities were to be taken at the end of the semester by the Signal Corps, U. S. Army, for training purposes. Some of the instruction courses are being transferred to Berkeley and Los Angeles, but it is expected to maintain the research and experimental field facilities under the supervision of the College of Agriculture.

**Colorado College and Station.**—Research on wool baling has shown that wool can be baled with half the amount of war-short burlap required when wool is marketed in bags. Tough wrapping paper supplements the burlap in baling in a cotton press.

The sections of home economics and mechanical engineering have planned and built an experimental dehydrator, in which about 20 Colorado fruits and vegetables have been tested. In cooperation with the Western Regional Research Laboratory, the station also is investigating the suitability of various varieties of Colorado fruits and vegetables for quick freezing.

Dr. N. A. Christensen, dean of the division of engineering, has been granted leave of absence at the request of the War Department. Dr. H. H. Stonaker has been appointed assistant in animal investigations, and Eugene Bertone, wool technologist.

**Connecticut [New Haven] Station.**—Dr. John W. Heuberger, plant pathologist, has resigned to engage in commercial work. He will continue his research for the Crop Protection Institute on organic fungicides at the Subtropical Experiment Station at Homestead, Fla.

**Purdue University and Indiana Station.**—A 623-acre farm, located near Carmel, has been given to the university for the use of the station by Charles J. Lynn of Indianapolis, together with his herds of 170 breeding Shorthorn cattle, 60 Percheron horses, 540 Berkshire hogs, and 100 head of feeding cattle. The farm, which is fertile and well equipped, will be used primarily as a source of seed stock for breeding animals.

The station was recently awarded a grant by the Nutrition Foundation, Inc., to investigate problems concerned with the vitamin C content of tomatoes and to determine the influence of breeding and selection upon these characteristics in existing strains of tomatoes as well as in the new strains which have resulted from hybridization of commercial strains of the wild species *Lycopersicon*. The work will be under the direction of the botany and agricultural chemistry departments, and Dr. J. W. Porter and G. M. Kohler have been added to the staff to carry it on.

At the northern Indiana Muck Soils Experimental Farm, extensive studies are being completed in cooperation with the U. S. D. A. Soil Conservation Service as a part of extensive studies on the influence of water levels in these soils upon such factors as crop production, fertility, and soil subsidence. L. B. Dumm has been given charge of the engineering phases of the project and Kent Ellis of the horticultural phases.

A cooperative project between the station and the U. S. D. A. Bureau of Entomology and Plant Quarantine and Plant Industry has recently been initiated which will be concerned principally with the development of resistant strains of corn and the testing of existing strains for resistance to the corn borer. The project is coordinated with a program approved by the station directors of the north central region to investigate problems concerned with corn borer control. Six men have been transferred to Lafayette from the Bureau of Entomology and Plant Quarantine to work on this program, and the corn breeding has been similarly transferred by the Bureau of Plant Industry.

Dean Emeritus Martin L. Fisher died December 1, 1942, at the age of 71 years. A native of Indiana, he was graduated from Purdue in 1903 and received the M. S. degree from the University of Wisconsin in 1912. He joined the Purdue staff immediately on graduation and had served continuously until his retirement in 1942. Beginning as instructor in agriculture, he became professor and assistant dean of agriculture in 1920 and was made dean of men in 1926.

Leave of absence has been granted to Dr. R. E. Nichols, assistant professor and associate in veterinary science, to enter military service and to four assistant agronomists, A. P. Bell, Sutton Myers, G. H. Robinson, and P. T. Veale, to work on a guayule project in California. Resignations from the station include R. L. Witz as assistant in agricultural engineering and Dr. E. D. Walter, R. L. Henry, and D. L. Johnson as assistant chemists. J. B. Kohlmeier has been appointed associate in land-use planning; P. C. Brown, assistant in veterinary science; M. A. Ewan and D. R. Bowman, assistants in agricultural chemistry; and T. L. Canada, technical assistant in agricultural economics.

**Kansas College and Station.**—A 57-acre tract in the Kansas River Valley, 6 miles from the college campus and adjoining a soil conservation nursery, has been purchased under a State appropriation of \$15,000 for the department of horticulture. The new farm will be used for student instruction and research in vegetable crops and pomology.

Leave of absence to enter the armed forces has been granted to Don E. Crumbaker, assistant in charge of the bindweed experiment field; Wilbert Greer, superintendent of the college poultry farm; and H. D. Hollembeak, assistant in cooperative experiments in agronomy. Dr. J. W. Faith, head of the department of chemical engineering, has resigned to accept a similar position in the University of Iowa.

**Kentucky University and Station.**—Leaves of absence have been granted for military service to Charles Bortner, assistant in agronomy; Dr. D. W. Bruner, associate bacteriologist in animal pathology; Donald W. MacLaury, assistant in animal industry; and J. R. Todd, analyst in agronomy. The resignations are noted of Dr. R. H. Allen, associate professor of farm economics; Florence P. Meier, technician in animal pathology; Merton D. Oyler, assistant professor and assist-

ant in farm economics; Dr. J. T. Spencer and Hugh G. Myers, assistants in agronomy; and Emmett Dozier, Jr., inspector in creamery license. Recent appointments include R. W. Pifer as assistant professor in animal industry, E. S. McConnell as instructor and assistant in animal industry, Dr. J. H. Hardison as assistant in agronomy, and W. C. Stammer as assistant chemist and spectroscopist in chemistry.

**Montana College and Station.**—Harold G. Halcrow, assistant professor of agricultural economics, and T. S. Aasheim, assigned to the agronomy department as research project leader of the U. S. D. A. Soil Conservation Service, have resigned to enter the armed forces. The latter has been succeeded by Ralph A. Cline of the field operations division of the Soil Conservation Service. Dr. Royse P. Murphy has been given leave of absence to become geneticist in the California guayule emergency rubber project.

**Cornell University and Station.**—Dr. Henry M. Munger, instructor and research investigator in the breeding of vegetable crops at the University of Wisconsin, has returned to Cornell as assistant research professor of plant breeding and vegetable crops and will carry on research on the improvement of vegetables by breeding and selection under a special appropriation recently provided by the State legislature.

**North Dakota Station.**—Dr. Bruno Vassel has been appointed assistant agricultural chemist.

**Ohio Station.**—Recent additions to the staff include H. R. Moore as associate in rural economics and sociology, Alfred Van Wagenen as associate in animal industry, and Lois Jones as assistant in dairy industry.

**Oklahoma College and Station.**—Dr. A. E. Darlow, chairman of the animal husbandry department at the Wisconsin University and Station, has returned to Oklahoma as head of the department of animal husbandry vice W. L. Blizzard, who continues as dean of agriculture. Horace S. Smith, agronomist in charge of the Oklahoma farm wheat improvement program, has been granted military leave.

**Puerto Rico University Station.**—Dr. Arthur H. Rosenfeld, special technologist for cane investigations from 1923 to 1926 and widely known as an authority on various phases of the sugar industry, died in Washington, D. C., on October 6, 1942, at the age of 56 years. A native of Virginia and a graduate of Virginia Polytechnic Institute, he had held numerous commercial positions and served as assistant in the State Crop Pest Commissions in Virginia and Louisiana, as State horticultural inspector in Illinois, as special field agent of the U. S. D. A. Bureau of Entomology and Plant Quarantine, and as entomologist and director of the Sugar Experiment Station of Tucumán, Argentina, and from 1932 to 1942 as sugarcane technologist for the Egyptian Ministry of Agriculture. At the time of his death he was under appointment with the Dominican Republic Settlement Association.

**Rhode Island College and Station.**—The resignations are noted of Quirino A. Trementoizzi, research assistant in chemistry, and William R. Gordon, rural sociologist, the former to engage in commercial work and the latter to accept a position with the extension service of the Pennsylvania College. John W. Stephenson has been appointed assistant agronomist; Harry L. Keil, assistant plant pathologist; Leonard P. Pepkowitz, assistant chemist; and Josephine Gardner, assistant home economist.

**Utah College and Station.**—D. C. Tingey, associate professor of agronomy, has been given leave of absence to accept a position with the U. S. D. A. Bureau of Plant Industry as senior agronomist in the guayule production project in California and other Southwestern States. Leroy Van Horn and Dr. Irvin F. Edwards have been appointed assistant professors of animal husbandry, the

former for sheep and wool work and the latter for meats and beef cattle teaching and investigations.

**Vermont Station.**—Collection of data on milk assembly has been completed for the State, and recommendations for changes in the interest of conservation of tires and trucks have been worked out. A copy of the recommendations for each plant has been sent to the plant manager or a representative of the producers, and maps of the assembly routes have been furnished where requested. The State representative of the Office of Defense Transportation has indicated his interest in this work, and it is believed that it will also be of substantial value in promoting understanding and acceptance of a central program by farmers and truckmen.

A tentative outline for a course on labor-saving methods in doing dairy barn chores has been prepared for use in the production courses which are given under the supervision of teachers of vocational agriculture. Additional material on causes of farm fires in Vermont has been furnished to the extension service and used by it in news releases urging fire prevention.

**New Journals.**—Two volumes per year are being issued of *Archives of Biochemistry*, published at 125 East Twenty-third Street, New York City. The initial number contains the following articles: Synthetic Peroxidases, by E. C. Gjessing and J. B. Sumner (pp. 1-8) (Cornell Univ.); A Method for Measurement of Yeast Growth in Bios and Vitamin Investigations, by L. Atkin, A. S. Schultz, and C. N. Frey (pp. 9-16); The Carotenoid Pigments of the Fruit of *Celastrus scandens* L., by A. L. LeRosen and L. Zechmeister (pp. 17-26); Heat Capacity and Bound Water in Starch Suspensions, by M. E. Freeman (pp. 27-39) (Mass. Expt. Sta.); The Metabolism of Crotonic Acid, by F. Lipmann and G. E. Perlmann (pp. 41-50); The Inverse Ratio Between Fluoride in Food and Drink and Dental Caries, by J. F. McClendon, W. C. Foster, and G. C. Supplee (pp. 51-57); Carbon Monoxide Inhibition of Nitrogen Fixation by *Azotobacter*, by C. J. Lind and P. W. Wilson (pp. 59-72) (Univ. Wis.); Environmental Temperatures and B-Vitamin Requirements, by C. A. Mills (pp. 73-81); Viscosimetric Studies on the Tobacco Mosaic Virus Protein, II, by V. L. Frampton (pp. 83-92) (Cornell Univ.); (E. S. R., 81, p. 662); Some Sulfanilamide Antagonists as Growth Factors for Lactic Acid Bacteria, by E. E. Snell and H. K. Mitchell (pp. 93-101); The Activation of Papain, by E. M. Scott and W. M. Sandstrom (pp. 103-109) (Minn. Sta.); Interference Between Bacterial Viruses—I, Interference Between Two Bacterial Viruses Acting Upon the Same Host, and the Mechanism of Virus Growth, by M. Delbrück and S. E. Luria (pp. 111-141); and Essential Steps in the Enzymatic Breakdown of Hexoses and Pentoses, by J. C. Wirth and F. F. Nord (pp. 143-153).

*Boletín del Departamento de Sanidad Vegetal* is being published semiannually by the Ministry of Agriculture at Santiago, Chile. The initial number contains much statistical and tabular data on the occurrence of plant and insect pests in Chile and several original articles, among them La antracnosis de la vid [Anthracnose of the Grape], by S. J. Tartakowsky H. and S. T. Arentsen S. (pp. 7-18); Antracnosis de la vid en Chile [Anthracnose of the Grape in Chile], by A. E. Jenkins and A. A. Bitancourt (U. S. D. A. et al.) (pp. 19-53); La nosemosis, enfermedad de las abejas [Nosemosis, a Disease of Bees] by L. Durán M. (pp. 54-60); and Contribucion preliminar al estudio de la polilla del frejol [The Pea Moth], by G. Brücher E. (pp. 63-69).

# EXPERIMENT STATION RECORD

VOL. 88

APRIL 1943

No. 4

## RECENT WORK IN AGRICULTURAL SCIENCE

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY

**The respiration and storage behavior of soybeans, P. E. RAMSTAD and W. F. GEDDES.** (Coop. U. S. D. A. and 11 expt. stas.). (*Minnesota Sta. Tech. Bul.* 156 (1942), pp. 54, figs. 8).—This presents an historical review and a full account of a detailed experimental investigation of the effects of moisture content, temperature of storage, and micro-organisms upon the respiration, seed viability, and resistance to spoilage of whole beans, and the behavior of split beans and oil meals in storage, together with the production of carbon monoxide by heated beans. Among numerous conclusions recorded, the authors note the observation that an electrical resistance moisture meter which had been calibrated and used for official grading gave significantly low results, especially at higher moisture contents, as compared with a method involving drying under reduced pressure after air drying. The two-stage "vacuum" oven method (the oven being used at not over 25 mm. pressure) gave the figure 15.6 percent, for example, for a sample which showed only 14.3 percent by the moisture meter method. At this moisture content soybeans were observed to heat when stored at laboratory temperature (25°–26° C.). "Since the permissible moisture limits for grades Nos. 1, 2, 3, and 4 are 13, 14, 16, and 18 percent [meter figures], respectively, grades Nos. 3 and 4 involve a great storage risk except for relatively short periods at low temperatures." The electric method has subsequently been recalibrated.

High carbon dioxide production and loss of viability appeared to be due, in large measure, to micro-organismic activity. Both high carbon dioxide production and heavy loss of viability were found associated with spoilage by molds and souring.

Carbon monoxide was detected by qualitative tests in the gas drawn from heating soybeans both in the elevator bin and in the small adiabatic respirometer.

**Butyl-acetonic fermentation of Jerusalem artichokes, R. T. WENDLAND, E. I. FULMER, and L. A. UNDERKOFER.** (Iowa State Col.). (*Indus. and Engin. Chem.*, 33 (1941), No. 8, pp. 1078–1081, fig. 1).—The authors show that the levulans of the Jerusalem-artichoke are converted to levulose by milk acid hydrolysis. After the acid is neutralized the resulting hydrolyzate is a suitable raw material for fermentation by the butyl acetone organism, *Clostridium acetobutylicum*. To secure maximum yields of products from the fermentations, it is necessary to add additional nutrients, in the form of corn meal or soybean meal, to the Jerusalem-artichoke hydrolyzates. Hydrolyzates prepared from extracts of dried Jerusalem-artichoke chips ferment somewhat more satisfactorily than hydrolyzed aqueous pulps of the dried chips or the fresh tubers. The solvents formed by the butyl acetone organism from fermentations of Jerusalem-artichoke

extract hydrolyzates are identical with those from fermentations of corn mash and are produced in about the same ratio.

**Effect of rate and extent of freezing on texture of asparagus,** M. A. JOSLYN and S. B. KILNER. (Univ. Calif.). (*Quick Frozen Foods*, 4 (1942), No. 12, pp. 14-15, 35, figs. 3).—Texture before and after cooking and the loss of weight due to "drip" in a 16-hr. defrosting period were compared in 2½-lb. samples of asparagus subjected to slow freezing in air at -5° F. and to quick freezing at -25° for periods of 3, 6, and 14 hr. The samples were tested after storage at -5° for 6 days and for 6 mo. After each of these storage intervals the texture of the slowly frozen sample was markedly inferior to that of the quick-frozen samples, and the loss of weight due to drip amounted to about 32 percent in the former as compared with about 24 to 26 percent in the latter samples. The extent of quick freezing from 3 to 14 hr. had no effect on texture; if anything, the completely frozen sample (14 hr.) was less desirable in texture than were the partly frozen samples.

**Methods of regulating the methoxyl content of pectins,** G. L. BAKER. (Del. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 22 (1942), No. 1, pp. 10-12).—Most manufacturers are interested in producing as high a grade of pectin as possible, regardless of any other characteristic, such as a fast or slow set. These makers should regulate the methoxyl content of their pectins to approximately 8 percent. Some manufacturers now wish to produce pectin preparations which can be standardized to produce low-sugar or nonsugar jellies with calcium, however. Research up to the present indicates that the better products for this purpose contain between 4.5 and 5.5 percent methoxyl. In either instance the value of the regulation of methoxyl content in the commercial manufacture of pectin is unquestionable.

Demethylation of pectin without excessive lowering of grade requires a temperature below 60° C., a high acidity (low H-ion concentration), and a relatively long period of time. The concentration of pectin-containing material (pomace, albedo, or undiluted pectin) in the mixture during the demethylation reaction is of little importance. Great care and exactness must be exercised in controlling the variable factors affecting demethylation, as otherwise duplication of results is impossible. Extraction and demethylation in dilute solution has produced pectinic acids of the highest grade but is, in general, impractical for commercial use. A process of high-temperature extraction, concentration, and adjustment of methoxyl content after concentration is outlined and is considered commercially feasible. In the enzyme method of regulating the methoxyl content of pectinic acids, the pectase must be comparatively free of pectinase, the pectin degradation enzyme, otherwise jellying values are ruined. The ease and accuracy of controlling demethylation of pectinic acids with pectase gives this method, theoretically, a distinct superiority over the acid method, but the product thus far actually obtained has been found inferior in jelly grade and calcium tolerance. The calcium tolerance of the pectin, or the sensitivity to calcium, in the preparation of calcium pectinate gels has been low. Optimum concentrations of calcium for gelation are also found to lie in a very narrow range. The method is impractical for producing pectinic acids of 8 percent methoxyl content for ordinary 65 percent soluble-solids jelly purposes. The data obtained thus far favor the acid-demethylated products, because these products appear to be able to make satisfactory jellies in a much wider range of calcium content.

Whether a pectinic acid has had its methoxyl content regulated by acid or enzyme treatment and whether it has been precipitated by alcohol or metallic salt, at a similar methoxyl content, as the soluble solids in a jelly are reduced, the calcium requirement is increased, the optimum pH of gelation is increased

slightly, the time of set is increased, the temperature of set is decreased, the melting temperature is decreased, and the tendency for marked syneresis increases.

**Promoting the oxidation of fats and oils: Relative effectiveness of different bands of the visible spectrum,** G. R. GREENBANK and G. E. HOLM. (U. S. D. A.). (*Indus. and Engin. Chem.*, 33 (1941), No. 8, pp. 1058-1060, fig. 1).—The effectiveness of different bands of light of the visible spectrum in promoting the oxidation of corn oil, cottonseed oil, lard, and butter oil was determined by the use of light bands obtained with filters and a monochromator and adjusted to equal intensity in each measurement.

The results indicate that the effectiveness increases with a decrease in the wave lengths employed. The energy of the blue end of the spectrum was most effective in promoting oxidation. Light absorption data upon samples of oils of the types used indicate that the light energy absorbed in the yellow, orange, and red regions (5,400-7,500 a. u.) of the spectrum is practically constant for each oil and exceeds 5 percent only for lard. Irradiation with light in these regions produced relatively small amounts of peroxides. With light of wave lengths shorter than 5,400 a. u., the light absorption and the quantity of peroxides formed increased progressively with decrease in the wave length. The magnitude of these increases varied with the type of oil used.

**The Lundegårdh apparatus: Its construction and use,** J. A. C. McCLELLAND and H. K. WHALLEY (*Jour. Soc. Chem. Indus., Trans.*, 60 (1941), No. 11, pp. 288-291, figs. 2).—"An account of the Lundegårdh apparatus for the examination of flame emission spectra is given. Details of the construction are included which would enable other laboratories to build a similar apparatus, for which there appears to be a demand; also of the interpretation of the spectrograms obtained and application of the flame technic which will give some indication of the type of problems that such an apparatus would solve in a spectrographic laboratory."

**Colorimetric microdetermination of iron,** C. P. SIDERIS. (Univ. Hawaii). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 9, pp. 756-758, fig. 1).—"Ferrous iron forms with nitroso R salt (1-nitroso-2-hydroxy-3,6-naphthalene disodium sulfonate) at favorable range of pH values (8 to 10) a green pigment which is in direct proportion to the amounts of ferrous iron present in the solution. The sensitivity of the reagent is very great, reaching the low limits of 0.2  $\mu$ g. of ferrous iron per cubic centimeter and ranging between 0.2 and 50  $\mu$ g. or more. Hydroxylamine sulfate was found highly satisfactory for the reduction of ferric to ferrous iron and sodium acetate or ammonium hydroxide for obtaining a satisfactory pH range for the development of the green pigment. Iron may be determined by means of a photoelectric colorimeter with the use of appropriate light filters."

**Modified methods for the chemical and biological determination of choline,** R. W. ENGEL. (Ala. Expt. Sta.). (*Jour. Biol. Chem.*, 144 (1942), No. 3, pp. 701-710).—"The chemical method, described in detail, involved prolonged and repeated extraction of the sample of biological material (containing from 4 to 8 mg. of choline) with 30-cc. portions of absolute methanol; evaporation of the combined extracts to near dryness under reduced pressure; hydrolysis of the residue with saturated barium hydroxide solution at 100° [C.] for 2 hr. followed by neutralization and filtration; precipitation of the choline from the hydrolyzate as the reineckate; solution of the precipitate (washed with small portions of cold ethanol) in acetone; and determination of the concentration of choline reineckate by means of a photoelectric colorimeter, the *L* value being referred to a standard curve obtained from readings on 12 solutions containing

varying concentrations of pure choline chloride. The biological assay consisted in comparing the amount of protection afforded by pure choline chloride (4 mg. daily) and by the food material (at levels supplying 4 mg., more than this, and less than this, daily) in prevention of kidney hemorrhages in weanling litter-mate rats on the choline-deficient diet previously developed (E. S. R., 86, p. 420). The chemical method gave reproducible results and satisfactory recoveries and was specific in that other possible reineckates failed to precipitate under the conditions of the test.

Results by this method were determined for different strains of yeast, liver from different mammalian species, peanut meal, soybean meal, and mature soybeans. In general the values for yeast and livers were from 30 to 50 percent higher than those reported by other workers. The bio-assay procedure gave quite uniform results when comparisons were restricted to rats within a litter and was highly sensitive, since variations of 10 percent in the test food material could be detected. The bio-assay apparently determined total choline value, since the protection afforded by certain materials (dried beef liver, for example) was greater than could be accounted for on the basis of the choline content as determined chemically.

**Determination of choline: A photometric modification of Beattie's method,** M. H. THORNTON and F. K. BROOME. (Ind. Expt. Sta. coop. U. S. D. A. et al.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 1, pp. 39-41, fig. 1).—Choline is precipitated as the reineckate, and the transmittancy of the red-colored acetone solution of this precipitate is measured by means of a photoelectric photometer. The value  $(\log I_0/I) \div L$ , which is the negative log of the transmittancy of the solution divided by the length of the cell in centimeters, is read against the standard curve established with choline reineckate solutions prepared from varying amounts of a known solution of pure choline chloride. Quantities of choline varying from 0.6 to 16.0 mg. in a concentration range from 0.3 to 6.5 mg. per cubic centimeter can be estimated with a maximum error of 2 per cent.

**Determination of beta-carotene and neo-beta-carotene with the visual spectrophotometer,** F. P. ZSCHEILE and B. W. BEADLE. (Ind. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 8, pp. 633-634).—The authors who successfully applied a photoelectric spectrophotometric method to the carotene analysis of certain vegetables, employed a double monochromator with the radiation from an incandescent source of continuous radiation. Since this type of optical equipment is not generally available, a study was made of the adaptation of this method to simpler and less expensive instruments. It was found that  $\beta$ -carotene and neo- $\beta$ -carotene could be determined in properly purified solutions from spinach extracts by means of a visual spectrophotometer, preferably with a type A-H4 mercury lamp. A photoelectric filter photometer did not isolate sufficiently narrow spectral regions for accurate analysis of the carotenoid mixture. The total carotene was calculated from the absorption at 4,358 a. u. and the percentage of either carotene from the absorptions at 4,358 and 4,916 a. u.

**Studies on the carotenoids.—II, The isomerization of  $\beta$ -carotene and its relation to carotene analysis,** B. W. BEADLE and F. P. ZSCHEILE. (Ind. Expt. Sta.). (*Jour. Biol. Chem.*, 144 (1942), No. 1, pp. 21-33, fig. 1).—Extracts of carotene prepared from fresh plant material differed spectroscopically from fresh solutions of pure  $\beta$ -carotene, the differences consisting of relatively decreased absorption toward the red and a slight shift of maxima toward the blue. When pure  $\beta$ -carotene was heated by refluxing in hexane, its absorption curve became similar to that of the plant carotene fractions. The same type

of spectrum was observed in a study of the mother liquor from recrystallized pure  $\beta$ -carotene. Solutions of these three types could not be chromatographically resolved on a column composed of equal parts of magnesium oxide and Hyflo super-cel, but were resolved into two zones on an alumina column. The  $\beta$ -carotene fraction eluted from this type of column possessed an absorption spectrum like that of the reference standard, while the pigment eluted from the brownish-yellow zone immediately below the  $\beta$  carotene gave maxima that were close to those of  $\alpha$ -carotene as far as wavelength was concerned, but not in relative intensities. This second component, designated as neo- $\beta$ -carotene, is an isomer of  $\beta$ -carotene. The quantitative absorption spectrum of neo- $\beta$ -carotene was obtained and employed as a reference in carotene analysis. The conversion of  $\beta$ -carotene to neo- $\beta$ -carotene was found to be reversible. Thus the conversion of  $\beta$ -carotene in hexane at 30° C. in the dark progressed gradually, as much as 25.1 percent of neo- $\beta$ -carotene being formed in a period of 101 hr. Similarly, there was a reversion of neo- $\beta$ -carotene to  $\beta$ -carotene in hexane in the dark at 40°, as much as 32.3 percent of  $\beta$ -carotene being present in the solution after 72 hr. Carotene fractions of a number of vegetables were found to contain from 79 to 90 percent of  $\beta$ -carotene, the rest being essentially the neo- $\beta$ -carotene. Blanching of spinach for 30 sec. did not alter either the total carotene content or the percentage of  $\beta$ -carotene. Cooking in boiling water did not alter the total carotene, but decreased the percentage of  $\beta$  carotene from 86 to 81 percent. The loss of carotene and the amount of isomerization during the routine analysis were found to be small.

**Studies on the carotenoids.—III, Distribution of pure pigments between immiscible solvents,** J. W. WHITE, JR., and F. P. ZSCHEILE. (Ind. Expt. Sta.). (*Jour. Amer. Chem. Soc.*, 64 (1942), No. 6, pp. 1440-1443, fig. 1).—The results of a quantitative study of the distribution of  $\beta$ -carotene, cryptoxanthol, and zeaxanthol between solvent pairs are presented for three different pairs of solvents, namely, hexane and aqueous solutions of methanol, diacetone alcohol, or 2-methyl-2,4-pentanediol. Curves were obtained showing the effect of water content of the alcohol solvent upon the partition ratios (ratio of concentration in epiphase to concentration in hypophase) of the three carotenoids for each of the three solvent pairs. From these curves values were selected for the optimum water content of the hypophasic solvent for separation of the several pigments. In the absence of cryptoxanthol it appeared that the partition of carotene-zeaxanthol mixtures between hexane and diacetone alcohol solutions (94.5-77.0 percent diacetone alcohol by volume) should be satisfactory for the separation of these two classes of pigment. In the presence of cryptoxanthol, extraction by 78.5 percent diacetone alcohol gave satisfactory separation of the carotene plus cryptoxanthol from the dihydroxycarotenes. Extraction of a hexane solution by a 92.0-percent solution of 2-methyl-2,4-pentanediol in water gave fair separation of cryptoxanthol from carotene, as shown by analysis of corn grain pigments.

**[Studies on the carotenoids.—IV], The carotenoids of yellow corn grain,** J. W. WHITE, JR., F. P. ZSCHEILE, and A. M. BRUNSON. (Ind. Expt. Sta. and U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 64 (1942), No. 11, pp. 2603-2606, figs. 4).—The carotenoids of corn grain were investigated by methods involving chromatography, partitionment between selective solvents, such as those noted above, and spectrophotometric examination of the pigments with a sensitive photoelectric spectrophotometer. Luteol,  $\gamma$ -carotene, and a compound tentatively identified as a hydroxy- $\alpha$ -carotene were found for the first time in yellow corn. A compound having some properties like those of the K carotene of Fraps and Kemmerer (*E. S. R.*, 87, p. 8) was also separated. Preliminary quantitative

absorption spectra of neocryptoxanthol and two neozeaxanthol isomers are presented.

**Studies on the carotenoids.**—[V], Spectrophotometric determination of the carotenoids of yellow corn grain, J. V. WHITE, JR., A. M. BRUNSON, and F. P. ZSCHEILE. (Ind. Expt. Sta. and U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 10, pp. 798–801, fig. 1).—The pigments were extracted from ground corn (mature or immature) with acetone, from which they were extracted with ether. The nonsaponifiable portion of the ether extract taken up in acetone was treated with the solvents, as noted above, for separation of the pigments into three groups—carotene, cryptoxanthol, and carotenol. Pigment concentration was estimated spectrophotometrically. "The analysis of the carotene and cryptoxanthol fractions of corn-grain carotenoids in terms of normal and neotype pigments was not highly successful, but it is probable that analyses of the fractions for total pigment content are reliable at 4,325 a. u. for the carotene fraction and at 4,375 a. u. for the cryptoxanthol fraction. Analysis of the carotenol fraction for luteol, zeaxanthol, and total neocarotenols was made by spectrophotometric methods. Analysis for total pigment in this fraction was made at 4,275 a. u. Four inbred corn lines were studied. Variations in content of mature grain were as follows: Total carotenols twofold, total carotenes fourfold, total cryptoxanthols sixfold, luteol fourfold, and zeaxanthol twenty-fivefold."

**Activation of dicalcium phosphate for the chromatographic determination of carotene**, L. A. MOORE. (Mich and Md. Expt. Stas.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 9, pp. 707–708).—Certain lots of dicalcium phosphate, previously proposed as an adsorbent for the chromatographic removal of noncarotene pigments in the determination of carotene from plant materials (E. S. R., 86, p. 586), were encountered which were not good adsorbents. A study was made, therefore, of the effect of various procedures in activating these inactive lots. Boiling an inactive dicalcium phosphate with disodium phosphate, trisodium phosphate, or potassium hydroxide increased the activity of the adsorbent, as judged by the quantity of chlorophyll adsorbed from a petroleum ether extract or dehydrated alfalfa leaf meal. Of these, potassium hydroxide was the most effective, indicating that alkalinity was the primary factor for the activation process. The filtration rate was decreased by the activation procedure, although certain grades, particularly Merek's reagent with a coarse granular crystalline structure, could be highly activated and yet retain a fairly rapid rate of filtration. Where a filter aid was needed to speed up the filtration process, Dyno, a commercial dextrose, was found effective. Neither the length of time of boiling nor the quantity of water used, in amounts from 500 to 1,500 cc., had appreciable effect on the activation process. The procedure finally adopted involved the addition of 5 gm. of KOH in 1 l. of water to a weighed quantity (less than 100 gm., since more usually caused bumping), of the inactive dicalcium phosphate in a 2-l. Erlenmeyer flask. After boiling for from 15 to 30 min., the contents of the flask were transferred to a Büchner funnel, washed with from 0.5 to 1 l. of water, then placed in an evaporating dish and dried for 24 hr. at 100° C., and finally broken in a mortar ready for use.

**Vitamin B<sub>1</sub> (aneurine) assay in white flour**, J. R. NICHOLLS, R. G. BOOTH, D. W. KENT-JONES, A. J. AMOS, and H. H. WARD (*Analyst*, 67 (1942), No. 790, pp. 15–17).—This report outlines the methods at present employed by the four control laboratories that from time to time check the thiamin content of white flour enriched according to the British plan with 0.2 gm. of thiamin per 280 lb. of flour. The procedure outlined in detail involves extraction of the thiamin, without the necessity of enzymic digestion, by the use of dilute HCl, and oxida-

tion of the extracted vitamin by potassium ferricyanide added after treatment of the extract with methyl alcohol and 30 percent NaOH. The thiochrome formed is extracted with isobutanol, and the intensity of fluorescence of the solution is measured either photoelectrically, using the Spekker fluorimeter, or visually against a standard thiochrome solution. The method of calculation is given, and a few general points applying to the methods are noted.

**The nature of the interfering chromogens encountered in the determination of nicotinic acid in cereal products**, E. B. BROWN, J. M. THOMAS, and A. F. BINA (*Cereal Chem.*, 19 (1942), No. 4, pp. 447-457).—In order to establish the cause of the wide differences obtained by different chemical procedures of analysis of nicotinic acid, experiments were planned to include determination of the nicotinic acid content of the same materials by different procedures. The results showed that the differences obtained were due mainly to the method of hydrolysis used in the preparation of the extracts. Extracts of cereal products or milk prepared by strong acid or alkaline hydrolysis contained interfering chromogens. These were not present, however, in similar extracts of yeasts. These chromogens were not removed by the decolorizing techniques employed by the different procedures for treatment of the extracts, with the exception of the hydrogen peroxide treatment. The use of hydrogen peroxide was not so desirable, however, because of the difficulty in removing the excess peroxide. The chromogen, colorless in solution prior to treatment with cyanogen bromide and the aromatic amine, produced a dark brown color when metol was used as the amine and a lemon-yellow color with aniline. The color complex produced by the action of the chromogen with *p*-aminoacetophenone and cyanogen bromide was not soluble in ethyl acetate and hence was not extracted by this solvent in the procedure employing it to extract the color produced by these reagents with nicotinic acid. The use of *p*-aminoacetophenone and ethyl acetate gave consistent results with cereals (and milk and yeast) subjected to hydrolysis with strong acid or alkali, and the values obtained were in accord with the low antipellagric properties found by animal experimentation. The alternative method for obtaining such results with cereal products involved extraction by autoclaving a water suspension and subsequently treating with takadiastase. Mild acid hydrolysis was sufficient to convert completely any amide present in such extracts to the acid without the production of interfering chromogens and with a minimum of color in the extract.

**Riboflavin estimation in fruits and vegetables**, G. MACKINNEY and J. M. SUGIHARA. (Univ. Calif.). (*Jour. Amer. Chem. Soc.*, 64 (1942), No. 8, pp. 1980-1981).—The method of Conner and Straub (*E. S. R.*, 87, p. 10) was used in extracting and preparing the sample, except that, in the case of fruits, pectinol was used in addition to the clerase, the pectinol being absolutely necessary in the case of prunes, apricots, dates, etc., to produce a satisfactory solution. Because of the unavailability of Supersorb, adsorption and the following step, elution with pyridine-acetic acid, were omitted, and the determination was continued instead on the aqueous buffered solution, which was treated with  $\text{KMnO}_4$  for destruction of interfering substances, decolorized with  $\text{H}_2\text{O}_2$ , and after filtering compared with buffered standards at pH 6.0 in a Coleman fluorophotometer. The  $\text{B}_2$  filter for the exciting light (mercury arc) cut out completely above 4,900 a. u. and for the fluorescent light below 5,100 a. u., thus eliminating any effect due to quinine sulfate and thiochrome. In the plant extracts tested there appeared to be no other interfering water-soluble compounds. Results obtained with a number of fruits and vegetables (asparagus, broccoli, peas, spinach, rice bran, apricots, prunes, dates, and grass, including some fresh and some dehydrated samples) showed values which, with two exceptions (peas and grass after dehydration), were slightly higher

than those obtained for the same samples by the adsorption procedure of Conner and Straub. The same samples measured after 20 hr. in the laboratory away from direct light showed the higher light stability of the aqueous extract. It is considered, therefore, that the simpler procedure is worth consideration where the adsorbent is unavailable, since comparative variations are reflected with accuracy in the figures; where absolute values must be considered, however, it is necessary to be more cautious.

**Some factors that affect the microbiological method for riboflavin, M. I. WEGNER, A. R. KEMMERER, and G. S. FRAPS.** (Tex. Expt. Sta.). (*Jour. Biol. Chem.*, 144 (1942), No. 3, pp. 731-735).—Extracts of whole-wheat flour, of rice, and of bran were prepared by autoclaving these materials with 0.1 N HCl for 15 min. at 15 lb. pressure. The whole-wheat flour extract, made alkaline and subjected to photolysis to destroy riboflavin, stimulated acid production by *Lactobacillus casei* in the microbiological method for riboflavin. The addition of such an extract to the basal medium did not, however, remedy the difficulties experienced in obtaining the true riboflavin values of cereal products. The concentrated extracts of rice bran, wheat bran, or whole-wheat flour passed through florisil to remove the riboflavin and then added to tubes containing riboflavin stimulated acid production by *L. casei* well above the present maximum, thus indicating the presence in the brans and the flour of some stimulating substance other than riboflavin and different from the substance produced by alkaline photolysis. The addition of these extracts to the basal medium was not feasible, owing to the inability to standardize the response when the extracts were present in the medium and to obtain a usable curve. Treatment of the whole-wheat flour extracts with takadistase and papain did not destroy the stimulating factors.

**Determination of thiamine in vegetables, J. C. MOYER and D. K. TRESSLER.** (N. Y. State Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 14 (1942), No. 10, pp. 788-790, fig. 1).—The vegetables used included peas, broccoli, cauliflower, and spinach, freshly harvested and held in freezing storage after blanching and freezing in a Birdseye multiplate froster; and commercially frozen asparagus, cut corn, string beans, and lima beans. Thiamin was determined by (1) bio-assay procedure, using the growth technic and the basal diet of Chase and Sherman (*E. S. R.*, 66, p. 410); (2) a thiochrome chemical procedure simpler than that of Conner and Straub (*E. S. R.*, 87, p. 9) and involving acid and then enzymic digestion of the sample, base exchange purification of the extract, and production of the thiochrome; and (3) the fermentation procedure of Schultz et al. (*E. S. R.*, 85, p. 727) involving the sulfite cleavage modification. In general, the results of the procedure of fermentation after sulfite cleavage were in good agreement with the thiochrome values. These thiochrome values in the case of lima beans (0.89  $\mu\text{g. per gram}$ ), cauliflower (0.43), and broccoli (0.88) were somewhat lower than the values obtained by bio-assay, these latter agreeing better with the fermentation values before sulfite cleavage. Bio-assay values for peas were appreciably higher than the thiochrome (2.60) or fermentation values. It is suggested that the basal diet of the animals might have been deficient in some known or unknown members of the B complex and that this deficiency was supplied by lima beans, cauliflower, broccoli, or peas, thus accounting for the higher response. Thiochrome values for asparagus (2.04  $\mu\text{g. per gram}$ ), corn (1.17), snap beans (0.64), and spinach (0.55) were somewhat lower than the bio-assay values except for spinach, in which case these two values were similar.

**A possible vitamin D assay technique with radioactive strontium, I. H. WEISSBERGER and P. L. HARRIS** (*Jour. Biol. Chem.*, 144 (1942), No. 1, pp. 287-288,

fig. 1).—Radiostrontium, which has been shown to follow the same course in the body as radiocalcium, was chosen for use rather than radiocalcium, which is hard to prepare, or radiophosphorus, which exerts an action similar to that of vitamin D. Radioactive strontium was administered by stomach tube to rachitic rats, to normal litter-mate controls, and to rachitic rats fed vitamin D. The amount of radioelement retained was determined indirectly by determining the amount excreted, through radioactivity measurements on the excreta (urine and feces). In normal animals the amount of radiostrontium excreted over a 5-day experimental period amounted to from 40 to 60 percent of the dose administered, while in rachitic negative controls nearly 100 percent was excreted. Rachitic rats receiving one dose of 1.3 units of vitamin D<sub>2</sub> given 3, 2, or 1 day prior to or at the same time as the strontium excreted 30, 39, 52, and 56 percent of the ingested strontium. The vitamin D apparently acted rapidly in promoting retention of the strontium (calcium), since the amount of strontium excreted was roughly proportional to the length of time elapsing between vitamin and isotope administration. In another series animals receiving graded doses of vitamin D<sub>2</sub> (0.25–8.0 U. S. P. units) 48 hr. before radiostrontium administration excreted between 57 and 24 percent of the dose. These observed relationships suggest the possibility of using the procedure for vitamin D assay.

The commercial dehydration of food in wartime (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 12, pp. 372–374).—This is a brief general discussion of dehydration, its possibilities, limitations, and requirements, including some illustrative examples of fruit and vegetable processing.

Swift puts meat dehydration on a production basis, E. S. STATLER (*Food Indus.*, 14 (1942), No. 10, pp. 47–49, figs. 6).—The method, developed as the result of months of experimental work and expanded from the experimental pilot-plant stage to industrial proportions, is described in some detail as to operations, equipment, and lay-out of the production line. The process is one of continuous operation and involves precooking of the coarsely cut beef with barely enough water to prevent sticking and with constant agitation under steam pressure of from 3 to 10 lb. and a temperature not lower than 165° F. nor higher than 175° for 30 min. After this process, which inactivates the enzymes, coagulates the meat juices, reduces total water, and permits the beef to absorb the water, the batch is transferred by conveyor to a fine grinder, and the finely ground beef is fed directly into the rotating drum of a horizontal drier where air heated to about 300° is forced at a velocity of about 800 ft. per minute through the bed of meat. To speed up the removal of water vapor and to aid in keeping the meat in a fine state of division, the heated air is directed through the tumbling meat mass by louverlike vents as it moves lengthwise of the rotating drum to the discharge end. By the time the meat reaches the discharge end of the drum and after 2 hr. of drying, the moisture content is reduced to below 10 percent. The dehydrated meat is forced under a pressure of about 2,000 lb. per square inch into airtight containers and sealed under a 22-in. vacuum for export shipment. The compressed dehydrated beef requires only about one-tenth of the shipping space needed by its equivalent in the carcass state and one-third that required in the fresh boneless state. A further saving in space results in that refrigeration in shipping and storage is not required.

The product contains about 55 percent protein, 30 percent fat, 10 percent moisture, and may have added not more than 3½ percent salt. The mineral content of the meat is entirely retained, and the proteins are considered to be affected no more than in household cooking. Relatively short exposure to atmospheric oxygen and light keeps fat deterioration low, and samples are reported to have remained wholesome over the test period of 5 mo. It is noted that some

production and packaging difficulties are yet to be worked out in the dehydration of pork, which presents a greater problem than beef in the matter of fat stabilization, and for the accomplishment of this a tentative two-step process is outlined.

**Develops dehydrating method for small meat plants, E. S. STALLER** (*Food Indus.*, 14 (1942), No. 11, pp. 52-53, fig. 1).—A method developed by E. L. Griffith and S. L. Komarik and still in the experimental stage is described for use in the production of dehydrated pork, beef, veal, lamb, or mutton. The process involves salting, curing, and precooking of the meat. This step is carried out in numerous small plants that transfer the meat thus processed to a central dehydration plant where it is further processed and packaged for export.

**Method developed for grading a dehydrated food, R. V. WILSON and H. M. SLOSBERG** (*Food Indus.*, 14 (1942), No. 9, pp. 56-58, figs. 6).—The procedure adopted after testing various methods of preparing and cooking samples of dried eggs involved the addition of 12 gm. of whole egg powder to 50 cc. of distilled water in a 2 by 4½-in. wide-mouth bottle, followed by from 10 to 15 min. of shaking in a mechanical shaker. When numerous samples were prepared at one time they could be held at room temperature for several hours or in a refrigerator at 40° F. for 24 hr. without effect on the final score, providing the reconstituted sample was shaken by hand for a few minutes just prior to cooking. The reconstituted eggs were cooked (without the addition of fat or salt), above water kept gently boiling in an aluminum household egg poacher of the type having four small square trays supported above the water level. The cooked eggs were scored for flavor according to a numerical score system beginning with 10 and descending to 1 as flavor decreased in the following stages: Excellent, very good, good, slight storage flavor, storage flavor (these 5 suitable for household use), slight off-flavor, definite off-flavor, old and unpleasant flavor (these latter not acceptable for household use), very old and unpleasant flavor, and inedible. By this system judges were able to check their own results, and the scores of various judges usually showed close agreement.

**Thoughts on the dehydration of fruits and vegetables, W. V. CRUESS.** (Univ. Calif.). (*Canner*, 95 (1942), No. 16, pp. 12-13).—This paper emphasizes the necessity of blanching vegetables preliminary to dehydration and of properly packaging the finished product to prevent absorption of moisture.

**Dehydration methods used in California, E. M. MRAK.** (Univ. Calif.). (*Food Indus.*, 14 (1942), No. 8, pp. 50-52, figs. 3).—This paper is concerned with dehydrators originally designed to handle prunes, raisins, apples, and other fruits in commercial practice on the west coast, and with their suitability for dehydrating vegetables. How these dehydrators are designed and operated (methods of heating, temperatures used, and air flow) is discussed, and a few observations concerning proper storage are presented.

**Notes on the dehydration of vegetables—past and present, W. V. CRUESS.** (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 12, pp. 368-370, fig. 1).—The author outlines the history of the process and points out some past experiences which should be taken into consideration in the present use of the dehydration process in the preparation of foods for military purposes.

**Simple tests reveal improper blanching, B. E. PROCTOR** (*Food Indus.*, 14 (1942), No. 11, pp. 51-52, fig. 1).—The importance of checking the adequacy of the blanching process in the dehydration of vegetables is stressed, and the readily applicable catalase and peroxidase tests as applied to dehydrated vegetables in the control of this step are described.

**Composition and utilization of the beach plum, S. G. DAVIS and A. S. LEVINE.** (Mass. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 21 (1942), No. 12, pp. 361-364).—Products made from the fruit of the beach plum

(*Prunus maritima*) have long been on the market and favorably received in the Cape Cod region of Massachusetts, and the manufacture of beach plum products has become an expanding industry. The pleasing, characteristic flavor of these products is developing a broad reputation, and to meet the increased demand, several commercial manufacturers have established facilities for handling the fruit in large quantities. In 1941 the estimated crop of beach plums in Massachusetts was approximately 15,000 bu.

In the investigation here reported upon, determinations of the composition of the beach plum were made, together with some studies of its vitamin content. Information concerning the preparation and standardization of various fruit products from the beach plum is offered.

**Dill pickles with more "eye appeal."** (Coop. U. S. D. A.). (*North Carolina Sta. Rpt. 1941, p. 48, fig. 1*).—Packing of dill pickles in a clarified brine in glass containers to improve their appearance is noted.

**Debitting of apricot kernels,** W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Vinegar Indus., 21 (1942), No. 12, p. 365*).—The bitterness (due to amygdalin) could be removed by a few minutes' heating in water at 140° F., removing the skins, and further heating with water. Temperatures below 140° caused discoloration before completing the removal of the bitter flavor. At 140° the reaction was rapid and the product of light color. Higher temperatures seemed undesirable. Lye treatments (0.5-1.5 percent sodium hydroxide) and treatment with dilute sodium silicate solutions were also successfully used, the silicate being more rapidly leached out after the treatment than was the hydroxide.

**Causes of darkening of packaged orange juice,** E. L. MOORE, W. B. ESSFLEN, JR., and C. R. FELLERS. (Mass. State Col.). (*Canner, 95 (1942), No. 16, p. 13*).—The deterioration of packaged orange juice was found to be markedly influenced by heat, especially in the presence of oxygen; light had an additive effect too small to be of significance under commercial conditions. The decomposition of the ascorbic acid in the juice was directly associated with the darkening. It is suggested, therefore, that the best means of controlling darkening in orange juice is to utilize packaging methods and storage conditions which best prevent the oxidation of ascorbic acid.

**Production of a bland sirup from apples,** M. A. BRADSHAW and H. H. MORTERN. (U. S. D. A.). (*Fruit Prod. Jour. and Amer. Vinegar Indus., 21 (1942), No. 12, pp. 356-358, fig. 1*).—The process described consists essentially in the sorting, washing, grinding, and pressing of the apples, the liming of the juice to pH 8, followed by heating to 175° F. and filtering, acidifying to a pH value between 5.0 and 5.5, an optional activated carbon and filtration treatment, and finally evaporation under diminished pressure to 75° Brix.

At a concentration of 75 percent solids the sirup was found to have an average content of levulose 40 percent, dextrose 13, sucrose 14, and nonsugar solids 8 percent. It is bland, without distinctive flavor of any sort, and is very sweet. It is of a light amber color. As a sweetening agent, this apple sirup will be superior to corn and sorghum sirups, about equal to maple sirup, and somewhat less effective than invert sirup and honey.

**Homemade sorghum sirup,** I. J. DUNCAN and E. J. WELHAUSEN (*West Virginia Sta. Cir. WS 5 (1942), pp. [8], fig. 1*).—This circular points out that a good crop of sorghum should yield about 100 gal. of sirup per acre and that the average family could use about 50 gal. per year. The circular very briefly discusses the handling of two varieties and takes up the processing, pressing, settling, and evaporating of the sirup, construction of the evaporating pans,

determination of the end point of the concentration by the end point of the sirup, the need for a suitable furnace, etc.

**Bulk fermentation process for sparkling cider**, D. K. TRESSLER, R. F. CELMER, and E. A. BEAVENS. (N. Y. State Expt. Sta. and U. S. D. A.). (*Indus. and Engin. Chem.*, 33 (1941), No. 8, pp. 1027-1031, figs. 8).—Semicommercial scale experiments on the production of sparkling cider by the secondary fermentation of cider in glass-lined pressure tanks indicated that the speed of carbon dioxide formation can be accelerated greatly by the addition of either apple juice or a concentrate prepared therefrom and a small amount of ammonium monohydrogen phosphate to the cider. Fermentations proceed more rapidly at 70° F. than at either a slightly higher or a slightly lower temperature. The choice of the strain of wine yeast is of great importance in determining the rapidity of carbon dioxide production. If the yeast food and supplements suggested are added to cider inoculated with a rapidly fermenting starter of the proper strain of champagne yeast, secondary fermentation occurs rapidly, 90 lb. per square inch carbon dioxide pressure developing in 3-4 days. Chilling and bottling require another 24-36 hr. Thus, the entire process of converting cider to sparkling cider requires only about 5 days. The flavor of the product is improved by the addition of tannin to the cider before fermentation and of a small amount of invert sugar and apple brandy at the time of bottling.

**Effect of storage on sulfur dioxide in wine**, D. R. MILLS and E. H. WIEGAND. (Oreg. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Vinegar Indus.*, 22 (1942), No. 1, pp. 5-9, figs. 2).—A direct iodine titration was found to determine sulfur dioxide comparatively accurately in all types of wine. The differences in alcoholic concentrations encountered in wine had no influence on sulfur dioxide loss during storage in full sealed containers. The relationship between free and combined sulfur dioxide during storage of wine was found to vary both with type and with different samples of the same type. The quantity of sulfur dioxide that may be lost during the storage of wine was affected by the original concentration of the reagent in the wine. The percentage of loss of sulfur dioxide during storage varied inversely with the sugar concentration in wine.

**The curing of vanilla**, A. K. BALIS and F. E. ARANA. (U. S. D. A. and P. R. Expt. Sta.). (*Indus. and Engin. Chem.*, 33 (1941), No. 8, pp. 1073-1075, fig. 1; *Span. trans., Rev. Agr., Indus. y Com., Puerto Rico*, 34 (1942), No. 2, pp. 167-172).—The authors find that the traditional methods of curing vanilla beans to produce the required aroma cause a noticeable increase in the proportion of carbon dioxide formed in the tissues. Chilling the beans has the reverse effect. Oxidation does not always generate carbon dioxide in the curing process, however, and oxidation may be brought about by enzymes of the peroxidase type. Vanilla beans contain much peroxidase, and a complicated peroxidase system (phenols, peroxide, and enzyme) is present even after the completion of the curing process.

It is suggested that vanillin may be an intermediate product in the development of the desired aroma, and that products resulting from its oxidation may contribute to the final odor and flavor.

**El uso de la sal en la destilación de hojas de malagueta: Datos utiles para ayudar a los destiladores a elaborar un producto mas uniforme y estimular su interés en la producción de otros aceites esenciales** [The use of salt in the distillation of oil of bay: Data useful to the distillers in elaborating a more uniform product and to encourage their interest in the production of other essential oils], N. G. ARBILLAGA and M. A. JONES. (P. R. Expt. Sta.). (*Rev. Agr., Indus. y Com., Puerto Rico*, 34 (1942), No. 2, pp. 129-137, figs. 6).—It was found that the addition of sodium chloride and other

salts to the water in the still improved both yield and quality of the essential oil distilled by steam from bay leaves. Sodium, potassium, and calcium chlorides, potassium and ammonium nitrates, and sodium triphosphate, carbonate, and sulfate were all treated. Five times normal sodium carbonate and all concentrations of the triphosphate proved excessive, and the contents of the still turned black. Of the three concentrations of calcium chloride, the 5-N solution caused the content of the still to turn dark after the distillation had continued long enough, and thereafter no more oil was obtained. This effect is attributed to the presence of carbonate in the calcium chloride. The nonalkaline salts increased the yields to a greater extent at the higher concentrations, up to 5 N, potassium nitrate giving the largest increase.

**Effect of mill operations on the number of bacteria found in paper and paperboard products**, J. R. SANBORN. (N. Y. State Expt. Sta.). [*Tech Assoc. Pulp and Paper Indus.*], *Tech. Assoc. Papers*, 25, ser., No. 1 (1942), pp. 336-340.—Many mills have found bacteriological count standards for paper and paperboard products to be useful guides for efficient mill operation and satisfactory quality. Studies have revealed important sources of microbiological growths which, unless properly controlled, may frequently be responsible for high counts in pulp, paper, and paperboard. Where micro-organisms are allowed to develop at one or more focal points, many varieties and species are usually encountered in stock systems which may also be found in finished paper and paperboard products. Various physicochemical and biological factors in mill systems exert a protective action on micro-organisms which enables them to resist the lethal effects of chemicals and heat. These factors are still not well understood and should receive careful and critical study.

## AGRICULTURAL METEOROLOGY

**Physical elements of geography**, V. C. FINCH and G. T. TREWARTHA (*New York and London: McGraw-Hill Book Co.*, 1942, 2. ed., pp. X+641, pls. 10, figs. [371]).—This book is designed to supply textual material covering the physical elements of geography in a form particularly suited to classroom discussion in beginning courses of college geography. Of special interest to agricultural meteorology are the following chapters: Air temperature (including isolation) (pp. 33-57); atmospheric pressure and winds (pp. 58-92), atmospheric moisture and precipitation (pp. 93-110); storms and their associated weather types (pp. 111-154); the tropical rainy climates (A) (pp. 160-176); the dry climates (B) (pp. 177-193); the humid mesothermal climates (C) (pp. 194-217); the humid microthermal climates (D) (pp. 218-238); polar climates and highland climates (pp. 239-252); plains in dry climates (pp. 374-386); water resources of the land (pp. 465-482); and the appendix on supplementary climatic data for selected stations (pp. 601-602).

**Physical climatology**, H. LANDSBERG (*State College: Pa. State Col.*, 1942, 2. ed., rev., pp. XII+283, figs. 79).—A slightly revised edition of the work previously noted (E. S. R., 86, p. 294).

**Xerothermic theory**, P. B. SEARS (*Bot. Rev.*, 8 (1942), No. 10, pp. 708-736).—This comprehensive review (80 references), after defining the theory and suggesting its importance, discusses its origins, the periods of dispute and of critical reexamination, current judgment, and the xerothermic theory in North America. The main assumption of the theory is that there was at least one segment of time since the last major glaciation during which the climate was drier and warmer than at present.

**Aerobiology**, edited by F. R. MOULTON ([Lancaster, Pa.: Science Press Ptg. Co.], 1942, pp. [10]+289, figs. [196]).—This symposium on aerobiology was presented at a meeting of the American Association for the Advancement of Science, Chicago, 1942. The individual papers, most of them provided with lists of literature references, are as follows:

*Extramural*.—The Field of Extramural Aerobiology, by E. C. Stakman (pp. 1-7) (Univ. Minn. and U. S. D. A.); Atmospheric Pollen, by R. P. Wodehouse (pp. 8-31); Air-Borne Fungus Spores as Allergens, by O. C. Durham (pp. 32-47); Microorganisms in the Upper Air, by B. E. Proctor and B. W. Parker (pp. 48-54); Microorganisms in Marine Air, by C. E. ZoBell (pp. 55-68) (Univ. Calif.); Local Aerial Dissemination of Plant Pathogens, by G. W. Keitt (pp. 69-77) (Univ. Wis.); Long Distance Dissemination of Plant Pathogens, by J. J. Christensen (pp. 78-87) (Minn. Expt. Sta.); and Insect Population and Migration in the Air, by P. A. Glick (pp. 88-98) (U. S. D. A.).

*Intramural*.—Air-Borne Infection as a Basis for a Theory of Contagion, by W. F. and M. W. Wells (pp. 99-101); Behavior of Microscopic Particles in the Air and in the Respiratory System, by T. F. Hatch (pp. 102-105); Atomizing of Mouth and Nose Secretions Into the Air as Revealed by High Speed Photography, by M. W. Jennison (pp. 106-128); Disinfection of Air by Air Conditioning Processes, by C. P. Yaglou and U. Wilson (pp. 129-132); The State of Suspension of Bacteria in the Air as Measured by Settling Rates, by E. B. Phelps (pp. 133-137); Standardization of Ultraviolet Lamps Used as Sources of Germicidal Radiation, by W. W. Coblenz (pp. 138-141); The Physiological Effects of Ultraviolet Radiation, by H. Laurens (pp. 142-155); Abiotic and Sublethal Effects of Ultraviolet Radiation on Microorganisms, by A. Hollaender (pp. 156-165); Production and Control of Bactericidal Ultraviolet Radiation, by H. C. Rentschler (pp. 166-170); Characteristics of Some Low Voltage Type Germicidal Lamps, by L. J. Buttolph (pp. 171-180); Practical Considerations in the Design and Maintenance of Ultraviolet Air Sanitation Equipment, by F. W. Robinson (pp. 181-183); Characteristics of Sperti, Inc., Ultraviolet Lamps, by J. Kruezkamp (pp. 184-185); The Importance of Air-Borne Pathogenic Bacteria in the Operating Room—A Method of Control by Sterilization of the Air With Ultraviolet Radiation, by D. Hart (pp. 186-192); The Growth-Promoting Role of Ultraviolet in Wound Healing, by L. G. Nutini (pp. 193-196); Clinical and Laboratory Observations in the Use of Ultraviolet Radiation in Surgery, by C. J. Kraissl and D. A. W. and M. H. Wilson (pp. 197-205); Environmental Control of Epidemic Spread of Contagion, by W. F. and M. W. Wells and T. S. Wilder (pp. 206-211); The Spread of Pneumococcal and Streptococcal Infections in Hospital Wards and in Families, by M. Finland (pp. 212-222); On the Control of Cross-Infections in a Children's Hospital, by E. C. Robertson and M. E. Doyle (pp. 223-227); Studies of Cross-Infection in the Infants' Hospital in Boston, by G. L. Brooks, U. Wilson, and K. D. Blackfan (pp. 228-232); Effect of Irradiation of Air in a Ward on the Incidence of Infections of the Respiratory Tract With a Note on Varicella, by L. H. Barenberg, D. Greene, L. Greenspan, and B. Greenberg (pp. 233-236); Studies on the Aerial Transmission of Hemolytic Streptococci in a Rheumatic Fever Hospital, by S. M. Wheeler and T. D. Jones (pp. 237-241); Observations on the Control of Respiratory Contagion in the Cradle, by I. Rosenstern (pp. 242-250); The Controlled Physical Environment for the Premature and Older Infant, by C. C. Chapple (pp. 251-253); The Control of Cross-Contamination by the Use of Mechanical Barriers—I, Principles and Instrumentation for Absolute and Partial Control With **Fixed** and Circulating Hosts, by J. A. Reyniers (pp. 254-259); The Control of Cross-Contamination by the Use of Mechanical Barriers—II, Testing the Efficiency of Mechanical Systems for Controlling Cross-Infection, by J. A. Reyniers

and P. C. Trexler (pp. 260-266) ; The Bactericidal Effects of Daylight and Sunlight on Chained Gram Positive Cocci in Simulated Room Environment—Theoretical and Practical Considerations, by L. (with appendix, List of Current Publications on Snow and Ice, by C. Elges, R. W. Burhoe, and L. Jacchia (pp. 981-1005) (Nev. Sta. et al.) ; and Report of Research-Committee of Eastern Snow-Conference, by G. A. Hathaway, C. F. Merriam, and J. Sweet (p. 1029).

**Regionalization of the United States on a precipitation basis, S. S. VISHNER** (*Ann. Assoc. Amer. Geog.*, 32 (1942), No. 4, pp. 355-370, figs. 27).—The main purposes of this article are to make more readily available the essence of numerous detailed precipitation maps, to offer a number of new precipitation maps, and to present concisely for each of the regions facts concerning the precipitation, many of which have not been generally known. There are many bibliographic footnotes.

**Rainfall and runoff in the upper Santa Cruz River drainage basin, H. C. SCHWALEN** (*Arizona Sta. Tech. Bul.* 95 (1942), pp. [3]+421-472, pls. 2, figs. 16).—The area as here considered includes that of the Santa Cruz River and its tributaries above Rillito Station on the Southern Pacific Railroad, contains some 3,500 sq. miles of which 380 are in Mexico, and varies in elevation from 2,060 ft. above sea level at Rillito Station to over 9,000 ft. on several of the mountain peaks. There are two distinct rainy seasons—one from the latter part of June and through September and the other through December to March, inclusive. In general, the summer rains comprise over 50 percent of the total and occur almost entirely in the middle or late afternoon as thundershowers. They are usually local, of short duration, and sometimes torrential in character, but the entire drainage area is usually subject to rainfall. Winter rains result from general cyclonic storm movements passing eastward, are usually of wide areal extent, several days' duration, and slow, steady intensity, and are not as dependable in amount or time of occurrence as the summer rains. The mean annual rainfall varies from a minimum of about 11 in. in the valley to over 37 in. at 8,000 ft. In the mountain areas with marked relief the rainfall in general increases directly with elevation. The mean annual rainfall for the drainage

area was found to be 16.5 in., or equivalent to about 3.1 million acre-ft. per year. Variations at individual stations have been from less than 50 to more than 200 percent of the mean annual rainfall.

The Santa Cruz River and its principal tributaries are purely ephemeral in character. Floods from summer rains are short-lived, but those from winter rains are in general of longer duration with lower flood crests. The minimum, maximum, and mean annual discharges and the peak discharges of the Santa Cruz River and Rillito Creek are presented. Frequency studies indicate that there is about a 1 percent chance of occurrence of a flood peak of 16,500 sec.-ft. in the Santa Cruz River and of 32,000 sec.-ft. in Rillito Creek.

But for years of exceptionally high rainfall and runoff, an extremely low percentage of the total rainfall was found to appear as runoff in the lower portion of the drainage area. However, the ratios of runoff to rainfall for individual storms, seasonal periods of excessive rainfall, and for small drainage areas at high elevations are much higher. It is apparent that the storm area, duration and intensity of the rainfall, topography and slopes of the drainage area, and the amount of water stored in the soil are the factors determining the amount of runoff and resulting runoff-rainfall ratio. The total amount of rainfall without consideration of these factors shows but little correlation with the runoff.

**The weather of Scotland in 1941**, W. A. HARWOOD (*Highland and Agr. Soc. Scot. Trans.*, 5. ser., 54 (1942), pp. 205-227).—This consists of a general description of the weather from month to month and a selection of rainfall returns in which each county of Scotland is represented by one or more stations. Temperature readings, unless otherwise stated, are from thermometers exposed in the regulation "Stevenson Screen."

## SOILS—FERTILIZERS

**The soils that support us: An introduction to the study of soils and their use by men**, C. E. KELLOGG (*New York: Macmillan Co.*, 1941, pp. XI+370, figs. 80).—This is a popular discussion in which "technical discussions and words have been avoided in order to deal with the main principles simply." Despite this avoidance of technicalities, however, much of the modern science of the soil is outlined for the general reader. The contents are arranged under the headings: In the first place, the building material for soils, life and the soil, the parts of a soil, the rains come and go, soils of little places and of big places, soils of the grasslands, soils of the desert, soils of the forested lands (temperate), soils of the forested lands (warm and tropical), men use the soil, soils for different crops, plowing and digging, fertilizers and lime, control of water on the soil, when do soils "wear out," planning the use of the soil, and soil and our future.

[**Soil and fertilizer investigations by the North Carolina Station**]. (Partly coop. U. S. D. A. et al.). (*North Carolina Sta. Rpt. 1941*, pp. 60-66, figs. 2).—These included the following subjects: Effect of grade of tobacco rows on drainage and erosion control; effect of heavy summer rain on soil losses from cultivated land; value of ground cover for controlling erosion; effect of compost, woods litter, and manure on soil losses and yields from cotton areas; a flood control study made in the mountains; soil acidity relationships as an aid in the classification of soils; the downward movement of lime in soils; effect of potash and magnesia losses on soil acidity; the necessity of boron for truck crops produced in the Wilmington area; value of copper on soils in southeastern North Carolina; increased yields of lespedeza and oats by lime and phosphate at the Piedmont Substation; and superiority of fertilizers neutralized with finely

ground dolomitic limestone as compared with those neutralized with coarsely ground limestone.

[**Soil investigations by the Vermont Station**] (*Vermont Sta. Bul.* 495 (1942), pp. 16-19).—Reported upon by A. R. Midgley are the effect of amendments in conserving the fertilizer value of cattle manure, the addition to which 10 lb. of boric acid per ton prevented nitrogen loss by volatilization for a period of fully 5 or 6 weeks and practically eliminated the fly population of the manure; effect of lime and organic matter on boron fixation and availability in soils; pasture improvement studies; effect of slope, plant cover, and contour tillage on soil erosion and water runoff; maintenance of permanent hay lands; and phosphorus fixation and unavailability in podzolized soils.

**Nomograms for rapid calculation of soil density, water content, and total porosity relationships**, G. B. BODMAN. (Univ. Calif.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 10, pp. 883-893, figs. 3).—Two nomograms and a table are presented in an attempt to facilitate calculations involving some of the most simple and elementary properties of soils in relation to water content and well-established empirical observations concerning penetration.

**Volume-freezing-point relations observed with new dilatometer technique**, A. B. C. ANDERSON and N. E. EDLFFSEN. (Calif. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 3, pp. 221-232, figs. 4).—Irreversible changes in the volume-freezing-point relations of a soil containing more water than is required to saturate it are produced by the presence of large quantities of dissolved air in the soil moisture. The dissolved air is expelled to form throughout the soil moisture great numbers of entrapped air bubbles, of which the volume depends on their temperature at the moment of entrapment. A new dilatometer technic permitting the elimination of the dissolved air is described. Seemingly irreversible changes were produced by the formation of minute water-vapor cavities around each soil particle whenever the temperature of the frozen water-soil mass was raised. This gave rise to a family of parallel curves (representing the volume-freezing-point relations of the soil under all conditions), the initial points of which all lie on a locus which is believed to represent the true volume-freezing-point relations of the soil in the absence of cavities. This locus is quite different, however, from that previously taken to represent the true volume-freezing-point relations of a soil more than saturated. Two methods for obtaining this locus are presented, together with a theoretical explanation of the reproducible family of curves representing the true volume-freezing-point relations of a soil under all conditions.

**Electrochemical relations between the root system and the soil**, H. LUNDEGÅRDH (*Soil Sci.*, 54 (1942), No. 3, pp. 177-189, figs. 3).—The surface layer of the protoplasm called the Z-layer, an amphoteric colloid with predominatingly acidic properties in contact with a solution containing ions, exhibits on both sides of the boundary an electrical double layer of opposite signs, such that the magnitude of the charge, in terms of H-ion concentrations, is shown by the equation

$$-P. D. = \frac{RT}{nF} \ln \frac{[H^+]_z}{[H^+]_0},$$

in which  $[H^+]_z$  is the concentration of H ions in the Z-layer and  $[H^+]_0$  is the concentration of H ions in the medium, and  $R$ ,  $T$ ,  $n$ , and  $F$  have their usual respective significations. As between the soil and the cell wall and liquid interphase, a similar relation exists and may be expressed by replacing the quantity  $[H^+]_z$  by the quantity  $[H^+]_i$  in the equation just stated. The difference between  $P. D.$  and  $P. D.$ , respectively, between the Z-layer and the interphase and between the soil colloids and the interphase can, therefore, be expressed as

$$P. D._2 - P. D._2 = \frac{RT}{nF} \ln \frac{[H^+]_2}{[H^+]_1}$$

a quantity which was determined by means of a device using a cathode-ray oscillograph as a voltmeter and a compensation circuit for calibration. A theory of the electrochemical properties of the surface of living roots, which control the absorption of nutrient ions, is developed and extended to the boundary between the roots and the soil. A number of determinations of the potential of cereal plants, grown in soil to which nutrient salts or commercial fertilizers were added, are discussed in relation to the theoretical considerations.

**Field study of response of the electrical resistance of 2- and 4-electrode plaster of paris blocks to variations in soil moisture**, N. E. EDLEFSEN, A. B. C. ANDERSON, and W. B. MARCUM. (Calif. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 4, pp. 275-279, figs. 2).—Plaster of paris blocks containing two electrodes (E. S. R., 83, p. 307) have been compared by two of the present authors with 4-electrode blocks (E. S. R., 88, p. 161) in laboratory experiments. The work here noted extended the trial to field conditions with the same comparative result, namely, that the 2-electrode blocks gave practically the same degree of reproducibility as did the 4-electrode system.

From results both in the laboratory and in the field it is concluded that at field capacity and higher moisture contents, for all the soils studied, the resistances of the 2-electrode blocks are nearly constant, having a value between 400 and 600 ohms, whereas the resistances when all the readily available moisture is used are in the neighborhood of 500,000 ohms. The fact that the blocks, in all the soils tested, have approximately the same resistances at the permanent wilting percentage makes them especially useful as indicators of need for irrigation. The resistance increases very rapidly with changes in moisture content in the neighborhood of the permanent wilting percentage.

**Present and future agricultural use of ground-water in a portion of the Southwest**, H. P. BURLEIGH. (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [23] 1942, pt. 1, pp. 15-19).—It is proposed to divide the ground-water areas in the Southwest into the two general classes (1) ground waters occurring in the relatively narrow alluvial channels along rivers, their major source of recharge being usually the surface discharge of the river coursing over the alluvium; and (2) ground-water areas in which the aquifer is exposed or underlies areas of considerable and irregular extent, and the major source of recharge usually is a portion of the rainfall. In class 1 ground-water areas there is a possibility of developing additional ground water, with an assured equivalent annual recharge, at a rate that probably will not exceed 122,000 acre-ft. annually. In three of the major areas of class 2, namely, the Winter Garden area, the San Luis Valley, and the Roswell Artesian area, total feasible development probably has been reached, as additional development appears precluded for legal and economic reasons. In the Estancia Valley area a probable total of about 20,000 acre-ft. can be developed. In the other two major areas, the Deming area in New Mexico and the various districts on the High Plains, the rate of development is entirely dependent upon the rapidity with which the water table is lowered beyond the point of profitable pumping, for in these areas pumped water comes from partial storage.

It is pointed out that major well-irrigation developments in the Southwest occur under conditions whereby the water table will eventually decline below the point of profitable pumping. It is, therefore, important that, as quickly as feasible, research efforts in the field of hydrology be intensified. Too little is known of the precise effect that varying rates of recovery will have upon the rate of decline of the water table. With a knowledge of the probable rates of lowering of the

water table, it is possible that more effective use of available water supplies would be made. In the field of agricultural research, knowledge that will lead to a more effective ratio between application and the actual consumptive requirements of crops must be attained. Application of ground water throughout the Southwest to crops that are not compatible with the general economy must be discouraged, and the application of ground water to crops most in harmony with the agricultural economy of the region must be encouraged.

**Evaporation and consumptive use of water empirical formulas**, H. F. BLANEY and K. V. MORIN. (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [23] 1942, pt. 1, pp. 76-83, fig. 1).—The authors show the development, in connection with the Pecos River joint investigation, of empirical formulas for estimating unit annual values of evaporation from free-water surfaces and consumptive use by native ground-water vegetation when records of temperature, daytime, and humidity are available. The formulas are developed for areas in which there is ample water to take care of evaporation and transportation. Of their use, the authors note that the evaporation formula may be used to estimate annual evaporation when a few monthly evaporation pan records may be missing, but monthly temperature and humidity data are available for the entire year; and that the consumptive-use formula is best adapted to native ground-water vegetation but may be used in estimating consumptive use by irrigated crops having access to an ample water supply, such as alfalfa, when some experimental evaporation transportation data for the crop are available, together with records of evaporation, temperature, and humidity.

**Some evidence regarding the kind and quantity of sediment transported by density-currents**, H. S. BILL. (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [23] 1942, pt. 1, pp. 67-73).—Observations of numerous authors are cited as showing that both aqueous and atmospheric density currents can and do transport enormous quantities of fine sediment. Analyses of various dust falls and loess and bottom deposits are tabulated. It is noted, however, that these data are not adequate for making other than very rough estimates of the total volume of sediment moved in this manner, and the need for fuller information for use in the solution of silting and soil loss problem is emphasized.

**Scour-control and scour-resistant design for hydraulic structures**, B. T. MORRIS. (U. S. D. A.). (*Amer. Geophys. Union Trans.*, [23] 1942, pt. 1, pp. 69-67, figs. 8).—The author advocates hydraulic laboratory study of specific scouring problems and analysis of the general problem as a phase of the mechanics of sediment transportation. The factors controlling the ability of a stream to scour and having a significant bearing upon the problem are listed as (1) the amount of sediment brought into the region of scouring action by the stream, (2) the sediment-carrying capacity of the flow in the downstream channel, (3) the resistance of the bed and bank materials to dislodgment and entrainment, (4) the mixing or sediment-suspending power of the eddies produced in the scour zone, and (5) the velocity of flow through the scour zone.

In experiments here described and illustrated by photographs and drawings, a jet was directed vertically downward onto a submerged bed of well-sorted sand. It was shown that, regardless of the ultimate intensity of the jet, during the first instant of jet flow the jet was simply deflected as if by a slab of masonry (0.5 sec.). In the corner the velocity energy of the stream produced a stagnation pressure, tending to hold the sand grains down. Only through fluctuations and eccentricities of velocity and pressure distribution could grains be loosened under this stabilizing force. Away from the corner and downstream, the pressure gradient and the high velocities were soon able to move grains along the bed. The suspending action of the eddies resulting from the shock loss at the bend was

relatively unimportant. Particles were transported a short distance and deposited close to the corner. The removal of even a few grains of sand changed the outlines of the flow, however (25 sec.). The jet then entered a rounded pit and had to turn more than  $90^\circ$  in order to leave over the growing dune of deposited material. More intense eddies were produced and still the stream was carrying only a small amount of bed load. As the pit deepened (47-60 sec.) the face of the dune of deposited material steepened. When the angle of repose (approximately  $30^\circ$ ) was exceeded, sliding took place (70 sec.), the direction of bed load motion reversed, and suspension became the only phase of transportation capable of removing sediment over the dune crest (110 sec.). The mixing system holding particles in suspension was composed of the eddies produced in the scour pit. The rate of growth of the scour hole became the rate of removal of particles suspended by the eddy system.

These experimental results are analyzed, and the application of their indications and of the five scouring control factors above enumerated to the design of structures are discussed.

**Mechanism of water attack on dry cohesive soil systems**, H. F. WINTERKORN (*Soil Sci.*, 54 (1942), No. 4, pp. 259-273, figs. 2).—The mechanism of water attack on dry cohesive soil systems was analyzed theoretically and on the basis of data obtained in experiments on five natural soils and on their homoionic modifications prepared by elutriation with the chlorides of the H-, Na-, K-, Mg-, Ca-, Ba-, Al-, and Fe-ions, respectively. Two main factors appeared to govern the consequences of the water attack: (1) The driving force or the affinity of the internal soil surface for water, and (2) the cohesive forces holding the system together. The relative magnitude of these forces was found to determine the general nature of the reaction. On the other hand, the speed with which the particular reaction occurs was shown to depend to a great extent on the permeability of the soil system and on the ease with which free and adsorbed gases may escape from the pore space. If this escape is prevented, a type of failure similar to an explosion, although liberating less energy than is usually associated with this term, may occur. The concept that the driving force is the affinity of the internal surface for water explains the behavior of certain moist cohesive soil systems which may be exposed to free water for any length of time without observable change. The affinity for water is satisfied in such systems, and no driving force for the water attack is left.

The experimental data obtained appeared to substantiate the developed theory as far as the erosive soils are concerned. With respect to the nonerosive soils the experimental techniques available did not furnish all the information necessary for testing, but no fundamental objections to the general theory appeared.

**Runoff, percolate, and leaching losses from some Illinois soils**, R. S. STAUFFER. (Ill. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 9, pp. 830-835).—A continuation of work reported earlier (E. S. R., 78, p. 454) on runoff and percolation studies made with erosion-type lysimeters for several important soil types of Illinois. The soils were kept bare and not cultivated. Any growth was removed with as little disturbance of the soil surface as possible. There was found to be considerable variation in runoff and plant nutrients removed from the soils by leaching from the different soil types.

**Controlling coastal sand dunes in the Pacific Northwest**, W. T. McLAUGHLIN and R. L. BROWN (*U. S. Dept. Agr. Cir.* 660 (1942), pp. [2]+46, figs. 24).—A comprehensive account of the development, extent, and methods of control of coastal sand dune areas in the Pacific Northwest.

**Influence of the chemical composition of organic matter on the development of mold flora in soil.** T. L. MARTIN, D. A. ANDERSON, and R. GOATTS (*Soil Sci.*, 54 (1942), No. 4, pp. 297-302, figs. 4).—The authors' experiments showed that the higher the percentage of readily decomposable carbohydrate materials, i. e., sugars, starches, and some hemicellulose and cellulosic materials, the greater was the predominance of species of *Mucor* and *Rhizopus* in proportion to other molds present in a soil-organic-matter mixture. When a stable hemicellulose and cellulose fraction had been produced in the soil, little of the more easily decomposed carbohydrate material remaining, such molds as *Penicillium glaucum* and *Aspergillus niger* predominated. When lignin was the chief constituent remaining of the original plant material, species of *Cladosporium*, *Alternaria*, and *Aspergillus minutis* were found in the greatest numbers.

**Distribution of antagonistic actinomycetes in nature.** S. A. WAKSMAN, E. S. HORNING, M. WELSCH, and H. B. WOODRUFF. (N. J. Expt. Stas.). (*Soil Sci.*, 54 (1942), No. 4, pp. 281-296).—From various soils, 244 cultures were isolated. Of these, 106 cultures or 43.4 percent possessed some antagonistic properties, and 49 cultures or 20 percent were highly antagonistic toward bacteria and fungi. Similar relations were observed by examining a large series of well-identified organisms kept for a number of years in a type culture collection. Although antagonistic forms were also found among the genera *Proactinomyces* and *Micromonospora*, they were most abundantly represented by members of the genus *Actinomyces*.

Some of the more active cultures were studied in detail, and several antibiotic substances were isolated. These antibiotic substances were found to vary greatly in their chemical composition and in their mode of action. They were shown to be highly selective in nature, affecting different organisms in a different manner. They were not only bacteriostatic but also bactericidal. Some were highly bacteriolytic, a property widely distributed among certain types of actinomycetes.

**The microbiological oxidation of ammonia in desert soils.—I, Threshold pH value for nitrification.** A. B. CASTER, W. P. MARTIN, and T. F. BUEHRE (*Arizona Sta. Tech. Bul.* 96 (1942), pp. [3]+475-510, figs. 6).—A laboratory incubation study was conducted with six typical but widely separated desert soils of varying texture to obtain information on the rate of microbial oxidation of ammonia in comparison with other types of nitrogen fertilizers commonly used. The results given in this publication are concerned mainly with the pH relationships involved in nitrification.

**Dependence of the rate of corrosion of buried iron on the oxygen supply of the soil.** H. VINE (*Soil Sci.*, 54 (1942), No. 3, pp. 159-176).—The author determined the loss of weight, due to corrosion, of strips of iron driven to various depths in the soil at a number of points in Trinidad, B. W. I., during the rainy season and removed, cleaned, and weighed after 2, 4, or 6 weeks. The measurements were replicated, and the statistical significance of the results was calculated. The loss in weight decreased very markedly with increasing depth, especially during the wettest periods. Except at one site, where, it is believed, pH values of 4.4 and 4.7 in the top and second 4-in. layers of soil may have been the cause of a high degree of corrosiveness, the losses in weight were independent of acidity and were closely related to the oxygen supply as indicated by texture and drainage. None of the soils were saline, calcareous, or gypseous. Manometric observations and gas analyses of three portions of a mixture of sand and clay, virtually free of organic matter and adjusted to different pH values, in which pieces of iron were allowed to corrode, showed that oxygen absorption predominated over hydrogen evolution when the oxygen

supply was plentiful, but that the latter also played a part; that it alone might be responsible for corrosion in anaerobic conditions; and that its rate increased with acidity.

**Determination of active manganese in soil,** G. D. SHERMAN, J. S. McHARGUE, and W. S. HODGKISS. (Ky. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 4, pp. 253-257).—The active manganese in the soil is defined as including the readily available manganous manganese and the easily reducible manganic manganese. The manganous-manganic manganese exists in an oxidation-reduction equilibrium reflecting the state of oxidation of the soil. The status of the manganous-manganic manganese equilibrium was found to be establishable by a measurement of the active manganese. In a procedure described, the forms of active manganese are determined in the leachates from successive extractions of the soil with distilled water, neutral normal ammonium acetate, and neutral normal ammonium acetate solution containing 0.2 percent hydroquinone. It is claimed that this procedure for determining the active manganese will identify (1) neutral to alkaline soils that are manganese-deficient for plant growth, (2) strongly acid soils that will become manganese-deficient with liming, and (3) soils with high and low capacity to oxidize added manganese salts.

**Significance of Donnan equilibria for soil colloidal systems,** L. E. DAVIS. (Univ. Calif.). (*Soil Sci.*, 45 (1942), No. 3, pp. 199-219, figs. 2).—In this paper emphasis is placed on an exact thermodynamic treatment. The customary discussion, with reference to clay systems, is found to be insufficient. A brief description of Donnan systems and Donnan equilibria is followed by a critical discussion of the thermodynamics of Donnan equilibria. The application of these principles to ideal and to real systems and the significance of Donnan equilibria with respect to soil colloids are considered. The expression Donnan equilibria is applied only to equilibria between phases upon which measurements can be made and not to equilibria between microregions in a suspension such as the "micellar" and "intermicellar" regions. For real systems, such approximate generalizations as the ion concentration product principle are shown not to be adequate. It is pointed out, however, that nothing is gained by substituting the term "activity" for "concentration" in a discussion, unless the quantities which have been measured are actually activities rather than concentrations.

Upon the basis of the conclusion that, although activities of electrolytes are thermodynamically definable, the individual activities of ions are not, it is suggested that the use of the concept of ionic activities be avoided; also that the importance of the Donnan equilibrium as a regulative principle in soil chemistry has been greatly overemphasized, although investigation of the Donnan equilibrium can be used experimentally in the study of certain soil colloidal properties.

**Forest soils: Origin, properties, relation to vegetation, and silvicultural management,** S. A. WILDE (*Madison, Wis.: Author, 1942, 2. ed., rev., pp. 319, figs. 65*).—A comprehensive treatment of the subject of forest soils intended to meet some of the needs of men engaged in forestry and related branches of land use. An extensive listing of publications related to the subject is given. The five parts of the mimeographed publication include genesis of forest soils, soil as a medium for tree growth, analysis of forest soils, forest soils in relation to silviculture and forest management, and management of forest nursery soils.

**Soil-freezing and forest-cover,** K. T. BELOTELKIN. (U. S. D. A. et al.). (*Amer. Geophys. Union Trans.*, [22] 1941, pt. 1, pp. 173-175, fig. 1).—Measurements of depth of frost in the ground were made at the Gale River Experimental Forest in northern New Hampshire. Under forest canopies soils did not begin freezing until continuous low temperatures set in about the beginning of December. Moisture present in the litter, humus, and upper layers of the mineral

soil formed snowlike crystals, enabling the soil to maintain a good degree of permeability far into the winter. Soils in the open field, on the other hand, began losing their permeability in early November, when they began freezing solidly for several days at a time. Observations made during and after a heavy rain in December 1937 showed that under the forest canopies most of the frost left the ground. What frozen patches remained in the forest were saturated with freely moving water. In the open field water remained standing in slight depressions or ran freely along the slope. Under the forest cover no traces of free water were observed on the surface during or after the rain. Thawing began and was completed earliest in the hardwood stand. The open field ranked second in this respect, followed by the spruce flat and spruce swamp in the order named. Snow cover affects soil freezing to such an extent that even slight trampling of the snow, thereby increasing its conductivity, was found to affect the next re-measurement greatly if this were taken too near the trampled area. Thawing of the ground from the surface was found not to begin until the snow has melted; that from the bottom starts somewhat earlier. Forest litter protects the soil from freezing and delayed the penetration of the frost. Under softwood stands frost remained in the ground longer than in the open or in hardwoods. From 5 to 10 days (in the swamp even more) before the last vestige of frost has disappeared, however, small patches with no frost may be found which would provide channels for infiltration of water.

In poorly drained soils frost was found to penetrate deeper and to stay in the ground longer than in soils with better drainage. In their influence on soil freezing, fine-textured soils resembled poorly drained soils. Coarse-textured soils resembled better-drained soils.

**The relation of various types of vegetative cover to soil drift, A. E. COLDWELL, P. R. LOEWEN, and C. J. WHITFIELD. (U. S. D. A.).** (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 8, pp. 702-710).—Results from wind erosion investigations are given for two areas in the vicinity of Dalhart, Tex., as determined from measuring erosion conditions along straight lines of comparatively great lengths, crossing fields with different covers. Changes in elevation of ground surface were measured from year to year. The recorded changes in elevation, caused largely by wind erosion, were found to vary greatly under different conditions of vegetative cover.

**Utilization of absorbed phosphate by cotton and oats, R. COLEMAN. (Miss. Expt. Sta.).** (*Soil Sci.*, 54 (1942), No. 4, pp. 237-246, figs. 2).—Cotton and oats supplied with a nutrient solution but with only that phosphate which had been adsorbed by the clay against acid and alkaline extracting solutions grew well on relatively small quantities of adsorbed phosphate whether it was held by the kaolinitic or the montmorillonitic clay, and the plants utilized a large percentage of the adsorbed phosphate present. Of the methods studied, Truog's (E. S. R., 64, p. 312) was the most effective in removing the readily available phosphate from the clays, but it failed to remove much phosphate that was available to the plants.

**Crop response to potash fertilization on important Ohio soils in relation to plant available potassium, S. R. OLSEN (Ohio State Univ., Abs. Doctoral Diss., No. 38 (1942), pp. 211-219).**—The response of corn to potash was determined for six Ohio soils from 1939 to 1941. Available potash in each soil was determined by chemical, Mitscherlich, and Neubauer methods. Field response to potassium was of the same order as was indicated from amount of available potassium measured by all of the methods.

**Potash available to crops unless lost by erosion, C. D. HOOVER (Miss. Farm Res. [Mississippi Sta.], 5 (1942), No. 11, p. 7).**—Removal of potash in harvest

crops and losses from leaching are small in comparison with the amount of potash applied in the average mixed fertilizer. Most serious losses of potash take place from erosion, effective control of which would, therefore, result in building up the supply of soil potash.

**Relation of liming to efficiency of fertilizers, W. R. PADEN.** (S. C. Expt. Sta.). (*Com. Fert.*, 65 (1942), No. 5, pp. 22-25).—Experimental results lend further support to the idea that liming acid soils increases the efficiency of fertilizers. The author points out that at the present time, when fertilizers are difficult to obtain and when efficiency is so important, every possible effort should be made to apply limestone to soils having moderate to strong acid reactions.

**Effect of dolomitic limestone on soils and crops when used as a neutralizing agent in complete fertilizers, E. R. COLLINS and J. J. SKINNER.** (N. C. Expt. Sta. and U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 10, pp. 894-901, fig. 1).—Non-acid-forming fertilizers made with dolomitic limestone produced significantly higher yields of cotton, sweetpotatoes, and Irish potatoes than were obtained with acid-forming fertilizers under coastal plain soil conditions in North Carolina. Neutralizing the fertilizer with dolomitic limestone maintained soil pH at approximately the original level, increased total magnesium in the plant and the available magnesium in the soil of the root zone, and increased total calcium in the plant with no appreciable change in the ultimate available calcium content of the soil or the potash content of the plant, indicating no appreciable liberation or fixation of the soil and fertilizer potash.

**Many soils, crops, may require boron for highest yields, R. COLEMAN** (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 11, p. 7).—Results of soil analyses showed that many soils in Mississippi may need applications of boron. This was found to be especially true in the southern part of the State.

**The selenium content of vegetation and the mapping of seleniferous soils, O. E. OLSON, D. F. JOENLIN, and A. L. MOXON.** (S. Dak. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 7, pp. 607-615, figs. 2).—The selenium content of *Agropyron smithii* was reported as being a relative index to the amount of selenium in soils which is available to common range plants.

**Inspection of commercial fertilizers for 1942, T. O. SMITH and H. A. DAVIS** (*New Hampshire Sta. Bul.* 343 (1942), pp. [1]+7).—A summary of analysis of 84 brands of fertilizer and fertilizer materials sold in New Hampshire in accordance with the provisions of the State fertilizer law.

**Commercial fertilizers—Concerning nitrogen supplies in war time, L. S. WALKER and E. F. BOYCE** (*Vermont Sta. Bul.* 496 (1942), pp. 27).—A statistical summary of the usual fertilizer analyses. There is also included a discussion of nitrogen supplies in wartime, as well as suggestions on fertilizer usage and a discussion of acid and nonacid fertilizers.

**Wartime recommendations on the use of commercial fertilizer, O. T. COLEMAN and A. W. KLEMME** (*Missouri Sta. Cir.* 242 (1942), pp. [4], fig. 1).—Fertilizer recommendations based upon analyses selected by the U. S. War Production Board are given for the principal crops of Missouri according to previous land use of the area to be used. Suggested rates and methods of application are also given.

**Delta soils vary in fertilizer needs for cotton growth, R. KUYKENDALL** (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 11, p. 2).—The importance of the proper program of fertilization for obtaining maximum yields on soil types of the Yazoo-Mississippi Delta is pointed out. The most profitable practice

was found to be winter legumes followed by cotton and fertilized with 20 lb. per acre of commercial nitrogen.

**A fertilizer triangle for small whole number fertilizer ratios, C. S. SLATER.** (Md. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 10, pp. 955-957, figs. 2).—Two figures are presented to show the location of small whole-number ratios at each intersection of three ratio lines and the distribution of small whole-number ratios that can be expressed in numbers not greater than six, using a modification of the equilateral triangle commonly used to illustrate ratio relationships.

**Availability of adsorbed ions to plants growing in quartz sand substrate, F. S. SCHLENKER.** (R. I. Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 4, pp. 247-251, figs. 6).—The author has previously shown (E. S. R., 84, p. 306) that when potassium, calcium, and magnesium permutites and nitric, sulfuric, and phosphoric acid aniline blacks are suspended in water, solutions of ions that will support the growth of plants are produced. The present paper reports experiments which further show that when the adsorption complexes are mixed with quartz sand and the whole mass is adjusted to an adequate moisture content, the adsorbed ions become available and support growth. A comparison of equal quantities of soluble salts and adsorbed ions showed that the adsorbed ions produce the greater plant growth. In general, crop yields, whether measured in terms of fresh weight or height, paralleled the fertilization.

**Factors affecting the interaction between organic matter and montmorillonite, L. E. ENSMINGER.** (Idaho Expt. Sta.). (*Soil Sci.*, 54 (1942), No. 3, pp. 191-197).—The combining capacity of gelatin was found to increase with acidity, at least to pH 0.5. The basicity of albumen increased with acidity to a pH value between 2.8 and 1.5 and remained constant. The equivalent combining weight of the gelatin cation was greater for montmorillonite than for hydrochloric acid. The equivalent combining weight of the albumen cation was about the same for montmorillonite and hydrochloric acid. The base-exchange data indicated that 12 percent of the nitrogen in gelatin and 8 percent of that in albumen are basic at pH 2.8. Composting increased the sorption of straw and alfalfa leaf meal by montmorillonite. Grinding increased the sorption of alfalfa leaf meal and its composts but had little effect on the sorption of straw. Organic materials containing alfalfa were sorbed to a greater extent than was straw. Acidity increased the sorption of composted alfalfa leaf meal more than it did that of the original material. The addition of lignin to gelatin decreased the basic properties of the gelatin.

**Influence of leguminous plant additions on the organic matter content and available nutrient supply of southern soils, F. MOSER.** (S. C. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 8, pp. 711-719, fig. 1).—Plant materials were added as green manures, hay mulches, and incorporated with the soil to determine the effect of the method of addition on the organic matter content, available soil nutrients, and crop yields. While the average content of organic matter in the cultivated soils of the Piedmont section of South Carolina is about 1 percent, the organic matter added by growing vetch, lespedeza, and crimson clover raised the percentage to 1.5. Growing lespedeza continuously on the same area for a number of years increased the organic matter to about 2.5 percent. Adding the leguminous plant materials increased the nitrate, acid-soluble phosphorus, and replaceable potassium content. The leguminous soil treatments also gave increases in yield with sorghum and rye used as the indicator crops.

**Phosphate reserves of Utah, revised estimate, J. S. WILLIAMS and A. M. HANSON** (*Utah Sta. Bul.* 304 (1942), pp. 24, figs. 2).—As a supplement to work previously reported in Bulletin 290 (E. S. R., 82, p. 156), this publication presents

a revised statement of Utah's reserve of phosphate by areas, by counties, and by quality of rock.

**Chemical properties of various commercial superphosphates before and after ammoniation**, E. W. HARVEY and L. V. ROHNER (*Amer. Fert.*, 97 (1942), No. 8, pp. 5-6, 24-26).—The  $P_2O_5$  reversion behavior of ammoniated commercial superphosphates during storage at various temperatures may differ markedly from product to product. Variations in the fluorine, iron, aluminum, and moisture contents of these products may be factors contributing to these differences in behavior. However, there are no consistent correlations between the contents of any of these and the content of reverted  $P_2O_5$  after ammoniation and storage at different temperatures. In general, a significantly lower citrate-insoluble content was indicated by the use of the 0.5-gm. method than by the 1-gm. method of determination. The extent of this reduction varied appreciably with the composition of the ammoniated superphosphate and with the storage conditions.

This study has not produced data which serve to simplify the problem of reversion, rather it raises questions relative to the validity of any explanations which attribute reversion primarily to any one constituent, e. g., formation of  $3[Ca_3(PO_4)_2].CaF_2$ .

**Waste pond phosphate compared with rock phosphate and superphosphate as a fertilizer**, G. W. VOLK. (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 9, pp. 823-829).—Greenhouse and field experiments indicate that superphosphate is far superior to waste pond or rock phosphate as a source of phosphorus for the growth of cotton, sorghum, hairy vetch, and Austrian Winter peas. Waste pond and rock phosphate were found to be about equal in their ability to supply phosphorus for plant growth. Increasing the application of waste pond or rock phosphate from 48 to 384 lb. of  $P_2O_5$  per acre did not result in any appreciable increase in crop yield.

## AGRICULTURAL BOTANY

**Division of Agricultural and Food Chemistry of the American Chemical Society: Abstracts of papers presented at Memphis, Tenn., April 20 to 24, 1942** (*Amer. Chem. Soc. Mtg.*, 103 (1942), *Abs. Papers*, pp. 1A-27A).—The following, of interest to botany, are included: The Effect of Some Minor Element Compounds on the Yield and Mineral Content of Oats, Wheat, and Potatoes, by J. S. McHargue, R. H. Hageman, G. D. Sherman, W. S. Hodgkiss, and E. S. Hodge (pp. 3-4); Zinc in Animal and Plant Nutrition, by E. Hove (pp. 5-6); The Effect of Source on Magnesium Absorption by Tobacco, by T. R. Swanback (pp. 13-14) (Conn. [New Haven] Expt. Sta.); Waxy Maize Starch—A Possible Competitor for Tapioca, by R. M. Hixon and G. F. Sprague (p. 16) (Iowa Sta.); The Structure of Starch and the Mechanism of Its Formation, by W. Z. Hassid and R. M. McCready (pp. 16-17) and Studies on Photosynthesis Using the Radioactive and Stable Isotopes of Carbon, Hydrogen, and Oxygen, by S. Ruben, M. D. Kamen, W. Z. Hassid, M. Randall, and T. H. Norris (pp. 17-18) (both Univ. Calif.); and The Fluorine Content of Certain Plants as Affected by Various Fertilizer Treatments, by W. H. MacIntire, S. H. Winterberg, and J. G. Thompson (p. 21) (Tenn. Sta. et al.).

**Abstracts of dissertations presented by candidates for the degree of doctor of philosophy, autumn quarter, winter quarter, 1941-42** (*Ohio State Univ., Abs. Doctoral Diss.*, No. 38 (1942), pp. VI+286, figs. 35).—The following are of interest to agricultural botany: A Critical Study of the *Avena* Test and Extraction Methods Used in Plant Hormone Investigations and Their Application to Certain Horticultural Problems, by W. P. Judkins (pp. 61-68); The

Effect of Culture Filtrates on Photosynthesis and Respiration in *Ochlorella vulgaris*, by C. A. Swanson (pp. 257-262); and The Formation of Adventitious Roots in *Forsythia suspensa*, *Ribes alpinum*, and *Caragana arborescens*, by J. C. Swartley (pp. 263-268) (coop. Cornell Univ.).

**Proceedings of local branches of the Society of American Bacteriologists** (*Jour. Bact.*, 44 (1942), No. 3, pp. 387-395).—Abstracts of the following papers are included: Some Experiments on the Excretion of Nitrogen Compounds From Legume Roots, by H. G. Myers (p. 388) (Ky. Expt. Sta.); A Study of Certain Factors Which Influence the Apparent Heat Resistance of Bacteria, by F. E. Nelson (p. 389) (Kans. Sta.); Galacturonic Acid, a Constituent of a Bacterial Gum, by C. E. Georgi, W. E. Miltzer, K. B. McCall, and D. A. Bixler (p. 390), and Utilization of Twenty-one Proprietary Peptones by Representative Aerobic and Facultative Bacteria, by M. McMaster and C. E. Georgi (p. 391), (both Univ. Nebr.); The Effect of Gramicidin and Tyrocidine on Various Bacteria, by C. M. Downs (p. 392); and Observations on the Anti-bacterial Action of Surface Active Cations, by E. I. Valko and A. S. DuBois (pp. 394-395).

**Validity of the genus *Alcaligenes***, H. J. CONN. (N. Y. State Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 353-360).—On the basis of evidence presented it is pointed out that the supposed similarity of *A. faecalis* to certain soil bacteria may not actually exist. It is believed that this genus can be retained only if its type species can be recognized, which cannot now be done. At present there are five intestinal inhabitants listed under it which might well make a genus by themselves. The only soil organism now placed here is *A. radiobacter*, which is plainly out of place if the type species is the intestinal organism which requires organic N. For this, the legume bacteria, and the crown gall and related phytopathogenic and saprophytic organisms the name *Igrobacterium* n. gen. is proposed, with *A. tumefaciens* n. comb. as the type species. It is hoped that the new genus will prove a convenient place for some forms which do not fit well into any of the genera recognized in past editions of Bergey's manual (E. S. R., 81, p. 489), and that workers adding species to the genus will include only those types covered by the definition here presented.

**Differentiation of the "intermediate" coli-like bacteria**, R. H. VAUGHN and M. LEVINE. (Iowa State Col. and Univ. Calif.). (*Jour. Bact.*, 44 (1942), No. 4, pp. 487-505).—On statistical bases, two species of intermediate colilike bacteria were recognized under the genus *Escherichia*.

**The status of *Bacillus subtilis*, including a note on the separation of precipitinogens from bacterial spores**, C. LAMANNA. (Oreg. State Col.). (*Jour. Bact.*, 44 (1942), No. 5, pp. 611-617).

**Studies on the luminous bacteria.**—I, Nutritional requirements of some species, with special reference to methionine. II, Some observations on the anaerobic metabolism of facultatively anaerobic species, M. DOUDOROFF. (Univ. Calif.). (*Jour. Bact.*, 44 (1942), No. 4, pp. 451-459, 461-467).—*Photobacterium fischeri*, *P. splendidum*, *P. scpiac*, and *Achromobacter harveyi* were studied in these contributions. There are 25 references.

**Entrance of non-motile bacteria and chemicals into water-soaked tobacco leaves**, S. DIACHUN, W. D. VALLEAU, and E. M. JOHNSON. (Ky. Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 387-388).

**Oxygen demand and oxygen supply**, O. RAHN and G. L. RICHARDSON. (Cornell Univ.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 321-332, figs. 6).—The multiplication rate of most bacteria remains constant only for a few hours because the dissolved O<sub>2</sub> of the medium is soon exhausted; from then on the rate is constant only at the surface where air is available. Experiments permitted the calculation that O<sub>2</sub> does not penetrate deeper than 2 mm., below which facultative

anaerobes multiply more slowly while strict aerobes do not multiply at all but usually decrease. Aeration does not necessarily increase the multiplication rate, but it maintains it constant for a long time and so ensures a much larger bacterial crop. The delayed start of aerated cultures is explained by the assumption that a solution saturated with  $O_2$  is harmful to resting cells whose enzyme mechanism is not working at the rate normal for multiplying cells. An old cell in a new environment establishes a zone of optimum conditions in its immediate vicinity, probably at the expense of reserve materials. If this is constantly disturbed the cell finally dies from exhaustion. The good growth on agar may be due to the prevention of convection currents. There are 14 references.

**Pyridoxine nutrition of lactic acid bacteria**, N. BOHONOS, B. L. HUTCHINGS, and W. H. PETERSON. (Wis. Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 4, pp. 479-485).—*Lactobacillus casei* was shown to store pyridoxine in amounts greater than necessary for growth. Its requirement depended on the  $O_2$  tension of the medium. Three of the six species of lactic acid bacteria studied did not require pyridoxine for growth and acid production, and they were all shown to synthesize the vitamin when cultured on a medium not containing it. The response of *L. casei* to a number of pyridoxine analogs paralleled rather closely the antidermatitic effect of these same compounds on rats.

**The production of active resting cells of streptococci**, A. J. WOOD and I. C. GUNSALUS. (Cornell Univ.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 333-341, figs. 5).—Resting streptococcal cell suspensions of high physiological activity, low endogenous respiration, and fair stability were produced by growth in a well-buffered medium, rich in N and accessory factors and low in carbohydrate, followed by washing in neutral phosphate buffer. Resting suspensions of cells grown under these conditions were shown to possess strong dehydrogenase activity. The cells should be harvested near the logarithmic growth phase from a medium not allowed to become more acid than pH 6.8. Methylene blue was not toxic to resting cell suspensions of group-B streptococci at 1-20,000, which (or less) is therefore satisfactory as a H acceptor in dehydrogenase studies.

**Production of active and inactive catalase by *Proteus vulgaris***, T. L. SWENSON and H. HUMFELD. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 8, pp. 391-403, fig. 1).—From experimental data presented, it is believed that except during the lag phase *P. vulgaris* produces catalase throughout its growth. Two forms, active and activable, are developed, the latter capable of change to the active form by an activator. Kolmer's cholesterolized antigen, used as activator, produced approximately a fourfold increase in active catalase. When a culture was treated with  $O_2$  up to 100 percent, concentrations up to 75 percent induced a progressive increase in catalase production, possibly attributable to the stimulating effect of  $O_2$  on the number of viable cells. No activation occurred at 0° C. up to 60 min., but marked activities took place at 37.5° in 5 min. In explanation of this, a correlation of bacterial activity and rate of activation is suggested. Instability of the enzyme at the higher temperature was indicated by the decrease in activity after 8 min. The activable form could not be extracted by acetone and therefore may be regarded as an integral part of the living cell, i. e., a desmo enzyme. When the viable cells were destroyed, the activable catalase was either destroyed or could not be activated in the absence of viable cells. There are 57 references.

**Thiamine production by *Actinomyces viridochromogenus***, J. A. HERRICK and C. J. ALEXOPOULOS (*Bul. Torrey Bot. Club*, 69 (1942), No. 8, pp. 569-572).—When this organism was grown on an alkaline liquid medium, the cultures were filtered, and the filtrate was acidified and autoclaved, it supported a heavier growth of *Stereum gausapatum* than control media not having supported the

actinomycete. Similar but more pronounced results were obtained when *Phycomyces blakesleeanus* was substituted for *Stercum*. When *P. blakesleeanus* was grown on agar plates previously inoculated with the actinomycete, *Phycomyces* produced a much denser mycelium and a crop of sporangiophores in the vicinity of the actinomycete colony. Since the growth of *P. blakesleeanus* is a recognized assay for thiamin, it is concluded that *A. viridochromogenus* produces this vitamin in culture.

**Bacterial morphology as shown by the electron microscope.**—III, Cell-wall and protoplasm in a strain of *Fusobacterium*, S. MUDD, K. POLEVITZKY, T. F. ANDERSON, and C. C. KAST (*Jour. Bact.*, 44 (1942), No. 3, pp. 361–366, figs. 7).—Continuing the series (E. S. R., 86, p. 300), bacteria are found to be cells with solid cell-wall and fluid or potentially fluid inner protoplasm distinct from the wall. Electron micrographs of cells of a strain of *Fusobacterium* showed striking differences in density within the protoplasm. Correlation of the significance of the differentiations observable by this technic with those seen by microchemical and staining methods is believed to present a challenging problem. There are 13 references.

**A study of *Thiobacillus thiooxidans* with the electron microscope**, W. W. UMBREIT and T. F. ANDERSON. (Univ. Wis. et al.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 317–320, figs. 6).—The cells were found to possess a thin cell wall differentiated from the internal protoplasm and to be differentiated morphologically and cytologically into three categories. The possible physiological interpretations of the observed structures are discussed.

**Selective antibiotic action of various substances of microbial origin**, S. A. WAKSMAN and H. B. WOODRUFF. (N. J. Expt. Stas.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 373–384, fig. 1).—In a comparative study of the bacteriostatic and bactericidal properties of various known substances of microbial origin, their action was compared with that of egg-white lysozyme and different common chemical disinfectants, using different test organisms and media. For example, 3–10 times as much actinomycin or streptothricin was necessary to cause the same inhibition in brain-heart-infusion agar as in nutrient agar, and inhibition by the slightly soluble products of *Bacillus brevis* was more marked in nutrient broth than in the agar media. Striking differences in selective action on bacteria were also observed. Gramicidin was most specific, acting primarily on gram-negative micrococci. Actinomycin, tyrothricin, tyrocidine, purified penicillin, gliotoxin, and the chemical detergent lauryl sulfate acted in low concentrations on gram-positive bacteria and only to a limited extent on gram-negative organisms. Pyocyanase, pyocyanin, and crude penicillin were similar in action over the whole range of test organisms used. Streptothricin was unique in being highly active against certain gram-negative bacteria and having no action against certain gram-positive organisms. On a weight basis, these microbial substances were much stronger bacteriostatic agents than the chemical antiseptics used. Marked differences were also obtained in the selective bactericidal action of the different preparations. Certain substances possessing high bacteriostatic properties were not necessarily also highly bactericidal.

**Relative inhibition of microorganisms by glucose and sucrose sirups**, L. TARKOW, C. R. FELLERS, and A. S. LEVINE. (Mass. Expt. Sta.). (*Jour. Bact.*, 44 (1942), No. 3, pp. 367–372).—The results of a study of the effects of 30, 40, and 50 percent aqueous solutions of glucose, sucrose, and mixtures of the two on *Saccharomyces cerevisiae* and *Aspergillus niger* are presented. In almost all cases the equal part mixture of both sugars yielded results intermediate between those of either sugar alone when used at the same concentration.

**Cultural characteristics of *Penicillium notatum* in relation to the production of antibacterial substance:** Indication of the dual nature of the antibacterial substance, W. KOCHOLATY (*Jour. Bact.*, 44 (1942), No. 4, pp. 469-477, figs. 4).—Among five strains of *P. notatum* tested, at least three—all varying widely in their production of antibacterial substance—seemed to produce two substances differing in antibacterial action. Using optimum (so far as known) conditions, a strain was found to produce an antibacterial substance which in amounts of 0.01 cc. of the crude culture filtrate added to 10 cc. of tryptose agar prevented growth of *Brucella abortus*. The Difference between purified penicillin and the substance found in the crude culture filtrate is discussed with reference to the possibility of the dual nature of the antibacterial material formed by the mold.

**Nutrilite requirements of osmophilic yeasts,** A. G. LOCHHEAD and G. B. LANDERKIN (*Jour. Bact.*, 44 (1942), No. 3, pp. 343-351, figs. 4).—*Zygosaccharomyces* (23 strains of 18 species) was studied with respect to requirements of inositol, biotin, pantothenic acid, thiamin, and pyridoxin, added to a basal solution of inorganic salts and 10 per cent glucose. Biotin proved essential to growth of all, and on their need for pantothenic acid they could be divided into three groups on the basis of its being essential, stimulating, or relatively unimportant.  $\beta$ -Alanine was able to replace pantothenic acid in providing the combined growth factor effect. Inositol was essential for optimum growth of 3 species, and in yeasts not requiring it the combined growth factor effect could be obtained with biotin and pantothenic acid. In some cases thiamin exerted slightly stimulating or depressing effects, and pyridoxin was still less important. Strains previously considered specifically identical on the basis of morphology and fermentative capacity showed good agreement in nutritive requirements, suggesting the value of the latter as a classificatory aid. There are 31 references.

**John Torrey: A story of North American botany,** A. D. RODGERS, III ([Princeton, N. J.]: Princeton Univ. Press; London: Oxford Univ. Press, 1942, pp. XI+352, [pls. 2]).—In the foreword, by S. W. Geiser, it is stated that "John Torrey's life in a sense epitomizes the history of botanical exploration in North America during the last century." This biography is thus a contribution to that history.

**Navajo Indian medical ethnobotany,** L. C. WYMAN and S. K. HARRIS (*N. Mex. Univ. Bul., Anthropol. Ser.*, 3 (1941), No. 5, pp. 76).—Material for this study consisted of over 1,200 plant specimens belonging to 80 families, 286 genera, and 515 species. Each specimen was named and its medicinal uses explained by 1-4 informants. Only plants used in medicine were collected, since others have published lists of plants used for food, dyes, or other economic purposes. The data were obtained by going into the field accompanied by an informant and (where necessary) an interpreter, and recording the names and uses of each specimen. The Navajo plant classification system is discussed in some detail, and the three main parts of the publication comprise, respectively, the Navajo name list, the botanical list, and the uses of the plants considered.

**Taxonomy and phylogeny, I-III,** W. B. TURRILL (*Bot. Rev.*, 8 (1942), Nos. 4, pp. 247-270; 8, pp. 473-532; 10, pp. 655-707).—In this monographic review the author is concerned mainly with the results of botanical studies, with stress on "the general problems of taxonomy and of phylogeny and the actual, supposed, and possible relationships between them." Emphasis is given to such subjects as seem in need of more study or the critical consideration of which might well lead to marked improvement in taxonomy or advance in knowledge of phylogeny or both.

Part 1 is introductory, presenting the scope of the paper, derivations and definitions of terms, and data on the historical development of plant classification. Part 2 considers the taxonomic and phylogenetic concepts and criteria, and data used in classification and phylogenetic studies. Part 3 takes up the classification and phylogeny in the major plant groups from bacteria through monocotyledons. Supplemental matter includes "logical" as opposed to "phylogenetic" classification, phylogenetic diagrams, and general conclusions. "The task of the systematist is twofold: To prepare as many special classifications as are needed for special biological investigations or to make available materials for others to construct such special classifications, and to make a general classification which shall express as far as possible in rational order all that is known concerning plants and animals. This last . . . is an ideal greater than the phylogenetic ideal which is included in it and one which in the process of attempted attainment must make taxonomy what it should be, the focal point of biology." There are 509 references.

**The botanical, erosion control, and economic significance of white poplar in Maryland**, S. GROBER (*Md. Univ. Off. Pub.*, 39 (1942), No. 13, pp. 17-18).—An abstract.

**Cornus sericea L. (C. stolonifera Michx.)**, F. R. FOSBERG. (U. S. D. A.) (*Bul. Torrey Bot. Club*, 69 (1942), No. 8, pp. 583-589).—A taxonomic study of forms centering around this species of dogwood.

**Trends in the development of geographic botany**, H. M. RAUP (*Ann. Assoc. Amer. Geog.*, 32 (1942), No. 4, pp. 319-354).—This paper is concerned not so much with the details of methods as with some trends in what might be called the logical approach to plant geography. The discussions are grouped around the following: Theophrastus to Humboldt—floristic plant geography, Humboldt to Darwin, current trends, the development of geography as a whole, and the nature of plant geography. There are about four pages of references.

**The plant communities of the Welaka area, with special reference to correlations between soils and vegetational succession**, A. M. LAESSLE (*Fla. Univ. Pub., Biol. Sci. Ser.*, 4 (1942), No. 1, pp. 143, pls. 14, figs. 29).—This monographic ecological contribution was made on the University of Florida Conservation Reserve (2,180 acres) in Putnam County. The study involved some 750 plant species. There are nearly two pages of references.

**Biochemical nitrogen fixation studies.—IV, Experiments with excised legume nodules**, F. E. ALLISON, S. R. HOOVER, and F. W. MINOR. (U. S. D. A.) (*Bot. Gaz.*, 104 (1942), No. 1, pp. 63-71).—In further studies of this series (E. S. R., 85, p. 317), using cultures of nodules from sweetclover, cowpea, crown vetch, soybean, and hairy vetch with N fixation determined by three methods, no fixation was observed with whole or crushed nodules in Warburg vessels at 28° C. in various gas mixtures and in a mineral-culture solution containing sucrose, glucose, or mannite. A 1-3 percent increase in N was noted in a few cases where nodules were kept in thin layers of a mannite-glucose medium at 4°-12° for 1-3 days. Pure *Rhizobium* cultures failed to fix N when supplied with oxalacetic acid, and a few tests with excised nodules gave negative or inconclusive results. Furthermore, in 15 series of tests in which many variables were considered, there was no evidence that juices extracted from nodules and sterilized by filter candle passage could fix atmospheric N when incubated in mineral-sugar solutions. There are 15 references.

**Effects of growth substances on reserve starch**, S. C. BAUSOR (*Bot. Gaz.*, 104 (1942), No. 1, pp. 115-121, figs. 8).—Indoleacetic or  $\beta$ -naphthoxyacetic acids in lanolin induced starch depletion in tomato cuttings kept 6 days in darkness in a mineral nutrient containing sucrose; controls still had an abundance. In

media containing maltose, levulose, dextrose, or lactose in place of sucrose, cuttings responded in the same way to the acids, and N-deficient plants also showed starch depletion under similar treatment. Starch was deposited in the root caps of primordia which resulted from treatment. Starch digestion was inhibited in thin sections by aqueous solutions of 0.02 or 0.002 percent indoleacetic acid; in controls starch depletion occurred rapidly. Lower acid concentrations were ineffective. On the other hand, in intact stems 0.02 percent indoleacetic acid in aqueous solution accelerated starch hydrolysis.

**The extraction of auxin from plant tissues, II, K. V. THIMANN, F. SKOOG, and A. C. BYER** (*Amer. Jour. Bot.*, 29 (1942), No. 8, pp. 598-606, figs. 4).—Continuing the series (E. S. R., 85, p. 26), the yield of auxin from *Lemna* and from tobacco leaves was greatly increased by short incubation with chymotrypsin or trypsin, and ficin had a similar but smaller effect. Though yield was greatly decreased by boiling, treatment with proteolytic enzymes raised the yield to that of unboiled material. It is concluded that auxin in green material is bound to protein or a proteinlike substance, and that the effect of boiling is in the main to destroy the enzyme system that liberates it. Prolonged incubation of plant material to allow autogenous enzymes to act is not a practicable method of extraction because of auxin production by bacteria which cannot be completely overcome by adding bactericides. The disadvantages of other methods with various plants are discussed, and suggestions are presented for a simplified procedure which is said to determine the bulk of the total auxin in green plant material with a minimum number of extractions.

**Total auxin extraction from wheat, G. S. AVERY, JR., J. BERGER, and B. SHALUCHA** (*Amer. Jour. Bot.*, 29 (1942), No. 8, pp. 612-616).—Total auxin yields from high and low protein wheats were about the same whether samples were extracted for 45 hr. at 22° C. or for 15 min. at 120°. The highest yields were obtained when extractions were made at pH 9.3-10.5, and lower ones at pH 4, 7, and 11.5 (but more at 11.5 than at 7). Marked auxin destruction from 5 or 6 samples tested occurred on 15-min. autoclaving with 1.0 N NaOH, in contrast to the alkali-stable auxin in corn kernels; thus 70 percent or more of the total auxin is a compound other than indoleacetic acid. Auxin yields were apparently unrelated to protein content. Auxin yields from wheat samples of different protein content differed in size as much as fourfold. The probable presence was established of two precursors which are converted into two auxins on hydrolysis at pH 10.5; they differed markedly in stability in presence of alkali.

**Biochemistry of salt absorption and accumulation by plants with special reference to the role of ether soluble organic acids, E. C. PIERCE** (*Md. Univ. Off. Pub.*, 39 (1942), No. 13, pp. 19-20).—An abstract.

**Effects of platinum chloride on bean and tomato, C. L. HAMNER** (U. S. D. A.). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 161-166, figs. 2).—Beans grown in sand at concentrations of  $15^{-5}$ ,  $9^{-5}$ ,  $3^{-6}$   $H_2PtCl_6 \cdot H_2O$  were inhibited in growth, had smaller leaf area, higher osmotic pressure, and a lower transpiration rate, resisted wilting much longer than controls, and were also less succulent. Beans grown in sand in the dark at concentrations of  $15^{-5}$ ,  $9^{-5}$ ,  $3^{-6}$  were inhibited in stem and hypocotyl elongation. Those grown in soil to which a  $15^{-5}$  concentration was added failed to show any response. Tomatoes grown in sand at concentrations of  $15^{-5}$ ,  $9^{-5}$ , and  $3^{-6}$  were inhibited in growth, had chlorotic lower leaves, and resisted wilting longer than controls. When the cut ends of severed bean or tomato plants were placed in dilute concentration they soon showed symptoms of toxicity and were killed.

**Volatile sulphur content of black mustard plants, S. V. EATON** (*Bot. Gaz.*, 104 (1942), No. 1, pp. 82-89).—*Brassica nigra* leaves contained more volatile S

than the stems; results on roots were inconclusive. The leaves contained more when the plants had been grown in sand with a complete nutrient solution than in soil. S and N are both components of allyl mustard oil. Growing plants in a minus-S nutrient solution caused an almost complete loss of pungency of the leaves. Minus-N leaves were somewhat more pungent than plus-N leaves. Young leaves contained more volatile S than older ones. More pungent were the upper leaves than the lower, and the leaves of plants grown for a short time than those of plants grown a longer time. Tissues of high water content contained less volatile S than those of lower water content. There are 16 references.

**Effect of nutritional levels on the elaboration of rotenone**, R. H. MOORE (P. R. Expt. Sta.). (*Rev. Agr., Indus. y Com., Puerto Rico*, 34 (1942), No. 1, pp. 111-113).—The results of the experiment reported indicate that derris, unlike sugarcane, develops its highest commercial value when growing vigorously, which means that the formation of rotenone and total extractives is favored by ample water and fertilizer.

**The response of *Achras zapota* in latex yield to wounding by the ibidem method of tapping**, J. S. KÄBLING (*Bul. Torrey Bot. Club*, 69 (1942), No. 8, pp. 553-560, figs. 4).—Tapping tests with *A. zapota* (principal source of chicle) in British Honduras involving application of the method ("ibidem") commonly used on *Hevea brasiliensis* indicated a lack of response to the stimulus of wounding. The initial oblique incisions in the cortex drained the latex from an area about 10-14 in. above and below, and daily purings of the lower margin of the incisions within such areas yielded no additional latex. These results indicate that this species cannot be tapped profitably by this method, and that successive incisions in the cortex must be spaced about 14-16 in. apart to secure the maximum yield per tapping. There are 19 references.

**The effects of l-proline on proliferation of cells and differentiation of protoxylem in roots of cotton and bean**, E. S. BARGHOORN, JR. (*Growth*, 6 (1942), No. 1, pp. 23-31).—In cultured cotton seedlings and excised bean root tips, 5/100,000 M and 2/100,000 M concentrations of proline tended to retard root growth in length, whereas 1/100,000 M. had no apparent influence. There was some evidence that this retarding effect is roughly proportional to the molecular concentration of proline in solution. No clear-cut evidence was obtained to show a specific effect of proline on the rate of protoxylem differentiation. Possible traumatic effects in excised roots must be considered in any conclusions drawn from such material.

**Susceptibility of *Colchicum* and *Chlamydomonas* to colchicine**, I. CORNMAN (*Bot. Gaz.*, 104 (1942), No. 1, pp. 50-62, figs. 8).—Excised *Colchicum* roots cultured in small vials proved immune to 1 percent colchicine. Mitosis in excised roots of *C. byzantium* was partly disrupted by 2.5 and entirely blocked by 5 percent colchicine, and in *C. autumnale* it was first disrupted and finally completely blocked by 10 percent. It is concluded that immunity results from an extramitotic protection, not from a difference in the mitotic mechanism. As judged by the reproduction rate, *Chlamydomonas pseudococcus* was resistant to both colchicine and acenaphthene. This immunity was not specific for colchicine and may represent the type of resistance in organisms not naturally containing it. There are 27 references.

**Plant tissue cultures**, P. R. WHITE (In *Annual Review of Biochemistry*, XI, edited by J. M. LUCK and J. H. C. SMITH. (Stanford University, Calif.: Ann. Rev., Inc., 1942, vol. 11, pp. 615-628).—A critical review with 129 references.

**Device for measuring entry of water into roots**, H. E. HAYWARD, W. M. BLAIR, and P. E. SKALING. (U. S. D. A. et al.). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 152-160, figs. 11).—A potometric device for quantitative determination of water

movement in roots is described and illustrated which can be attached to any part of a root. Tests with young corn roots indicated that the rate of entry increases from the zone proximal to the root cap to a point 10 cm. from the root tip. In most cases the rate decreased above this level in roots over 10 cm. long. Lateral entry into older parts of citrus roots proved measurable, and they probably provide the major avenue of entrance during some seasons of the year. The root lenticels may be structures through which water most readily enters older parts of the root.

**Water uptake by excised root systems of the tomato due to non-osmotic forces, J. VAN OVERBEEK** (*Amer. Jour. Bot.*, 29 (1942), No. 8, pp. 677-683, figs. 6).—The osmotic pressure of the exudate of decapitated plants grown in culture solution was considerably lower than that with which the roots absorbed water. The latter pressure (root pressure) was determined as the osmotic pressure of a mannitol solution placed around the roots which reduced the exudation rate exactly to zero. It is concluded that the pressure with which healthy root systems of decapitated tomato plants absorb water is made up of two components—an "active" pressure and a pressure of osmotic origin. Roots kept in distilled water during the test developed an average root pressure of 1.4 atmospheres, of which 71 percent was active pressure and 29 percent pressure of osmotic origin. Roots kept in Hoagland solution during the test absorbed water with an average pressure of 2.68 atmospheres, 48 percent of which was active. The active component of the root pressure could be reversibly eliminated by KCN.

**Chloroplast substance of spinach leaves, C. L. COMAR** (*Ind. Expt. Sta.*). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 122-127).—Preparations of chloroplast substance isolated by fractional centrifugation exhibited less protein contamination than by the methods of flocculation by  $\text{CaCl}_2$  or freezing. The chloroplast substance of spinach leaves contained about 54 percent protein, 34 percent lipid, 5 percent chlorophyll, and 7 percent ash. About 11 percent of the total N was accounted for by chlorophyll. There are 19 references.

**Effect of light quality on growth and mineral nutrition of bean, L. M. ROHRBAUGH** (*Bot. Gaz.*, 104 (1942), No. 1, pp. 133-151, figs. 9).—Using equal amounts of incident energy, the lengths of red kidney bean hypocotyls and first internodes were least in plants receiving light from nearly all parts of the visible spectrum and light from daylight and blue tubes produced very little differences in the plants. Considering only the plants grown under lamps and filters emitting light from rather narrow regions of the spectrum, the effectiveness in inhibiting elongation was greatest in the red and least in the blue regions, and the average leaf area was least in the green and slightly greater in the red than in the blue. Average leaf area and dry weight production were greatest with more balanced radiation. Visible flower buds developed earlier in green than in other light, but many of these buds abscised. No significant differences in total ash or in amount of K or Mg therein were found under the different lamps. The amount of Ca in the leaves was closely correlated with dry weight and was highest with radiation from most of the visible spectrum and lower when narrower regions were used. High Ca content of the leaves was correlated with low Ca content of the stems, and vice versa. The amounts of P in plants under the more balanced light of daylight and pink and blue tubes without filters were almost equal. It was higher in plants receiving no radiation in the blue and in those receiving none from the red end of the spectrum, and still higher when light from both ends was absent. There are 28 references.

**Effects of photoperiod on microsporogenesis in Biloxi soybean, C. S. NIELSEN** (*Bot. Gaz.*, 104 (1942), No. 1, pp. 99-106, figs. 19).—In three experimental series, photoinductive treatments of 2-10 cycles were given consisting of 8 hr. of natural daylight followed by 16 hr. of darkness, after which series 1 and 2 were placed on cycles of long photoperiod (21 hr. light and 3 hr. darkness) and series 3 on cycles of 16 hr. light and 8 hr. darkness. Of the three control types, one group was kept on long photoperiod, none flowering; the other two groups, kept on natural and short photoperiods, respectively, both flowered. In the second and third control groups floral development was normal and meiosis was as described by previous workers. In all the experimental groups the floral structures developed normally until sporocyte differentiation in the anthers had occurred, following which various meiotic abnormalities were observed. With 5 or fewer photoinductive cycles the sporocytes might begin to enlarge, accompanied by marked vacuolization of the cytoplasm and final disintegration of nuclei, and only a few sporocytes attained metaphase in meiosis I. With 6 or more photoinductive cycles of short photoperiod microsporocyte degeneration in some anthers occurred, but in others meiosis was apparently normal and four groups of chromosomes were formed. In some cases degenerative changes occurred at this point before cleavage into microspores, in others cleavage was followed by degeneration before the development of normal microspores, whereas in a very small proportion of cases apparently normal microspores were formed. With even as many as 10 photoinductive cycles of short photoperiod, a high percentage of degenerated microspores were observed. The long postinductive photoperiod used appeared to have played a significant role in inducing the degenerative changes found and in suppressing mature-flower development.

**An analysis of the wood of the three commercial species of white pine, E. B. MATZKE and R. L. HULBARY** (*Bul. Torrey Bot. Club*, 69 (1942), No. 8, pp. 573-582, figs. 5).—In the course of work on lumber, it became necessary to distinguish microscopically between the wood of three species of pine. The pits of the ray parenchyma cells in contact with the tracheids proved to be large and oblong in *Pinus strobus*, somewhat smaller and lemon-shaped in *P. lambertiana*, and intermediate in *P. monticola*. In ray parenchyma pit characters the last species is a little closer to *P. lambertiana* than to *P. strobus*, but in other features, gross and microscopic, *P. monticola* also is intermediate between the other two. The series thus formed on the basis of wood characters coincides with that appearing in the manuals and conforms to the distribution of these three species in nature, though other species undoubtedly also belong in this series.

**Development of the gametophytes and fertilization in Camassia, F. H. SMITH.** (*Oreg. State Col.*). (*Amer. Jour. Bot.*, 29 (1942), No. 8, pp. 657-663, figs. 30).—This paper was prepared to give more extensive descriptions of the development of the gametophytes and of the fertilization processes in *Camassia* and to recommend its use in the classroom in place of *Lilium* to demonstrate the development of the angiosperm gametophyte.

**Microsporogenesis and development of seed in Lobelia cardinalis, G. O. COOPER.** (*Univ. Wis.*). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 72-81, figs. 40).

**Development of the macrogametophyte of Miersia chilensis, M. S. CAVE.** (*Univ. Calif.*). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 185-187, figs. 10).

**Development of the node in Ricinus communis, M. E. REYNOLDS.** (*Univ. Calif.*). (*Bot. Gaz.*, 104 (1942), No. 1, pp. 167-170, figs. 9).

**Development of the pistillate flower and structure of the fruit of tung (Aleurites fordii), L. P. McCANN.** (*U. S. D. A.*). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 8, pp. 361-378, pls. 4, figs. 4).—This study was undertaken to

determine the general morphological and developmental characteristics of the fruit, many particulars of which were hitherto unknown. This information is particularly important as a basis for further studies of the origin of the oil and the nature of its elaboration, and details of the results obtained are presented. The species is commonly monoecious and predominantly synoecious, but trees producing preponderantly staminate or pistillate inflorescences are not uncommon. Pistillate flowers are initiated from late May to late October, and development of the inflorescence is basipetal but that of the individual flowers is acropetal. From setting to maturity, growth of the fruit can be divided into two major periods: (1) Growth in size of structural elements of hulls and seed coats and (2) structural and physiological filling of seeds by growth of endosperm and embryo, the latter initiated about the time maximum size of fruit is attained. Tung fruit is morphologically distinct and not readily allocated to any specific conventional classification such as dry drupe or capsule. There are 29 references.

### GENETICS

Wheat phylesis and wheat breeding from a cytogenetic point of view (cytogenetic indices for the rôle of interspecific hybridization in the origin of wheat species and for applying interspecific hybridization in producing valuable wheat forms), D. KOSTOFF (In *Bibliographia Genetica*. 's Gravenhage (The Hague): Martinus Nijhoff, 1941, vol. 13, No. 2, pp. 149-224, figs. [7]).—In this monograph the genus *Triticum* and allied genera are dealt with, but the principles outlined are said to be successfully applicable to other genera. All wheat species from tetraploid and hexaploid groups studied were found to have originated by chromosome doubling in species hybrids, i. e., they are all allopolyploid species. Cytogenetic investigations show that plant breeding work cannot be successfully carried out when interspecific and intergeneric hybridization is employed without knowledge of the phylogeny of the species and genera crossed, hence cytogenetic and phylogenetic investigations are solid bases on which such breeding work may rest. Knowing the cytogenetic behavior of the  $F_1$  species hybrids, the behavior of their amphidiploids and some other polyploid forms may in many respects be predicted. There are nine pages of references.

Awn inheritance in barley, J. L. MYLER. (Calif. Expt. Sta.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 9, pp. 405-412, fig. 1).—Awn inheritance in Atlas  $\times$  Awnless was found due to the factors  $Lk_1l_1$  and  $Lk_2l_2$ ; long-awned plants carry both dominants, short-awned plants have  $Lk_1$  dominant and  $Lk_2$  recessive, and awnletted plants have  $Lk_1$  recessive and  $Lk_2$  dominant, while plants carrying both recessives are awnless. This two-factor explanation also held true in Black Hull-less  $\times$  Awnless and C. I. No. 5628  $\times$  Awnless. In the two-rowed, long-awned, Redrachis  $\times$  Awnless a two-factor difference with a 15:1 ratio was shown. In Nepal  $\times$  Awnless the varieties differed by three factors for awn development. Nepal carries  $Lk_1Lk_2$  and  $Lk_3Lk_4$  and  $KK$  for hood development. Awnless carries the three recessives. Development of hooded plants requires the presence of both dominant awn factors and the hood factor.  $KK$ , in a few cases, tends to flatten and to cause a bend or twist near the end of the short awns, and also tends to cause a minute fork at the tip of the awnlet of a few central spikelets in awnletted segregates.

The problem of haploidy (cytogenetic studies on *Nicotiana* haploids and their bearings to some other cytogenetic problems), D. KOSTOFF (In *Bibliographia Genetica*. 's Gravenhage (The Hague): Martinus Nijhoff, 1941, vol. 13, No. 1, pp. 148, figs. 40).—In this monograph, haploid *N. langsdorffii*, *N. sylvestris*, *N. rustica*, and *N. triplex* as well as haploids of the type of  $F_1$  hybrids from the

amphidiploids *N. rustica-paniculata*, *N. sylvestris-tomentosiformis*, and *N. glauclandsdorffii* are described. The bibliography covers nearly 14 pages, and an author-subject index is provided.

**Asynaptic Gossypium plants and their polyploids**, J. O. BEASLEY and M. S. BROWN. (Tex. Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 9, pp. 421-427, figs. 3).—An  $F_2$  progeny of American upland (*G. hirsutum*)  $\times$  sea-island (*G. barbadense*) cotton included sterile asynaptic plants in a ratio of 15 fertile:1 sterile. The fertile plants at first metaphase had the normal 26 pairs of chromosomes, while asynaptic plants averaged from 6 to 12 pairs. Doubling chromosome number by colchicine treatment of grafts of sterile asynaptic plants failed to restore normal chromosome pairing and fertility.

**Chromosome degeneration in relation to growth and hybrid vigor**, D. F. JONES. (Conn. [New Haven] Expt. Sta.). (*Natl. Acad. Sci. Proc.*, 28 (1942), No. 2, pp. 38-44).—This is a discussion of underlying principles and theoretical aspects.

**Studies on the cytology of Vaccinium species**, G. M. DARROW, W. H. CAMP, H. E. FISCHER, and H. DERMEN. (U. S. D. A. et al.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 187-188).—Information is presented on the chromosome complements of a large number of blueberry seedlings. In general, the tetraploid species were taller and more vigorous, had larger leaves, flowers, and berries, and suckered less freely than diploids. No triploids were discovered. A vigorous pentaploid, similar to *V. amoenum*, was collected in the wild in southeastern Georgia. Pentaploids were easily produced by crossing the tetraploid *V. australe* with the hexaploid *V. ashei*. Apparently species with the same number of chromosomes hybridize easily in nature.

**Colchicine induced univalents in diploid Antirrhinum majus L.**, A. H. SPARROW (*Science*, 96 (1942), No. 2494, pp. 363-364).

**Colchicine-induced tetraploidy in Oenothera**, A. HECHT (*Ind. Acad. Sci. Proc.*, 51 (1941), pp. 87-93, figs. 8).—Tetraploids were obtained on about 14 races and hybrids following colchicine treatment of the germinating seeds. They differed from the diploids in general enlargement of all parts and in several other characters peculiar to the individual species. Whereas pollen grains from diploid *Oenothera* are three-lobed, many of those from corresponding tetraploids were at least four-lobed. If the diploid configuration is a circle of four chromosomes that of the tetraploid tends to be a circle of eight, but not all cells form circles as large as this. The bivalents tend to become tetravalents, but some of the associations of four fail to do so. The evolutionary significance of polyploidy in *Oenothera* is briefly discussed.

**Breeding new tetraploid grape varieties**, H. P. OLMO. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 225-227).—A study of various tetraploid grapes showed that most of these varieties have certain defects, such as poor growth, irregular setting of fruit, and low yields. Because of the inconsistent behavior of tetraploids, some being satisfactory and others not, the author concludes that it is impossible to predict the effects of doubling the chromosomes of a given variety. The particular genotype of the original variety appears to determine the behavior of the new tetraploids more than the simple doubling of the chromosomes. Crosses between the tetraploid Muscat of Alexandria and a tetraploid Sultanina yielded three seedlings, two of which were pentaploid and one triploid. A later cross of the same two tetraploids yielded 10 tetraploids with a range in chromosomes of  $76$  to  $76 \pm 4$ , and with material differences in growth habit and fertility.

**[Genetic studies with violets by the Vermont Station]**. (*Vermont Sta. Bul.* 495 (1942), pp. 27-28).—Progress reports are presented on studies by A.

Gershoy of polyploidy in violets, fertility relations among violet species, effect of colchicine treatments, and pollen tube development in the violet.

**Breeding and improvement of farm animals**, V. A. RICE (*New York and London: McGraw-Hill Book Co., 1942, 3. ed., pp. XX-750, figs. 213*).—This book (E. S. R., 72, p. 311) has been enlarged and revised into four sections. In section 1 the present status of animal breeding is given with the origin of both man and animals and the broader aspects of the evolutionary process. Section 2 deals with the mechanisms of reproduction in animals from the theoretical and practical standpoint, with the addition of chapters on the endocrine basis of reproduction and lactation and artificial insemination, by F. N. Andrews. Section 3 is devoted to the mechanisms of heredity and brings into use genetic principles. In section 4 the application of genetic principles to practice in the breeding of livestock is described.

**Hydrocephalus, a lethal in cattle**, C. L. COLE and L. A. MOORE. (Mich. Expt. Sta.). (*Jour. Agr. Res. [U. S.], 65 (1942), No. 10, pp. 483-491, figs. 5*).—Among 27 calves produced in matings of their sire to his daughters there were 5 lethals manifesting an internal hydrocephalus and several cases of asymmetry. Abnormalities of the skull and malformations of the humeri and femurs of the lethal animals were also noted. In this group there were 2 with a marked lack of muscular coordination and control. The three conditions are thought to be recessive and nonlinked. The probability that a single sire would carry the three rare genes seems very small.

[**Breeding and cross-breeding studies with chickens and turkeys by the North Carolina Station**] (*North Carolina Sta. Rpt. 1941, pp. 56-58, figs. 3*).—Results are briefly given on the development of Barred Plymouth Rocks and Rhode Island Reds of superior growing and breeding quality; superiority of crossbreds between the several breeds and purebreds of the Barred Plymouth Rock, New Hampshire, and White Leghorn for egg and broiler production; and improvement of turkey families for laying and viability.

**Breeding Rhode Island Reds for rapid feathering**, F. A. HAYS and R. SANBORN (*Massachusetts Sta. Bul. 396 (1942), pp. 24, pls. 6*).—Over 30,000 chicks bred in three lines in 10 generations were examined at 8 weeks of age as follows: (1) Complete back feathering at 8 weeks; (2) absence of back feathering at 8 weeks; and (3) control line selected for high fecundity regardless of rate of feathering. There appeared to be an important relationship between the recessive sex-linked gene *sl* for rapid feathering and the development of tail feathers at 12 days of age and the degree of feathering over the back at 8 weeks of age. A dominant autosomal gene *X* seemed to exert a cumulative effect with *sl* to produce complete feathering over the back at 8 weeks of age, and essentially eliminated sex-dimorphism in the rate of feathering in the rapid feathering stock of Rhode Island Reds selected for several generations. No relation was found between the rate of feathering and egg production. In nine feather tracts, it was noted that head, leg, and abdomen were slowest to complete feather development. The most rapid feathering occurred in the shoulder and thigh regions in which feather development was completed at rather early ages. The relation of tail feathering at 12 days and back feathering at 8 weeks was ascertained for birds of the different genotypes. Illustrations are presented to show the feathering of chicks of different genotypes at 12 days and 4 and 8 weeks of age.

**Hereditary chondrodystrophy in the fowl**, W. F. LAMOREUX. (Cornell Univ.). (*Jour. Hered., 33 (1942), No. 8, pp. 275-283, figs. 4*).—Among 1,713 chicks from heterozygous parents there occurred 22.5 percent chondrodystrophic progeny which seemed little affected by the change of seasons. The condition behaved as a simple autosomal recessive factor, with the symbol *ch* suggested. Sex

did not seem to cause a significant difference in the occurrence of chondrodystrophy. In its expression it ranged from normal to birds with short curved beaks and shortened and bent tibiae and tarso-metatarsi. The viability was low. The occurrence of the condition was attributed to descendants of a single ♂.

**Form and function in Frizzle fowl: The interaction of hereditary potentialities and environmental temperature,** W. LANDAUER. ([Conn.] Storrs Expt. Sta.). (In *Biological Symposia*, VI, edited by J. CATTELL. Lancaster, Pa.: Jacques Cattell Press, 1942, vol. 6, pp. 127-166, figs. 27).—The reactions of the Frizzle fowl to temperature variations are presented much as in a previous publication (E. S. R., 75, p. 764).

**On the topping of combs in White Leghorn females,** C. D. MUELLER and F. B. HURT. (Cornell Univ.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 430-436, fig. 1).—In four strains of Single-Comb White Leghorns, involving 6,625 pullets having lopped combs, 73 percent showed a tendency to lop to the right, but there was no relation to age, body weight, viability, or number of eggs laid to 500 days. Although differences were shown in different years, 5.3 percent having erect combs tended to be inferior to their lopped-comb sisters.

**The developmental mechanics or hereditary abnormalities in the chick,** V. HAMBURGER (In *Biological Symposia*, VI, edited by J. CATTELL. Lancaster, Pa.: Jacques Cattell Press, 1942, vol. 6, pp. 311-336, pls. 2, figs. 4).—Embryonic development of the creeper fowl (E. S. R., 85, p. 605) is described for homozygous creepers which die on the third or fourth day of incubation, homozygous creepers which survive, and heterozygotes. Limb transplantations were made between these classes and with normals. All from the heterozygous embryos showed symptoms characteristic of chondrodystrophy. Transplants from homozygous donors developed all characteristics of phocomelia, and some were viable. In creepers there was shown to be an effect on early yolk sac circulation, disturbance of ossification, and eye abnormalities, resulting from disturbances of the head mesoderm and effects on growth. The creeper gene was complex and needed the combined interpretation of the geneticist, embryologist, and physiologist.

**Further progress with artificial selection,** H. D. GOODALE (*Amer. Nat.*, 76 (1942), No. 766, pp. 515-519).—The author describes progress made in the development of four stocks of mice with different amounts of white. All were descended from five foundation animals previously noted (E. S. R., 78, p. 610). One stock was characterized by a few white hairs and continued by random breeding. In another stock the few white hairs were eliminated. The third and fourth stocks were selected for total white, but no progress seemed to have been made for the appearance of white in exact locations. Under wild conditions these stocks might constitute new species or subspecies.

**An aberrant ratio in *Peromyscus*,** R. R. HUERTES and V. PIESTRAK (*Jour. Hered.*, 33 (1942), No. 8, pp. 289-291).—Significant deviations in the ratios of silver flexed tail mice occurred in the  $F_2$  of crosses involving these genes with the normal. The situation was considered to result from differential viability with some overlapping of the flexed tail class with wild type and linkage between silver and flexed tail genes. In the  $\chi^2$  test  $P$  was less than 0.001. The greatest deviation was 1 in the double recessive class when 67 were expected among over 1,000  $F_2$ s.

**The physiological genetics of coat color of the guinea pig,** S. WRIGHT (In *Biological Symposia*, VI, edited by J. CATTELL. Lancaster, Pa.: Jacques Cattell Press, 1942, vol. 6, pp. 337-355, figs. 3).—There seems no logical limit to the degree of complexity of organization which may arise in an orderly way in the embryo of a largely contained system. An example showing this is taken from the color factors in the guinea pig (E. S. R., 76, p. 775).

**A case of parallel embryonic development in the rat and its bearing on the question of superfetation, C. K. WEICHERT** (*Anat. Rec.*, 83 (1942), No. 4, pp. 511-519, pl. 1).—There is described the parallel development of two sets of embryos in a ♀ rat suckling nine young and inseminated during the post-partum oestrus. Only one ovulation had occurred, but the embryos were 4.5 days apart.

**Studies on experimental teat and mammary development and lactation in the goat, S. J. FOLLEY, H. M. S. WATSON, and A. C. BOTTOMLEY** (*Jour. Dairy Res.* [London], 12 (1941), No. 3, pp. 241-264, pl. 1, figs. 12).—Teat growth in five castrated and three normal goats was shown to be isometric relative to the general body growth, thus indicating that the testes were not responsible for maintaining isometric growth of the teats as in the guinea pig (*E. S. R.*, 80, p. 753). Oestrogen administration either from the natural or synthetic material caused the teats to grow allometrically even at 41 days of age in virgin ♀s. Teat growth ceased during rutting. Application of diethylstilboestrol or its dipropionate by inunction caused an increase in udder growth and artificial lactation. Photomicrographs of the mammary glands are presented.

**Mammogen and unilateral mammary gland growth in the rabbit, A. A. LEWIS and C. W. TURNER** (*Mo. Expt. Sta.*). (*Endocrinology*, 30 (1942), No. 6, pp. 985-989).—Percutaneous treatment with oestrone dissolved in olive oil of mammary glands and teats of ♂ rabbits after shaving the hair showed that oestrogen seemed to possess characteristics and properties not present in skin irritants such as turpentine. It was noted, however, that these irritants caused local subcutaneous hyperemia.

**Studies concerning the mechanism controlling the initiation of lactation at parturition, I-IV, J. MEITES and C. W. TURNER** (*Mo. Expt. Sta.*). (*Endocrinology*, 30 (1942), No. 5, pp. 711-733, fig. 1; 31 (1942), No. 3, pp. 340-344, fig. 1).—Four studies in this series are presented.

**I. Can estrogen suppress the lactogenic hormone of the pituitary?** (pp. 711-718).—The amounts of lactogenic hormone in the pituitary of lactating rats were not decreased by the daily administration of 2 mg. of diethylstilboestrol or testosterone propionate for 6 days, although 38 and 11 percent, respectively, of the young died during the first week after birth. The lactogen content of the pituitaries of ♂ guinea pigs was increased in spite of the administration of 100 mg. of diethylstilboestrol per day for 10 days. Decreases in milk production are thought due to a decrease in the other pituitary hormones.

**II. Why lactation is not initiated during pregnancy** (pp. 719-725).—Study of the lactogen content of the pituitaries of immature ♀ guinea pigs showed that 5 days' administration of 25-200 I. U. of oestrone caused increases of 11-112 percent in the lactogen production. No increase was produced by progesterone alone or with oestrone, and there was indication of inhibition in lactogen production. Progesterone is considered to explain the failure of lactation during pregnancy.

**III. Can estrogen account for the precipitous increase in the lactogen content of the pituitary following parturition?** (pp. 726-733).—The subcutaneous injection of ♂ guinea pigs with 0.3 mg. of oestrone over periods of 1-30 days showed that oestrogen was capable of exerting a remarkably quick stimulus on lactogen production of the pituitary. This mechanism is considered responsible for milk secretion in the rat, guinea pig, and rabbit 2-5 days post partum. The study was carried out with 40 ♂ guinea pigs, divided in groups of 5 each, receiving the same total amounts of oestrone over different periods. The increases after 10 days were not significant. Studies with 4 rabbits showed that there was an increase in the lactogen content of the pituitary 5 days after hysterectomy on the twentieth

day of gestation, further supporting the role of progesterone inhibiting the lactogen production by the pituitary.

IV. *Influence of suckling on lactogen content of pituitary of postpartum rabbits* (pp. 340-344).—The act of nursing in the rabbit seemed to stimulate milk secretion and the lactogen content of the pituitary. The study was conducted with 72 New Zealand White rabbits, one half of which were allowed to suckle their litters after birth, and the litters of the others were removed immediately. Considerably more secretion was found in the mammary glands of rabbits allowed to suckle their young than was present in does from which the young were removed at birth.

**Lactogenic hormone content of anterior pituitary gland of albino mouse as compared to other species**, V. HURST and C. W. TURNER. (Mo. Expt. Sta.). (*Endocrinology*, 31 (1942), No. 3, pp. 334-339, figs. 2).—The lactogen content of the pituitary glands of ♀ mice assayed in pigeons was relatively low in the virgin animal, but increased 88 percent by the tenth day of pregnancy with an additional 63 percent after parturition. By the fifth day post partum the peak lactogen content was reached, with a decline thereafter. The curve for lactogen content of the pituitary followed in general the results from other species. The pituitary lactogen content per unit weight was not altered by ovariectomy or thyroxin injections administered alone.

**Selection of nipples by suckling rats and its effect upon mammary system**, C. K. WEICHERT (*Endocrinology*, 31 (1942), No. 3, pp. 349-353, figs. 3).—Observations on suckling in 67 lactating rats with litters of 1-6 showed a tendency to select the nipples in the anterior-posterior sequence, with the smaller litters confining themselves to the anterior pectoral region. Mammary tissue of neglected nipples retrogressed.

**Progesterone-like activity of some steroid compounds and of diethylstilbestrol in stimulating mammary lobule-alveolar growth**, J. P. MIXNER and C. W. TURNER. (Mo. Expt. Sta.). (*Endocrinology*, 30 (1942), No. 5, pp. 706-710, fig. 1).—The lobule-alveolar responses of ovariectomized virgin mice, using progesterone as a standard according to the technique recently developed (E. S. R., 86, p. 671), showed that when injected with oestrone pregnenolone had an activity of approximately one-half, desoxycorticosterone acetate and dehydroandrosterone of one-third, diethylstilbestrol of one-fourth, acetoxypregnenolone of one-sixteenth, and methyl testosterone of one twenty-fifth that of progesterone. Testosterone and testosterone propionate failed to stimulate lobule-alveolar growth when administered in doses of 10 mg. There were employed for each dose level from 2 to 12 animals.

**Influence of thyroxine upon mammary lobule-alveolar growth**, J. P. MIXNER and C. W. TURNER. (Mo. Expt. Sta.). (*Endocrinology*, 31 (1942), No. 3, pp. 345-348).—The percentage of castrate ♀ mice responding with lobule alveolar growth to progesterone and oestrone administration was significantly increased with optimum doses of thyroxin. On the other hand, thyroidectomy inhibited these responses.

**Effects of purified pituitary preparations on the nonprotein nitrogen constituents of blood**, J. and H. FRAENKEL-CONRAT and H. M. EVANS. (Univ. Calif. et al.). (*Amer. Jour. Physiol.*, 137 (1942), No. 1, pp. 200-212).—Studies of the changes in the blood composition of about 650 normal and 120 hypophysectomized rats resulting from purified hormone injections indicated that thyrotropic hormone lowered blood urea directly as well as through stimulation of the thyroid, and controlled the amino acid level by direct action. The decrease in blood urea appeared due to a decreased production of urea in the liver. The

changes produced by the pituitary hormones on the blood nonprotein nitrogen of normal and operated animals are summarized.

**Premature expulsion of eggs by hens following injection of whole posterior pituitary preparations**, W. H. BURROWS and T. C. BYERLY. (U. S. D. A.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 416-421).—Studies of premature expulsion of eggs from hens following injection of pituitary preparations by different routes (E. S. R., 54, p. 510) are reported. Intravenous injection of obstetrical pituitrin caused premature expulsion of the eggs in about 3 min. after they had entered the uterus but not at higher oviducal levels. Administration by intravenous means was about 10 times as effective as subcutaneous, intramuscular, or intraperitoneal routes. The expulsion of soft-shelled eggs required greater dosages than hard-shelled eggs.

**Experiments on the source of ovarian androgen in the mouse**, C. A. PFEIFFER and C. W. HOOKER (*Anat. Rec.*, 83 (1942), No. 4, pp. 543-571, pls. 2).—When ♂ mice were castrated and litter mate ovaries grafted in the ears with daily treatment with pregnant mare serum, there was distinct stimulation of the seminal vesicles, but no such androgenic effects followed injection with pregnancy urine, pituitary powder, follicle stimulating hormone, luteinizing hormone, progesterone, or smaller amounts of the pregnant mare serum. The androgen is thought to be secreted by vacuolated epithelioid cells derived from the old corpus luteum. The possibility is discussed that two factors may be involved—one in the formation of the granular cells, and another causing the vacuolation. In the conduct of the study 59 ♂s were castrated, and there were administered various gonadotropins with studies of the effects of androgens on the seminal vesicles.

**Effect of testosterone propionate on spermatogenesis in hypophysectomized rats following the injection of gonadotropins**, J. H. LEENTHEM (*Anat. Rec.*, 83 (1942), No. 4, pp. 579-585, pl. 1).—Spermatogenesis was maintained for 30-35 days in hypophysectomized rats by testosterone propionate administrations. Testes weight was maintained in the androgen-treated rats, and many spermatozoa were present in the epididymides. Normal litters were sired by two hypophysectomized ♂s treated for 30 days with androgen injections.

**Changing concepts of the antisterility vitamin (vitamin E)**, K. E. MASON (*Yale Jour. Biol. and Med.*, 14 (1942), No. 6, pp. 605-617, pl. 1).—The role of vitamin E and its synthetic product, the tocopherols, in the prevention of sterility and muscular dystrophy is noted in different classes of animals.

**On the sex ratio in cattle**, J. W. GOWEN. (Iowa and Maine Expt. Stas.) (*Jour. Hered.*, 33 (1942), No. 8, pp. 299-301, fig. 1).—In 3,559 cattle births there were 1,799 ♂s and 1,760 ♀s. Within sires' and dams' progeny and the effect of age the distribution of sexes was essentially at random.

**Albinism in the Virginia deer**, H. B. KELLOGG, JR. (*Jour. Hered.*, 33 (1942), No. 8, pp. 274, 284, fig. 1).—A note is given of a true albino Virginia deer found in Wisconsin.

**The decline in annual egg production with age**, D. V. ZANDER, I. M. LERNER, and L. W. TAYLOR. (Univ. Calif.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 455-461, fig. 1).—Data on 3 years' egg production pauses and persistency of 117 Single-Comb White Leghorns were analyzed statistically. These data showed general declines in the several components of egg production, all of which seemed to indicate that this decline as age advanced was not due to oocyte exhaustion but rather to the effects of senescence, as expressed by these component factors of annual production, and noted by Brody et al. (E. S. R., 50, p. 577). The major factor in the reduction in variance was accounted for by shortening of the length of the laying year with the decline in the rate, making a small but significant contribution to the decrease.

**A "slide rule" for determining time intervals, D. MACLAURY.** (Ky. Expt. Sta.). (*Poultry Sci.*, 21 (1942), No. 5, pp. 462-463, fig. 1).—An ingenious slide rule method for indicating age at first egg, age at death, and other time intervals is illustrated and described.

### FIELD CROPS

[Field crops research in North Carolina, 1941]. (Partly coop. U. S. D. A. et al.). (*North Carolina Sta. Rpt.* 1941, pp. 14-21, 22-27, 28-31, 32-38, figs. 10).—Progress reports are made on experimentation (E. S. R., 86, p. 33) concerned with production of their own hybrid corn seed by farmers; superiority of locally developed corn hybrids; poor adaptation of Corn Belt hybrids; increase of quality of table corn by sweet corn hybrids; increase of corn yields by turning under legumes; increase of cotton quality in North Carolina; improvements in yield and quality by recent developments in cotton breeding; breeding cotton for strength; variation of fiber diameter in improved varieties of cotton; influence of water relations within the cotton plant on fiber quality; number of cotton fibers as determined by growing conditions at blooming; importance of seed purity in all new cotton varieties; disease-resistant varieties as the best control for cotton wilt; obtaining more cotton seedlings from reginned and acid-delinted seed; search for more effective materials for treating cottonseed; K needs of cotton in rotation with peanuts; the value of lime and P in improving quantity and quality of feed and in increasing carrying capacity of pastures; stressing of better soil fertility in cooperative pasture demonstrations; profitable pasture improvement in Franklin County; lespedeza as a crop to precede grasses on poor land; better grassland plants for North Carolina; Ladino clover as a promising legume in lower coastal plain pastures; improvement of carpet grass pastures by disking and legumes; small grains as good grazing crops; a wide variety of grazing crops used in the coastal plain; feeding of soybean silage to heifers; B as essential for good production of alfalfa; control of leafhopper on alfalfa by delayed cutting; cutting sericea lespedeza at correct time for good hay; need of red clover for lime, P, and K; nutrient deficiency symptoms in peanuts; response of peanuts to lime and K; peanuts as a soil-depleting crop; increase in peanut yield due to early planting and seed inoculation; yield differences among peanut varieties and strains; varieties of soybeans for seed; low small grain yields resulting from poor cultural and fertility practices; value of applying P to small grains in western North Carolina; Sunrise, a new winter barley for North Carolina; release of oats resistant to cold and disease to North Carolina farmers; development of rust-resistant wheats; introduction of new varieties of flue-cured tobacco; gains in tobacco quality and yield as due to fertilizer placement, more K, and rye cover crop; poorer root growth of tobacco on extremely acid soils; need for less fertilizer on tobacco plant beds; controlling weeds and disease in tobacco plant beds; rotations as factors in control of tobacco root diseases; and *Fusarium* wilt of sweetpotato as also attacking tobacco.

[Crops for wartime farming] (*West Virginia Sta. Cir.* WS 1 (1942), pp. [8]; WS 2, pp. [8], fig. 1; WS 3, pp. [8], figs. 3; WS 4, pp. [8], fig. 1; WS 9, pp. [8], figs. 7).—The circulars in this group are entitled Plant Hybrid Corn for Victory, for Profit, by E. J. Wellhausen; Supplementary Pastures, by F. W. Schaller and H. O. Henderson; Soybeans, by R. O. Weibel; Grass Silage for West Virginia, by H. O. Henderson, E. A. Livesay, and A. H. VanLandingham; and Winter Barley, by R. O. Weibel. Practical information is given on varieties, cultural methods, and management and harvesting practices.

**Pastures for the Coastal Plain of Georgia, J. L. STEPHENS.** (Coop. U. S. D. A.). (*Georgia Coastal Plain Sta. Bul.* 27 (1942), pp. 57, pl. 1, figs. 3).—

**Methods for establishing lowland and upland permanent and winter and summer pastures** are outlined; the merits and adaptations of native and introduced grasses, lespedezas, clovers, bur-clovers, and kudzu are set forth; and seed mixtures are indicated for different situations. The information is based largely on studies in grass nurseries and grazing tests on lowland (mainly Plummer sandy loam) and upland (Norfolk and Tifton sandy loams) soils.

For lowland permanent pasture, a seed mixture of carpet grass 10 lb., Dallis grass 8, common lespedeza 12, and white clover 5 lb. is recommended. In fertilizer tests on lowland pasture such a mixture gave the highest gain in beef per acre on a 6-12-6 complete fertilizer. Growth of white clover and lespedeza was best on pastures receiving P fertilizer. On lowland pastures gains in beef per acre were most rapid in early spring and diminished soon in late summer, which indicated the desirability for supplemental summer temporary pastures. The ratio of grass yield to beef gains has varied with different fertilizer treatments.

Kudzu has given excellent gain in beef per acre when grazed continuously throughout the summer if not overgrazed. Best results have been obtained on heavy type soils when stable manure (1-2 gal. per hill) was used at the time of setting out the crowns. The growth of kudzu after 5 or 6 yr. of grazing could be invigorated by applying from 2 to 5 tons per acre of manure during winter, then in late February, when crowns are ordinarily planted, the field plowed deeply with a two-horse turn plow.

For upland pasture, Bermuda grass and common lespedeza have given best gains. New selections of Bermuda grass, e. g., "Tift" Bermuda, are upright in growth and heavy yielders, promising for hay when fertilized or for grazing. Maintenance of Bermuda grass pasture by breaking with a turn plow at intervals about every 3 yr. appeared to be very important. Centipede grass has not provided satisfactory grazing even when fertilized. Oats, mixed with hairy vetch, has given highest beef gains on winter temporary pastures, and oats or Abruzzi rye also have been good winter temporary pastures. The best summer temporary pastures tested were cattail millet, lespedeza, and soybeans. In fertilizer tests Bermuda, carpet, and centipede grasses responded most to N on semiupland soils previously in cultivation, but the maximum yield came from complete fertilizer. Pastures on soils never in cultivation have responded well to P, especially when legumes were included in the seed mixture. From 400 to 600 lb. per acre of 6-12-6 fertilizer on carpet grass have given most economical increase in yield. Application of all fertilizer in spring gave the best distribution of grass growth through the summer and also gave a greater total yield of grass than split applications.

**1939 and 1940 reports of the uniform alfalfa nurseries, H. L. WESTOVER and H. M. TYSDALE.** (Coop. 41 expt. stas.). (*U. S. Dept. Agr., Bur. Plant Indus., 1940, pp. [3]+59; 1941, pp. [2]+27*).—Resembling previous reports (E. S. R., 82, p. 177) in general scope, these publications give detailed data on characters of alfalfa strains concerned with forage and seed yields, disease resistance, and stand longevity, as well as on various growth characteristics as reported from stations in 31 States and one Canadian Province in 1939 and in 29 States and one Province in 1940.

**Smooth bromegrass in Missouri, E. M. BROWN.** (Coop. U. S. D. A.). (*Missouri Sta. Cir. 243 (1942), pp. [2]*).—Brief recommendations are made on soils, choice of strains, seeds mixtures, companion crops, seedbed preparation, and planting practices involved in growing smooth bromegrass (*Bromus inermis*) for hay, pasture, and seed in Missouri.

**Yields of corn hybrids harvested for silage, and methods to determine best time to harvest.** W. B. NEVENS and G. H. DUNGAN (*Illinois Sta. Bul.* 494, (1942), pp. 385-412, figs. 2).—Yields of hybrid corn for silage were compared with those of open-pollinated corn, and certain Illinois hybrids were compared for silage with commercial hybrids at the station 1935-41. Hybrid corn surpassed open-pollinated corn in quantity and quality of forage produced. The Illinois hybrids and commercial hybrids were equally satisfactory for silage purposes, and both were superior to the open-pollinated variety used for comparison.

Station Yellow Dent, an open-pollinated variety found in previous trials to be high yielding for both grain and forage and used as the check entry from 1935-39, had a lower percentage of ears and fewer tons of dry matter than most of the hybrids. It showed more lodging, and this probably was partly responsible for the lower yields and a smaller percentage of ears than the hybrids. Most of the Illinois hybrids tested proved satisfactory for silage purposes, their performance in terms of yields of dry matter, percentage of ears, and lodging resistance usually equaling or surpassing that of Station Yellow Dent and of Funk Hybrid G-94, the commercial hybrid used as a check entry 1940-41. Only a few Illinois hybrids were considerably below average in performance, and their lower ratings were due largely to poor adaptability to the region where they were grown and in a few instances to their tendency to lodge. The best Illinois hybrids for use as silage in central Illinois, according to these tests, are Illinois Hybrids 206, 442, and 863. Ratings of hybrids for adaptability to different sections of Illinois, for yields of forage for silage, and for yields of grain are tabulated.

When the corn crops in this study contained about 30 percent dry matter (a suitable silage-harvest stage), the ears contained from 40 to 50 percent and the stalks about 20 percent. Since the leaves had about the same percentage as the entire crop, the suggestion was that the dry matter content of the leaves can be used with nearly as good results as the dry matter content of the entire crop, as an index to the best harvesting time for silage. Earlier recommendations of the station were confirmed by these trials, i. e., a dry matter content of 30 percent in the corn crop is a good stage for silage harvest. Kinds of corn which usually mature the grain should be chosen for silage purposes. Practical directions for finding dry matter content are outlined.

**Leoti for starch.** R. L. CUSHING (*Nebraska Sta. Cir.* 69 (1942), pp. [41]).—Leoti sorgho, a popular sorghum giving satisfactory yields in most parts of Nebraska and also suitable for sirup, has a waxy endosperm found to produce starch with properties similar to those of tapioca starch. Experimental data indicate that on the average, Leoti may be expected to yield about 70 percent as much as Early Kalo, the most widely used grain sorghum variety in Nebraska, while in areas where sorghums are best adapted, particularly in the central and south-central area, Leoti may be expected to compare favorably with corn in grain yield. Cultural practices and harvesting methods permitting saving of the grain and utilizing the forage efficiently are set forth briefly. Suggestions on how to produce Leoti grain for the starch industry call for planting only seed proved by chemical test to have pure waxy endosperm, avoiding cross-pollination by other sorghums, and treating sorghum seed for control of kernel smut.

The station recommendation is that "if a farmer is planning to grow some forage sorghum anyway, he might plant suitable seed of Leoti. In this way he will be satisfying his forage requirements and should also have some grain to sell, should the market materialize. At the present time, no expansion of the Leoti acreage is encouraged solely for the production of grain."

**Gibson and Patoka soybeans**, G. H. CUTLER and A. H. PROBST. (Coop. U. S. D. A.). (*Indiana Sta. Cir.* 270 (1942), pp. 8, figs. 8).—Gibson is a new yellow-seeded variety selected from Dunfield × Midwest and Patoka a pure line yellow-seeded selection from P. I. 70218-2. Data are given on their adaptations, agronomic and chemical characteristics, and yields in comparison with standard varieties. Gibson, ripening in about 145 days, and Patoka, in from 138 to 141 days, are later than the available standard yellow-seeded varieties, as Dunfield, Illini, Manchu, Mandell, and Richland, give higher yields of better-quality grain, and are generally better adapted to the important soybean producing area of southern and southwestern Indiana. These two varieties have compared favorably with Kingwa in tonnage but do not produce hay of as fine quality.

**Las habichuelas soya, un nuevo cultivo para Puerto Rico** [Soybeans, a new crop for Puerto Rico] (*Agr. Expt. [Puerto Rico Univ. Sta.]*, 2 (1942), No. 4, pp. [12], figs. 9).—Practical information on growing soybeans in Puerto Rico, based in part on experiments by the station, deals with varieties; cultural and harvest practices; value of soybeans as food, feed, and forage and green manure, and for industrial purposes; and composition of soybeans compared with other legumes and cereals. Productive adapted varieties include Mammoth Yellow, U. S. D. A. 82284, Tokio, Arisoy, Biloxi, Pee Dee, Ootootan, Clemson, Avoyelles, Macoupin, Richland, and Palmetto, and the edible types Easycook and Rokusum. Recipes for edible soybeans (E. S. R., 87, p. 740) are included.

**Results of seed tests for 1942**, B. G. SANBORN (*New Hampshire Sta. Bul.* 341 (1942), pp. [1]+11).—Germination and purity percentages are tabulated for 298 official samples of field and forage crop seed collected from dealers in New Hampshire during the year ended June 30, 1942.

**Coco or nut grass can be eliminated by persistence with plow, hoe, cultivator**, O. A. LEONARD (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 11, pp. 1, 8).—Effective control of nutgrass by cultivation is reported.

## HORTICULTURE

[**Horticultural studies by the North Carolina Station**]. (Partly coop. U. S. D. A.). (*North Carolina Sta. Rpt.* 1941, pp. 39-40, 41-45, 46, 49-50, figs. 8).—Among studies, the progress of which is reviewed, are the storage of apples in modified atmospheres, the use of nematode-resistant Shalil peach rootstocks, the use of chloropicrin and other chemicals for disinfecting soils from which old peach trees were removed, chemical control of peach tree borers, the nutritive requirements of the strawberry, the time factor in fertilizing strawberries, vitamin C in sun-ripened v. shade-ripened strawberries, the renovation of strawberry beds, the breeding of carnations, and the development of a new pecan named Cape Fear.

[**Horticultural studies by the Vermont Station**] (*Vermont Sta. Bul.* 495 (1942), pp. 29-30, 31, 32-34, fig. 1).—Among studies by M. B. Cummings and C. H. Blasberg, the progress of which is reviewed, are fruit setting and progeny fertility in pears, nature and causes of bitter pit in apples, methods of preventing biennial bearing in the apple, spraying apple trees with naphthalene acetic acid and its derivatives, and fertilization of apple trees.

**An accurate fertilizer applicator for field test plots**, J. P. FAIRBANK and P. A. MINGES. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 310-314, figs. 3).—The construction and operation of an effective machine are discussed.

**A summary of starter solution experiments on tomatoes and cabbage at State College, Pennsylvania**, E. M. RAHN. (Pa. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 305-309).—As a result of 4 years' work with tomatoes

and 1 year with cabbage, the conclusion is reached that certain starter solutions are effective in increasing yields, particularly early yields of both vegetables. There were indications that phosphorus is probably the most important element for the tomato and nitrogen for early cabbage, but that starter solutions containing nitrogen, phosphorus, and potassium should be used in general practice. Certain effective formulas are outlined. Treatment of roots of tomato transplants with 10 p. p. m. solutions of indolebutyric acid and vitamin B<sub>1</sub> did not increase yields, and in one season the indolebutyric acid reduced total yields.

**The influence of irrigation water on the yield and quality of sweet corn and tomatoes, with special reference to the time and number of applications,** H. B. CORDNER. (Okla. A. and M. Col.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 475-481, figs. 2).—Yields of sweet corn and tomatoes when grown in north central Oklahoma may be increased substantially by a few well-timed irrigations. With sweet corn, irrigations applied at silking time and later when the ears were developing were most helpful. Presilking irrigations appeared to promote vegetative growth without benefit to yield of ears. With tomatoes, light irrigations which undoubtedly caused marked variations in surface soil moisture were actually detrimental to fruit set. In most cases increased yields obtained from irrigated tomatoes were attributable to increased plant size and not to increased fruit set. Irrigations applied during the preharvest period were most beneficial to fruit production. In certain plots irrigated during the harvest period, the percentage of fruits affected with blossom end rot was increased. The greatest yields were obtained when the tomato was irrigated throughout its entire growing season.

**Influence of photoperiod on the time of flower primordia differentiation in the Perfection pimiento (*Capsicum frutescens* L.),** H. L. COCHRAN. (Ga. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 493-497, fig. 1).—Perfection pimiento peppers grown in 6-in. pots filled with fertile potting soil were given different periods of light exposure. No flower bud differentiation occurred in plants under the 0- and 6-hr. day lengths, but it did take place under 8-, 10-, 14-, 18-, and 24-hr. periods and in normal (12-hr.) days. Differentiation occurred first in the normal-day plants, 23 days after they emerged from the soil. A total of 26, 26, 27, 28, and 31 days was required under the 8-, 10-, 14-, 18-, and 24-hr. treatments, respectively. With but one exception, the time of appearance of the first visible buds occurred in the same order under the various photoperiods as the primordia were differentiated. Growth of the plants at the time of primordia differentiation, as measured by height and green weight, varied directly with the photoperiod under which they were grown.

**Field plot technique studies with tomatoes,** J. D. HARTMAN and E. C. STAIR. (Purdue Univ.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 315-320).—Calculations based on uniformity trial data with tomatoes showed that when one treatment or variety is to be compared rather accurately with a few others, and when comparisons between any two of these other treatments or varieties are of secondary importance, the use of long alternate row check plots seems to be an efficient and practical design. From alternate check plots the data should be analyzed as differences between the yields of rows of treatments other than the check and the means of the two adjoining check rows. The use of smaller plots with 24 complete blocks did, however, give more reliable means for treatments than did the alternate row check method. With complete blocks, of course, all comparisons were equally accurate.

Even with only 16 different varieties or treatments, the arrangement of 5 replicates of single-row plots 96 ft. long in balanced incomplete blocks produced a standard error of a mean difference as small as could have been obtained with 7 replicates had the plots been grouped only in complete blocks. For either 4 or

16 different treatments, single-row plats 96 ft. long seem preferable to 4-row plats 24 ft. long when rows are spaced 6 ft. apart. This statement is true when plats of each shape are arranged in designs best adapted to their shapes.

**Correlation between fresh weight and area of tomato leaves, F. A. ROMSHE** (Okla. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), p. 482).—The fresh weight of tomato leaves in plants grown in the greenhouse proved to be an accurate measure of relative leaf area and could be used in comparative studies involving this factor. The ratio of area to weight of the leaflets was 5.7:1 and for the entire leaves 3.4:1.

**Sand culture studies of the effects of various concentrations of added salts upon the composition of tomato plants, R. F. WALL and E. L. HARTMAN** (Okla. A. and M. Col.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 460-466, figs. 6).—The results of investigations with Marglobe tomatoes grown in fine quartz, supplied with a nutrient solution to which various salts were added, indicated that the coordinated effects of temperature, light, relative humidity, transpiration, and respiration as they affect salt absorption must be considered in adequately defining salt toxicity, as salt absorption (and therefore salt injury) parallels the transpirational and respirational processes of the plants and the variations so produced are very large. Salt toxicity is apparently due to high ionic concentration, reduction in availability and/or absorption of the other ions, and the effect of the induced pH. The pH toxicity exceeds the other toxic factors with  $\text{NaHCO}_3$ ; with other salts the pH effect is subordinate.

**Experiments in plowing under coarse organic matter for tomatoes, J. D. HARTMAN and E. C. STAIR** (Purdue Univ.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 471-474).—The comparatively light-colored Crosby silt loam and silty clay loam tomato soils of central Indiana rarely produced as well as the darker Brookston silty clay loam, even when supplied with relatively large amounts of fertilizer. The addition to Crosby soil of large quantities of organic matter and sufficient nitrogen to make a nitrogen to carbon ratio of 1:20 in the added material failed to increase significantly the yields of tomatoes. This was true when organic matter was added to the soil in spring and when it was grown on the ground the summer preceding the tomato crop. There was, in fact, some indication of a detrimental effect of plowing under large amounts of coarse organic material.

**Effect of nutrient root media on loss in weight and amount of rot in stored tomatoes, J. H. MACGILLIVRAY** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 289-292).—Best of All tomatoes grown in various soil and nutrient media were picked at the usual greenhouse-ripe stage and stored at 55° and 77° F. All of the plants had made average or better growth, but analyses of the leaves and fruit showed certain compositional differences associated with the nutrient supply. Fruit yields indicated a somewhat greater variability in physiological state than did the analyses. As to behavior in storage, the various media did not materially affect the amount of rot or weight loss of the fruit.

**Studies of gray-wall of tomato, O. A. LORENZ and J. E. KNOTT** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 445-454, figs. 2).—"Gray-wall," manifested in a grayish discoloration of the surface, is due to the development of a dark chlorophyll layer in the parenchymatous cells of the wall tissues. Since the wall on the side of the fruit which was exposed to the sun may be less than one-third as thick as that on the unexposed side, the authors suggest that the name "thin-wall" would be more descriptive than gray-wall. In severe cases over 20 percent of the tomatoes may be discolored in the packing sheds. It is believed that the trouble results from the high light in-

tensity prevailing in California. The heat effect accompanying the high light is believed to cause the thin-wall condition. In fruits that develop to their approximate size in the shade of the vines and are then exposed, sunscald usually develops without pronounced symptoms of thin-wall. The authors recommend the use of varieties that produce an abundance of foliage to protect the fruits and the protection of plants from defoliation. Fertilizers that promote vigorous growth are desirable.

**Wheel injury to tomatoes during spraying and dusting operations**, J. D. HARTMAN and R. W. SAMSON. (Ind. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 467-470, fig. 1).—Wheel damage to tomato vines during spraying and dusting operations resulted in an average reduction in yield of 5 percent in rows which were injured on one side only and 8 percent on rows injured on both sides. All wheels were equipped with vine shields. The degree of injury was practically the same whether the plants were sprayed or dusted five times or received only two delayed applications. When the total yield from all rows covered by the boom was considered, the average reduction in yield for a 6-row sprayer was 2.3 percent. For 8-, 10-, and 20-row outfits the average reductions were computed at 1.8, 1.4, and 0.7 percent, respectively.

**Pruning, fertilization, and spraying are necessary for successful home orchards**, E. A. CURREY (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 11, p. 1).—Information is presented on the pruning, spraying, and fertilization of fruit trees.

**Dormant sprays for scale insects and orchard diseases**, T. H. JONES (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 11, p. 8).—Information is given on the preparation and application of various sprays for the control of such pests as San Jose scale, peach leaf curl, etc.

**Choice of parent as influencing seed germination in fruits**, H. P. OLMO. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 171-175).—Poor seed germination in cultivated fruit may be avoided by proper selection of the mother parent. The Pearl of Csaba grape, when selfed or crossed, yielded less than 2 percent of fertile seeds. Pearl of Csaba pollen applied to Champion stigmas yielded many seedlings. Other cases of good results from the use of ovule parents with high seed viability are mentioned. A similar situation was observed in the peach, where Mayflower (ovule parent) was crossed with Lukens (pollen parent) and yielded a high percentage of fertile seed, while the reciprocal yielded none. Seed abortion of some fruit varieties, since it is largely determined by the genotype of the maternal tissue and not so much by hybridity of the developing zygote, must be attributed to the abnormal growth or nutrition of the maternal tissues, the abortion of the embryo or endosperm being a secondary reaction.

**Studies of alternate bearing in the apple**, M. J. DORSEY and R. L. McMUNN. (Univ. Ill.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 37-44).—Yield records on young trees of Grimes Golden, Jonathan, and Delicious showed a marked persistence of biennial bearing following the first heavy crop. The trees were neither fruit thinned or treated in any special manner and thus represented the normal picture of fruiting in apple trees. Fruit removal studies indicated that varieties respond differently to such treatment. Timeliness of defruiting was a definite factor, with evidence that after a certain period it is probable that not even the complete removal of the fruit will result in sufficient fruit bud formation to produce a crop the succeeding season. Complete crop loss at any time up to full bloom resulted usually in a heavy bloom the next season.

**Root-inducing substances effective on apple cuttings taken in May**, A. E. HITCHCOCK and P. W. ZIMMERMAN (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp.

292-297, figs. 2).—Cuttings of McIntosh, Grimes Golden, Northern Spy, Rhode Island Greening, Stayman Winesap, and Yellow Transparent were treated with various root-inducing substances gave relatively high percentage of rooting in from 5 to 6 weeks when the cuttings were collected in the orchard by 9 to June 3. Better success was attained during this period when cuttings were placed in sand than when in a sand-peat mixture. The detrimental effect of peat was not shown by cuttings taken in June and later. Treated cuttings rooted satisfactorily when the air was about 70° F. during the day and when cheesecloth was placed over the cuttings. It is suggested that apple cuttings should be made when the new shoots are from 4 to 7 in. long, treated with an 8 mg./gm. powder preparation of indolebutyric acid, and then planted in sand in shaded greenhouse benches.

**Trunk diameters of young apple trees on clonal stocks, J. K. SHAW.** (Mass. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 269-271).—Data are presented on the diameter of the trunks of several varieties of apples grown on clonal rootstocks. There appeared to be no correlation between the known vigor of the top variety and the enlargement at the bud union. In all cases the diameter below the union was larger than that above. Apparently the behavior at the union of the young trees in their first 3 yr. in the orchard gave little evidence upon which to base orchard value.

**Growth and yield of Steele Red apple trees as influenced by the use of various double-worked interstocks, F. N. HEWETSON.** (Mich. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 264-268).—Red Canada (=Steele Red), a variety with a reported lack of vigor, was top-worked on a number of intermediates including Fameuse, Haas, Jonathan, Northern Spy, Red Astrachan, Tolman Sweet, Virginia Crab, and Yellow Bellflower. Trees on Red Canada and seedling interstocks were introduced for comparison. Trees on Northern Spy intermediates were among the largest as well as the most productive. Fameuse, Haas, Jonathan, and Red Astrachan appeared to invigorate the top but not necessarily the yields. In fact, Red Astrachan interstocks reduced yields to a significant degree. Virginia Crab resulted in the smallest trees but by far the highest yields.

**Further observations on a narrow-leaf variation of the apple, A. P. FRENCH and L. SOUTHWICK.** (Miss. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 245-247, figs. 2).—In this second paper (*E. S. R.*, 72, p. 335) there is discussed the growth of young nursery trees propagated from narrow-leaf branches of Baldwin, McIntosh, and Red Astrachan. With Baldwin, from a total of 50 successful buds only 2 produced entirely normal Baldwin growth and 3 both normal and abnormal parts. The normal growths on these trees originated always as laterals near the base of the whip. Attempts to obtain entire trees of the narrow-leaf type by repeated pruning of the normal shoots were unsuccessful, with indications that the normal type of tissue would apparently eventually prevail.

**Preliminary observations on the fruiting of varieties other than Grimes on Virginia Crab stocks, J. A. McCLINTOCK.** (Ind. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 275-276).—Among trees of several varieties top-worked on Virginia Crab and planted in 1936, Golden Delicious was first to come into production with some fruit in 1939. Turley and Gallia Beauty bore fruit in 1940. Grimes Golden, McIntosh, and Blaxtayman fruited first in 1941, while Blackjon Jonathan, Richared Delicious, and Starking Delicious had not produced at all through 1941.

**Respiration and oxidase and catalase activity of apples in relation to maturity and storage, B. D. EZELL and F. GERHARDT.** (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 65 (1942), No. 10, pp. 453-471, figs. 12).—The effect of maturity

rity on the rate of aspiration and on the oxidase and the catalase activity of apples was studied. Respiration decreased during the early part of the growing season and reached a maximum prior to the commercial harvesting of the fruit. The time intervening between harvest and the measurement of the respired carbon dioxide may determine whether or not a later increase is shown. Oxidase activity decreased during the growing season and may or may not increase if the fruit is left on the tree past the normal harvest season. Catalase activity increased from July to November. Fruit harvested when fully mature usually showed a higher respiratory activity, a higher catalase activity, and a lower oxidase activity in storage than did fruit picked when less mature.

**Orchard identification of stone fruit rootstocks, L. H. DAY.** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 272-274, fig. 1).—The author points out some of the distinguishing morphological and color characteristics of the roots of the apricot, Myrobalan plum, almond, peach, and mahaleb and mazzard cherries that would be useful in identification of the rootstocks upon which orchard trees had been propagated.

**Overgrowth produced by edible cherry on Sargent cherry (*Prunus sargentii* Rehd.), L. E. JOLEY.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 40 (1942), pp. 277-278, fig. 1).—In a test of the Sargent cherry as a possible rootstock for edible cherries, successful unions were obtained in most varieties, but in all cases the scions quickly overgrew the stocks. This overgrowth was so striking, even in young nursery trees, that the author concluded that the Sargent cherry is not adapted as a rootstock for cherries.

**Rest period requirements for blueberries, G. M. DARROW.** (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 189-194, figs. 3).—Tests of the length of rest period requirements of the standard highbush blueberry varieties in comparison with the rabbiteye species of north Florida showed none of the highbush varieties to grow at all when introduced into the greenhouse either on October 15 or November 15. On the other hand, the rabbiteye variety Pecan did not start well in the October 15 lot but grew vigorously when brought in on November 15. In the December 15 lot, the highbush varieties all made more or less growth of flower buds, with variations in vegetative development. The January 15 and February 15 lots started both flowers and vegetative buds freely. In the following season, determinations were made of the approximate number of hours of chilling required. Pecan appeared to have completed its rest after 250 hr. of chilling. Weymouth, Rancocas, Wareham, and Cabot appeared to have partially completed their rest after 650 hr., but did better after 800 hr. For all others, except Jersey, 1,060 hr. appeared adequate.

**Effect of renovation of beds after harvest on yield and grade of strawberries, E. B. MORROW and G. M. DARROW.** (N. C. Expt. Sta. and U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 195-197, figs. 4).—Data presented on the renovation of strawberry beds showed that 2-year-old beds produced greater yields than renovated beds. The 1938 yield for Blakemore was 61 percent greater than for the old double row, 22 percent for the old triple row, and 57 percent greater for the old matted row. In 1941 the 2-year-old beds outyielded both the renovated and 1-year-old beds for Blakemore and Fairmore. The berries were larger and the percentage of No. 1 fruit was greater on the 1-yr. plants. However, the differences in size and grade were not enough to make up for the considerably lower yields in comparison with the old beds.

**Examples of incompatibility between grape varieties and rootstocks, H. E. JACOB.** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 201-203).—Among examples of serious degrees of incompatibility were Emperor.

Mollinera (Red Malaga), Palomino, and Aramon on the stock Berlandieri  $\times$  Rupestris 57-Richter. Not a single successful bench graft was obtained, although buds succeeded normally when placed on other roots. Other failures were Grenache on Berlandieri  $\times$  Riparia 5-A (Teleki) and Cortese and Barolo on Aramon  $\times$  Rupestris No. 1 (Ganzin). Tinta Amarella on Mourvedre  $\times$  Rupestris 1202 (Couderc) failed after a brief period.

**Nitrate content of grape leaf petioles as an indicator of the nitrogen status of the plant.** A. ULRICH. (Univ. Calif. et al.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 213-218).—Significant differences were recorded in the nitrate, soluble, and total N contents of leaf petioles in favor of the N-treated plats on each sampling date. With insoluble N, significant differences were recorded in the May 14 and September 3 samples, but not in the July 10 samples. When hog manure was used as a fertilizer, the yields were not increased the first season but later equaled those of plats receiving ammonium sulfate. The nitrate content of the leaf petioles failed, however, to equal that of the ammonium sulfate plats. Applications of grape pomace to vines over a 3-yr. period did not appreciably increase yields or the nitrate content of the petioles. The nitrate content of grape leaf petioles from the most recently matured leaves reflected the N status of the vines to a greater degree than did the nitrate content of the blades or the soluble, insoluble, and total N content of the petioles or blades.

**Potassium content of grape leaf petioles and blades contrasted with soil analyses as an indicator of the potassium status of the plant.** A. ULRICH. (Univ. Calif. et al.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 204-212, figs. 2).—Analyses of leaf samples collected periodically from grapevines growing on two different soils with approximately the same K content, as shown by the Nembauer and replaceable methods, reflected more closely the true K status of the vines than did the soil data. The yields for three consecutive summers were directly related to the K contents of the leaf petioles, and petiole determinations were more satisfactory than those made on leaf blades. The earlier the occurrence during the growing season of minimum K values in grape leaf petioles, the greater was the possibility of a response from K applications.

**Storage of grape pollen.** H. P. OLMO. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 219-224).—Pollen of three vinifera grapes, Muscat of Alexandria, Sultanina, and Monukka, maintained viability best at a temperature of  $-12^{\circ}$  C. ( $10.4^{\circ}$  F.) and a relative humidity of 28 percent. One lot of Monukka pollen following an initial germination of 34 percent showed 21 percent viability after 4 yr. Pollens showing 3 percent or less germination in vitro were practically worthless, while those of 6 percent or higher may give berry sets equivalent to normal. Pollen stored under the most favorable conditions gave, after 4 yr., berry sets equal to fresh material. Seedlings grown from pollination with 3-year-old pollen appeared as vigorous as those produced with fresh pollen.

**Pollen germination in the avocado.** C. A. SCHROEDER. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 41 (1942), pp. 181-182).—Numerous attempts to germinate avocado pollen by ordinary technics using sugar solutions failed, apparently because of the lack of some essential substance or condition necessary to growth. The addition of yeast, vitamin B<sub>1</sub>, and crushed stigmatic tissues did not affect germination. Satisfactory germination was obtained by placing pollen grains directly on the stigmas at temperatures of  $40^{\circ}$  F. or above. Pollen of the Leucadia variety germinated readily after storage for

32 days at 40° in a desiccator over calcium chloride. Fuerte pollen germinated after 153 days at 59°.

**Nut tree culture in Missouri**, T. J. TALBERT, (*Missouri Sta. Bul.* 454 (1942), pp. 32, figs. 16).—Information is presented relative to the several nut species that grow in Missouri, cultural requirements, propagation by grafting and building, handling of the scions, uses of nut trees, value of nuts for food, uses of the wood, etc.

## FORESTRY

**[Forestry studies by the Vermont Station]** (*Vermont Sta. Bul.* 495 (1942), pp. 25–27).—Included are reports on studies by G. P. Burns and W. R. Adams of photosynthesis in forest trees, the effect of tree spacing on diameter development, natural reproduction in forest plantations, and thinning and related silvicultural practices in natural-seeded and planted forests.

**The virgin upland forest of central New England: A study of old growth stands in the Pisgah Mountain section of southwestern New Hampshire**, A. C. CLINE and S. H. SPURB (*Harvard Forest Bul.* 21 (1942), pp. 58, figs. 12).—This is a study of species, succession, and influence of various factors such as fire and streams.

**Effect of thiamin and niacin on growth of jack-pine seedlings**, D. W. BENSEND. (Minn. Expt. Sta.). (*Jour. Forestry*, 40 (1942), No. 11, pp. 883–884).—Seedlings grown in jars of sterile sand supplied by irrigation from below with a standard balanced cultural solution were treated differently with respect to thiamin and niacin. Under the conditions of the experiment neither substance had any effect on the root or stem growth of the seedlings. There was no significant difference in the thiamin content of the seedlings receiving or not receiving thiamin, suggesting that jack pine, if given the proper raw materials, can synthesize enough thiamin for its own use.

**Early responses to weeding in some eastern mountain hardwoods**, A. A. DOWNS. (U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 11, pp. 865–872).—Analyses of repeated measurements on permanent study areas in the southern Appalachians showed that weeding was generally beneficial except for a negative reaction in the dominant crown class of yellow poplar. Weeding stimulated diameter growth particularly in the lower crown classes, increased height growth somewhat in the lower crown classes, and reduced mortality. Weeding was particularly beneficial in raising or maintaining the crown class of released trees, thus preventing suppression. Response to weeding differed between species, increased with lower crown class, and increased with better vigor.

**Results of second remeasurement of Adirondack cutting plots**, A. B. RECKNAGEL and M. WESTVELD. (Cornell Univ. and U. S. D. A.). (*Jour. Forestry*, 40 (1942), No. 11, pp. 837–840).—An analysis of measurements taken in the fall of 1940 on a series of five 28-acre plats established in 1930 and measured in 1941 (*E. S. R.*, 70, p. 341) led to the conclusion that in mixed spruce-hardwood stands of the character involved no net increase in merchantable volume of spruce and fir would probably occur for a period of at least 9 or 10 yr. after cutting. Following cutting in mixed spruce-hardwood stands, the unmerchantable size class is the major softwood-contributing component. Advance conifer reproduction, usually plentiful prior to cutting, may be reduced seriously during logging. When stands are cut for conifers only, the remaining hardwoods are likely to impede the development of understory softwoods for many years unless girdled or removed. In young growth, the usual predominance of spruce over fir is reversed and future pulpwood crops will have a greater proportion of fir than did the original stand.

## DISEASES OF PLANTS

[Abstracts of papers on plant diseases and their control] (*Assoc. South. Agr. Workers Proc.*, 43 (1942), pp. 46-49, 173-174, 202-207, 208-209, 210).—The following are included: Results Obtained in Breeding Disease-Resistant and Hardier Oats for the South, by T. R. Stanton, F. A. Coffman, and H. C. Murphy (pp. 46-47) (U. S. D. A.); Disease Studies With White Clover in Alabama, by H. R. Albrecht (p. 48) (Ala. Expt. Sta.); Seed Treatment Studies of Vegetable and Ornamental Plants, by L. H. Person and S. J. P. Chilton (pp. 48-49) (La. Sta.); Effects of Certain Cropping and Cultural Treatments on Cotton Root Rot, by C. H. Rogers (p. 49) (Tex. Sta.); Recent Developments on the Control of Cucurbit Diseases, by C. J. Nusbaum (p. 173) (S. C. Sta.); Iron Deficiency of Tung in Florida, by R. D. Dickey (pp. 173-174) (Fla. Sta.); Varietal Rating of Plums With Reference to Canker Resistance, by W. S. Flory, Jr. (p. 174) (Tex. Sta.); Breeding Tobacco for Black Root-Rot Resistance, by R. G. Henderson (p. 202) (Va. Sta.); Results of Seed Treatment Tests on Peanuts, by L. Shaw (pp. 202-203) (Univ. N. C.); Results of Cottonseed Treatment Tests in 1941 in Texas, by C. H. Rogers (p. 203) (Tex. Sta.); Studies on Soil Sterilization With Urea and Calcium Cyanamid, by R. G. Henderson (pp. 203-204) (Va. Sta.); Chemical Control of Root-Knot, by A. L. Taylor (p. 204) (U. S. D. A.); Results of Preliminary Experiments on the Control of Root Diseases of the Peach, by L. Shaw (pp. 204-205) (Univ. N. C.); Further Studies on the Reaction of Commercial Cotton Varieties to Root-Knot Nematode, by A. L. Smith (p. 205) (U. S. D. A. and Ga. Sta.); Root-Knot Resistance of Five Soybean Varieties, by A. L. Taylor (p. 205) (U. S. D. A.); Populations of Root-Knot Nematode Larvae in Two Kern County, California, Fields, by G. Thorne, M. W. Allen, J. Hare, and M. A. Lindsay (pp. 205-206) (U. S. D. A. et al.); and Observations on the Distribution of the Root-Knot Nematode in High Ridge Plantings of Potatoes and Tomatoes, by G. Thorne (p. 206) (U. S. D. A.); Cotton Seed Treatments and Angular Leaf-Spot Control, by V. H. Young (p. 207) (Ark. Sta.); Oospore Production in Cabbage Seedlings by *Peronospora parasitica* (Pers.) Fr., by F. J. LeBeau and J. A. Pinckard (p. 207) (Miss. Sta.); Cottonseed Treatment With Dust Preparations Containing Hormones Alone and in Combination With Ceresan and Spergon, by S. G. Lehman (p. 208) (Univ. N. C.); The Effect of Depth of Planting on Fuzzy and Acid-Delinted Cotton Seed, by W. W. Ray (p. 209) (Okla. A. and M. Col.); The Importance of Determining the Concentration of Carbon in Plant Extracts in Diagnosing Mineral Deficiencies by Plant Tissue Tests, by E. M. Emmert (p. 209) (Univ. Ky.); and Performance of Copper Dusts From the Standpoint of Their Inert Ingredients, by A. A. Nikitin and E. G. Anderson (p. 210).

[Papers on plant protection] (*Internatl. Crop Impr. Assoc. Ann. Rpt.*, 23 (1941), pp. 8-38, fig. 1).—The following are included: Opportunities in Seed Certification, by A. L. Clapp (pp. 8-11); Seed Certification a National Asset, by R. I. Throckmorton (pp. 11-15) (Kans. State Col.); A National Policy on Plant Disease Control, by C. R. Orton (pp. 15-21) (W. Va. Univ.); Effect of Seed-Borne Micro-organisms on Germination, by W. Crosier (pp. 22-25) (N. Y. State Expt. Sta.); Disease Infection in Hybrid Seed Corn, by B. Koehler (pp. 26-31) (Ill. Sta.); and Transmission of Diseases on and in Cotton Seed, by W. N. Ezekiel (pp. 32-38) (Tex. Sta.).

**Division of Agricultural and Food Chemistry of the American Chemical Society: Abstracts of papers presented at Memphis, Tenn., April 20 to 24, 1942** (*Amer. Chem. Soc. Mtg.*, 103 (1942), *Abstr. Papers*, pp. 1A-27A).—The following, of interest to plant pathology, are included: Sulfur Dusting for Leaf-Spot Control—A Major Factor in Peanut Production, by L. I. Miller (pp. 9-10)

(Va. Expt. Sta.) ; and Cotton Diseases and Their Control, by R. F. Poole (p. 11) (Clemson Agr. Col.).

[Phytopathological work by the North Carolina Station] (*North Carolina Sta. Rpt. 1941*, pp. 31-32, 40-41, 46, 47, 48-49).—Brief reports are included on current experimental work, including peanut leaf spot control by Cu-S dusts, emergence improvement by seed treatment, and root, stem, and fruit decay associated principally with fungi; apple bitter rot control by split lime-sulfur and bordeaux spray program; leaf burn of blueberries caused by high S fertilizer; potato diseases in the State; lettuce damping-off (principally *Rhizoctonia*) control by Cu and Hg fungicides; tomato susceptibility to Granville bacterial wilt; and cucumber leaf disease control by Cu dusts.

[Plant disease work by the Vermont Station] (*Vermont Sta. Bul. 495* (1942), pp. 19-20, 30, 34-35).—Potato nutritional studies (particularly with P) in relation to leaf roll, by A. R. Midgley; proprietary spray materials for apple scab control, by M. B. Cummings and C. H. Blasberg; and the pathology of potato scab, and factors influencing the development of virus diseases in basic strains of seed potatoes, by B. F. Lutman, are noted.

Principales enfermedades parasitarias que fueron objeto de consulta en el primer semestre (enero-junio) de 1941 [Principal parasitic diseases of plants, January-June, 1941] (*Bol. Sanid. Veg. [Chile]*, 1 (1941), No. 1, pp. 79-82).—An annotated list.

Principales enfermedades no parasitarias que fueron objeto de consulta en el primer semestre (enero-junio) de 1941 [Principal nonparasitic diseases of plants, January-June, 1941] (*Bol. Sanid. Veg. [Chile]*, 1 (1941), No. 1, p. 83).—An annotated list.

Diseases of village crops in Ceylon, M. PARK and M. FERNANDO (*Colombo: Ceylon Govt. Press, 1941*, pp. vi+72, pls. 32).—This manual, written in relatively nontechnical language, is intended as a textbook and general reference work.

The virus: Life's enemy, K. M. SMITH (*Cambridge, Eng.: Univ. Press, 1941*, pp. viii+176, pls. 9, fig. 1).—In this semipopular account of the virus diseases of both plants and animals, the eight chapters are concerned with their discovery, methods of study, their nature, how they get about, the relationship between viruses and the insects which spread them, the virus and the living cell, important virus diseases, and their prevention and control. An appendix lists some important virus diseases, and an index is provided.

Progressos teóricos e práticos no campo da virologia [Theoretical and practical progress in the field of virology], K. SILBERSCHMIDT (*Bol. Soc. Brasil. Agron.*, 5 (1942), No. 1, pp. 78-83).—A review of recent virus research, with special reference to plant infections.

Influência da temperatura no desenvolvimento e frutificação do *Coryneum longistipitatum* Berl. et Bres. [Influence of temperature on the development and fruiting of *C. longistipitatum*], A. CORDEIRO ZAGALLO (*Agron. Lusitana*, 3 (1941), No. 2, pp. 121-127, pls. 2, figs. 2; *Ger. abs.*, pp. 126-127).—The conidia germinated in culture at 2°-28° C., with the optimum at 22°. At 29° no spores germinated, but they retained their power of germination up to 30°. At the optimum temperature 97.8 percent of the spores germinated after 9 hr., but the percentage decreased as the temperature was lowered from that point. The mycelium also grew best at 22°. The conidia were developed from 5° to about 22°, with optimum at 12°-14°. Below 5° and above 22° the mycelium remained sterile.

Notes on Oklahoma Cercosporae, II, W. W. RAY. (*Okla. A. and M. Col.*). (*Mycologia*, 34 (1942), No. 5, pp. 558-562).—Continuing the series (*E. S. R.*, 85,

p. 357), descriptions are given for the following new leaf-infecting species: *Cercospora cocculicola* on *Cocculus carolinus*, *Cercospora kolkwitziae* on *Kolkwitzia amabilis*, *C. physocarp*i on *Physocarpus bracteatus*, and *C. corylina* on *Corylus rostrata*. A list of 20 species placed in the local herbarium is given.

*Monilinia amelanchieris*, E. E. HONEY. (Univ. Wis.). (*Mycologia*, 34 (1942), No. 5, pp. 575-578).—This is described as the perfect stage of *Monilia amelanchieris* pathogenic on species of *Amelanchier*.

**Nuclear behavior in the Mucorales.**—II, The *Rhizopus*, *Phycomyces*, and *Sporodinia* patterns, V. M. CUTTER, JR. (Cornell Univ.). (*Bul. Torrey Bot. Club*, 69 (1942), No. 8, pp. 592-616, figs. 21).—A continuation of the cytological study previously noted (E. S. R., 88, p. 310).

Two new chytrid genera, A. J. WHIFFEN. (Univ. N. C.). (*Mycologia*, 34 (1942), No. 5, pp. 543-557, figs. 52).—*Solutoparies pythii* n. gen. and sp. parasitizing *Pythium* sp. and *Septosperma rhizophidii* n. gen. and sp. parasitizing *Rhizophidium macrosporum* and *S. anomala* n. comb. are described.

**Host-parasite relationship in a seed-borne disease of barley caused by *Helminthosporium sativum*** Pammel, King, and Bakke, H. W. MEAD, (*Canad. Jour. Res.*, 20 (1942), No. 10, Sect. C, pp. 501-523, pls. 3, figs. 6).—A hulled barley kernel is a caryopsis enclosed by tightly adhering floral glumes. The testa, formed from the inner integument of the ovule, becomes increasingly resistant to fungi. Spikelets may become parasitized during flowering and afterwards by air-borne spores and mycelial fragments of *H. sativum*, which may cause blighting, shriveling, and discoloration of the spikelets and maturing kernels, the injury depending on the time of inoculation. Irregular dark thick-walled mycelium may become massed in the parenchyma of the glumes, pericarp, and lodicules, and ungerminated spores between the glumes and pericarp. This dormant mycelium remains viable for 2-5 yr., germinating when the kernel germinates and infecting the young tissues of the plumule and radicle as they expand and force their way through and past the infected tissues. It also colonizes the nearby soil to a limited extent. Embryo blight and pre- and postemergence blight with malformation, stunting, and lesioning of the seedling may follow infection, the amount of each depending on certain environmental factors. There are 23 references.

**Relation of loose smut to yield of barley**, W. SEMENIUK and J. G. ROSS. (Univ. Minn. et al.). (*Canad. Jour. Res.*, 20 (1942), No. 10, Sect. C, pp. 491-500, figs. 3).—To study the effect on yields a simple technic was developed to inoculate barley with *Ustilago nuda*, and the infected seed lots were mixed in different proportions with normal seed to provide at least six levels of infection from zero to the maximum. No significant correlations were found in the 1939 trials, but in 1940 a direct linear relationship was obtained between the percentage incidence of loose smut and yield reduction. For every 1 percent increase in smut, yield was reduced 0.85 percent at St. Paul, Minn., 1.4 percent at Edmonton, and 1.2 percent at Fallis, Alta. Smut did not affect tillering noticeably. Similar infections were obtained at all stations for comparable seed lots, and higher infections were noted as the rate of seeding was increased. Smut incidence at Edmonton was the same on the basis of smutted spikes as on that of smutted plants.

**Variation in reaction of Anthony oats to stem rust, *Puccinia graminis avenae***, I. W. TEVET and H. HART. (Minn. Expt. Sta. et al.). (*Phytopathology*, 32 (1942), No. 12, pp. 1087-1090, fig. 1).—In 1939 and 1940 many plants of the stem rust-resistant Anthony oats at Crookston, Minn., were found susceptible to stem rust, isolations from the pustules invariably giving race 5, which is common in the Mississippi Valley and one to which Anthony oats is usually

resistant. No morphological differences were found in susceptible and resistant plants of Anthony oats. Greenhouse attempts to render this variety susceptible to stem rust by varying the light, temperature, and moisture were unsuccessful, as also were field tests made with both major and minor fertilizing elements, in all cases about 15 percent of the plants becoming severely rusted. The progeny of seed from rust-susceptible plants were also susceptible. It is concluded that there are two strains of Anthony oats, indistinguishable morphologically and spectroscopically but differing in reaction to stem rust race 5, and that the lots of Anthony oats in use in Minnesota contain up to 15 percent of stem rust susceptible plants.

**The production of grey speck of oats in purified sand cultures,** R. H. HAGEMAN, J. S. MCHARGUE, G. D. SHERMAN, and E. S. HODGE. (Ky. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 34 (1942), No. 8, pp. 731-735, fig. 1).—Oats developed gray speck when grown in Mn-free sand culture. The chemicals used in unpurified nutrient salt solution contained sufficient Mn to prevent the trouble from becoming serious. Culture solutions containing 2 p. p. m. of Mn produced normal growths of oats. The gray speck produced on these sand cultures was identical with that occurring on Mn-deficient soil. There are 13 references.

**Relative resistance of alfalfa species and varieties to rust caused by *Uromyces striatus*,** J. M. KOEPFER. (Kans. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 12, pp. 1048-1057, figs. 4).—Using simple inoculating technic developed for obtaining heavy rust infection, laboratory, greenhouse, and field tests showed marked differences in the resistance of varieties and species of *Medicago* to *U. striatus*. *M. ruthenica* carried the highest form of resistance, while Turkestan and Hairy Peruvian proved most susceptible. A plant selection of Ladak exhibited the most resistance of any strains or varieties of the *M. sativa* group.

**Treatment of sheared beet seed,** L. D. LEACH. (Univ. Calif.). (*Spreckels Sugar Beet Bul.*, 6 (1942), No. 11, pp. 65, 68).—*Pythium* and *Rhizoctonia* were found effectively controlled on sheared seed by seed treatment with Ceresan or New Improved Ceresan, but other fungicides tested proved less satisfactory. Seed treatment failed to control water mold (*Aphanomyces*), but early planting avoided infection.

**A study of the nature of resistance of dent corn to *Diplodia zeae* (Schw.) Lev. stalk rot,** A. D. HOADLEY (*Md. Univ. Off. Pub.*, 39 (1942), No. 13, pp. 11-13).—An abstract.

**La humedad de la semilla del algodónero relacionada con su poder germinativo y con la presencia del *Aspergillus wentii*** [Moisture content of cottonseed in relation to germinability and the presence of *A. wentii*], M. A. DI FONZO (*Argentina Min. Agr., Junta Nac. Algodón, Bol. Mens.* No. 85-86 (1942), pp. 156-168, figs. 13).—The germinability of the seed was lowered and the pathogenicity of the fungus was increased by high moisture content. Control measures are suggested.

***Epichloe typhina* on imported fescue seed,** C. C. WERNHAM. (Pa. State Col.). (*Phytopathology*, 32 (1942), No. 12, p. 1093).—The author describes an outbreak of "choke" in fescue plantings originating from systemic infection of seed of *Festuca rubra genuina* and *F. rubra nemoralis* imported from Hungary in 1939.

**Las enfermedades del lino [Flax diseases],** G. GARCIA RADA ([Peru] *Min. Fomento, Dir. Agr. y Ganad., Informe No. 54* (1942), pp. 11-19, pls. 4).—A brief conspectus including *Rhizoctonia* disease, pasmo, rust, wilt, and dodder, with control measures. All except wilt are illustrated in color.

**La "fusariosis" o marchitamiento del lino en la Republica Argentina debida al "Fusarium lini" Bolley ["Fusariosis" or wilt of flax in Argentina due to *F. lini*],** C. J. M. CARRERA ([Argentina] *Min. Agr., Dir. Propag. y Pubs., Pub. Misc. No. 113* (1942), pp. 4, pl. 1).—An informative leaflet.

**Breeding flax resistant to rust,** A. C. DILLMAN. (U. S. D. A.). (*Oil, Paint, and Drug Rptr.*, 142 (1942), No. 17, pp. 3, 40B, fig. 1).—This note discusses the serious reductions of the 1942 crop from rust and the successful development of rust-resistant varieties of flax yielding high-quality oil by the North Dakota and Minnesota Experiment Stations. Seed of these varieties is being increased as rapidly as possible. Reference is also made to similar work at the Montana Station. In the meantime, recommendations are given on sanitary measures for use with the rust-susceptible Bison variety.

**Compilation of results in control of potato ring rot in 1941,** T. P. DYKSTRA. (U. S. D. A.). (*Amer. Potato Jour.*, 19 (1942), No. 9, pp. 175-196).—The results of the reports presented indicate that *Phytophthora septiconica* does not spread from hill to hill or from row to row. It may overwinter in tubers in the soil, but tests as to overwintering in the soil itself gave negative results in practically all cases. The outstanding effectiveness of  $HgCl_2$  and acidulated  $HgCl_2$  was confirmed, and iodine was almost as effective in disinfecting cutting knives, whereas nearly all other chemicals tried were unsatisfactory. Boiling water at 5, 10, and 15 sec. exposures gave good results and offers possibilities for ring rot control. Some of the best results in controlling spread between healthy and infected seed pieces followed use of  $HgCl_2$  (1-500). Acidulated  $HgCl_2$  and Cinnex Special also gave very satisfactory control. Injury to seed pieces from these treatments varied from serious to practically none. Many disinfectants used as sprays gave highly satisfactory results in disinfecting pieces of wood contaminated with the pathogen, but fumes of the chemicals tested were mostly ineffective. The ultraviolet method of detecting infected tubers continued to give satisfactory results but must be operated under proper conditions.

**Potato scab in relation to calcium, soil reaction, and the use of acid-forming and non-acid-forming fertilizers,** H. T. COOK and T. J. NUGENT (*Virginia Truck Sta. Bul. 108* (1942), pp. 1783-1795).—Scab index data analyzed on the basis of kind of fertilizer used indicated that in 3 or 4 yr. significantly more scab developed on potatoes from plats treated with non-acid-forming than with acid-forming fertilizers. This result is accounted for by the fact that most of the samples from acid-forming fertilizer plats had soil reactions unfavorable to scab, whereas the reverse was true for the non-acid-forming fertilizer plats. Divided on the basis of soil reaction there was a significantly larger amount of scab on potatoes from sections of plats with higher soil reactions (pH) than from those with lower reactions. This relationship was found when samples from both acid-forming and non-acid-forming fertilizer plats were analyzed together, as well as when analyzed separately according to kind of fertilizer. Addition of extra Ca to the soil as gypsum caused no important change in soil reaction or significant differences in amount of scab with either type of fertilizer. It is concluded that the amount of scab is closely correlated with soil reaction and only indirectly with fertilizer reaction or its Ca content to the extent that the fertilizer may change the soil reaction. It is also concluded that Ca has no effect on scab development and that Ca compounds affect it only to the extent that they may change the soil reaction. Concrete fertilizer recommendations are given. There are 25 references.

**Sample size and reliability,** D. FOLSOM. (Maine Expt. Sta.). (*Amer. Potato Jour.*, 19 (1942), No. 9, pp. 197-199).—Potato tubers are sometimes planted in the greenhouse and in the South to determine as early as possible how much

virus disease is present in the seed stock represented. The larger the number of tubers used, the more reliably will they forecast the disease incidence in future field plantings, but increasing the number of samples also increases the cost of the tests. The decision as to the best compromise between reliability and expense may be made easier by the availability of a table presented which shows the minimum sample size that may be expected to give reliability of a certain degree. The use of such a table is explained in detail.

**The pathogenicity and genetics of some sorghum smuts, S. VAHELDUDDIN** (*Minnesota Sta. Tech. Bul.*, 154 (1942), pp. 46, pls. 6, figs. 4).—Since there are four smut fungi attacking sorghum, it seemed desirable to ascertain to what extent new biotypes might arise in nature as a result of intraspecific and interspecific or intergeneric hybridization.

A study of *Sphacelotheca sorghi* revealed it to comprise a great many haploid biotypes differing in sex and culture characters. The 74 haploid derivatives from 28 chlamydospores grouped themselves into about 16 types on the basis of culture characters, and there were apparently at least 60 sex groups among them as determined by the Bauch test. When haploid lines were sexually compatible, they hybridized freely and produced new morphologic and physiologic types. Peridial color and color of smutted heads appear to be due to genetic factors. When monosporidial lines from chlamydospores obtained from brown heads were crossed the smutted heads were brown, and when the brown  $\times$  brown crosses were continued to the sixth generation only brown heads appeared. However, when haploid lines from chlamydospores of the gray type were crossed two types of heads resulted, brownish gray and gray. When a brown  $\times$  gray cross was made the  $F_1$  head type was brownish gray, and crosses between haploid lines therefrom produced brown, brownish-gray, and gray head types. Of the three possible explanations of this situation, the most likely is believed to be that the factors for brown and gray in brown  $\times$  gray dicaryophytes may have been so delicately balanced as to account for considerable variation in the color.

Conclusive evidence was obtained that dicaryophytes with different pathogenic capabilities may arise as a result of the union of haploid lines, and it is thus well to be prepared for changes in varietal resistance. It was found for *S. sorghi* that early planting, when soil temperature is likely to be low, tends to decrease the amount of smut. In 2-yr. tests of a large number of fungicides it was completely controlled by seed treatment with New Improved Ceresan, and Ceresan, Koppers "Flotation" sulfur, wettable sulfur, powdered flowers of sulfur, gas sulfur, and Kolo dust were also effective without seed injury in any case.

When 5 haploid lines of *S. cruenta* were paired with 7 haploid lines of *Sorosporium reilianum* in 18 combinations, all of them produced infection and the hybrids were fertile. Some of the  $F_1$  sori resembled one parent, others the other, and some were intermediates, but, most remarkable, there were a number resembling those caused by *Tolyposporium filiferum* and accompanied by pronounced hypertrophy of the affected host tissues. The  $F_1$  chlamydospores were intermediate between those of the parents but germinated at high temperatures better than those of either, in this respect also resembling *T. filiferum*. There was marked evidence of heterosis in promycelia, sporidia, and hyphal branches from the promycelia. The promycelia and sporidia of the hybrid were much larger than for the parents. Furthermore, some of the haploid lines from  $F_1$  chlamydospores tolerated ammonium phosphate far better than any of those of the parents. Studies of the  $F_2$  generation substantiated, in general, the findings for  $F_1$ .

The results show clearly that there are many freely interbreeding haploid biotypes within the species of sorghum smuts studied and that hybridization between biotypes of different genera can take place readily. Different morphologic types of smut sori and dicaryophytes differing in pathogenicity may result; consequently, hybridization may have far-reaching implications in the taxonomy and pathogenicity of these fungi.

**New fungicides and reduced fungicide dosages for the control of kernel smut of sorghum, R. W. LEUKEL.** (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 12, pp. 1091-1093).—In replicated tests at seven stations (1942), Spergon, Thiosan, Dubay 870, and morpholine thiuram disulfide improved the emergence and controlled kernel smut in Sharon kafir when applied at 3, 1.5, or 0.75 oz. per bushel. Captax proved effective at the 3-oz. dosage, but Sanosed was relatively ineffective. Smut in the controls ranged from 7.8 to 43.4 percent.

**Quantitative measurement of a strain of tobacco-etch virus, F. O. HOLMES** (*Phytopathology*, 32 (1942), No. 12, pp. 1058-1067, figs. 3).—Under some environmental conditions, conspicuous necrotic primary lesions were produced in leaves of *Physalis peruviana* 5-10 days after inoculation with the severe-etch strain of the virus. Assaying this virus by using the number of lesions resulting from each inoculation as an index of infectivity, several hosts were compared as potential virus sources, *Nicotiana glutinosa* apparently being the best among them. Tobacco and tomato furnished less infective extracts but were fairly satisfactory sources 10 days after initial inoculation. Virus activity in expressed juices of tobacco reached a maximum about 10 days after inoculation and then rapidly declined. Severe-etch virus withstood drying for at least 10 days in juice samples or diseased leaves, although in both cases there was a reduced infectivity with time. It retained activity well for at least 10 days in acid-buffer solutions at pH 4.5-6 held just above or just below freezing. It retained some infectivity after heating for 10 min. at 53° C., but was completely inactivated in 10 min. at 55°; it was still viable to some extent after 30 min. at 51°, but was wholly inactivated at 53° for 30 min. There are 21 references.

**Vegetable diseases in Nebraska, J. E. LIVINGSTON** (*Nebr. Agr. Col. Ext. Cir.* 1801 [1942], pp. 36, figs. 15).—A general account.

**1942 vegetable diseases as affected by the weather** (*New Jersey Stas. Plant Disease Notes*, 20 (1942), No. 6, pp. 23-26).—Notes are presented relative to weather effects on tomato defoliating diseases, anthracnose, and shoestring disease; bacterial blight of lima bean; and *Helminthosporium* blight of sweet corn.

**Notas sobre une doenç de virus em feijão de porco (*Canavalia ensiformis*, D. C.) e outra em feijão comum (*Phaseolus vulgaris* L.)** [Notes on virus diseases of Chickasaw lima bean and of common bean], K. SILBERSCHMIDT and N. R. NORREGA (*Biologico*, 8 (1942), No. 5, pp. 129-133, pls. 2; *Eng. abs.*, p. 133).—The disease of *C. ensiformis*, characterized by interveinal chlorosis and vein-banding of young leaves and a mosaic pattern without blistering, was transmitted by sap inoculations to healthy plants of this host as well as to *Soja* sp., sweet pea, and garden pea, but not to several other leguminous and solanaceous species tested. The bean disease, exhibiting mosaic patterns on young and medium leaves and slight wrinkling and savoying of older leaves, was transmitted in the same way to certain varieties of bean and pea but not to other varieties or to cowpea.

**1942 sweet corn hybrid tests** (*New Jersey Stas. Plant Disease Notes*, 20 (1942), No. 7, pp. 27-30).—Further variety and hybrid comparisons (E. S. R., 87, p. 815) are discussed and tabulated with reference to their reactions to bacterial wilt and smut.

**Diseases of greenhouse cucumbers**, L. W. KOCH (*Canada Dept. Agr. Pub.* 741 (1942), pp. 12, figs. 5).

**Doenças das sementeiras da cebola** [Seed-bed diseases of onions], O. A. DRUMMOND (*Ceres [Minas Geraes]*, 3 (1942), No. 16, pp. 251-258, pls. 2).—Anthraxnose and other diseases and their control are considered.

**Spinach wilt caused by *Fusarium* sp.** (*New Jersey Stas. Plant Disease Notes*, 20 (1942), No. 5, pp. 19-22).—This disease, reported to have been gradually increasing in incidence in northern New Jersey during recent years, was found limited to fields continuously in spinach and to be largely dependent on seasonal conditions. The above-ground and root symptoms are described. Pending further research, indirect control measures are suggested.

**Control of diseases attacking vegetable crops**, R. S. KIRBY. (Pa. State Col.). (*Veg. Growers Assoc. Amer. Ann. Rpt.*, 1940, pp. 173-187).—A brief conspectus for the principal tomato diseases.

**Control of spotted wilt of tomatoes**, C. J. MAGEE, W. L. MORGAN, and A. N. JOHNSON (*Jour. Austral. Inst. Agr. Sci.*, 8 (1942), No. 3, pp. 115-117).—Spraying the plants with tartar emetic bait greatly reduced the number becoming infected in the two series of treated plats reported upon. These results were supported in tests by commercial growers, and paris green also showed promise.

**A ring-spot type of virus disease of tomato**, R. W. SAMSON and E. P. IMLE. (Ind. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 12, pp. 1037-1047, figs. 2).—This disease, found in field and garden plantings throughout Indiana, is characterized by intricate patterns of necrotic rings and sinuous lines on young leaves, streaks on the stems, and concentric, brown, necrotic rings on the fruit. Infected tomato plants outgrow the necrotic phase and subsequently show either no detectable symptoms or only a vague mottling, but the virus is still present in the symptomless parts. Transmission tests with *Thrips tabaci* were unsuccessful and inconclusive. In the greenhouse development is more rapid and destructive at 80° than at 70° or 62° F. The susceptibility of 78 species in 27 families was tested, disease symptoms being produced on 2 species of the Amaranthaceae, 1 of the Martyniaceae, and on 19 species and varieties of the Solanaceae. It was recovered, by return inoculation to jimsonweed and tomato, from *Amaranthus tricolor* and from 16 species and varieties of the Solanaceae. Studies of the properties of the virus in tomato-plant extract are reported. Differences in symptoms, host ranges, and properties clearly indicated that the tomato ring spot virus is distinct from those of tobacco ring spot and potato ring spot and ring mosaic. The symptoms on tomato are highly suggestive of those produced by the spotted wilt virus, but it has a more restricted host range and a higher thermal death point. Tomato plants affected with tomato ring spot were not protected from infection by a suspected culture of the spotted wilt virus.

**Resistance of watermelon to the wilt disease**, A. E. BRAUN. (Univ. Idaho). (*Amer. Jour. Bot.*, 29 (1942), No. 8, pp. 683-684).—In this study more acetic acid was found in the Citron, a variety of watermelon less susceptible to *Fusarium oxysporum niveum*, than in the Kleckley Sweet, a more susceptible variety. Further investigations, however, will be needed to prove definitely that the acetic acid is the basis of resistance.

**Algunas enfermedades de las plantas en la zona frutera de Boyacá** [Some diseases of the fruit zone of Boyacá], R. ORREGÓN BOTERO (*Rev. Facult. Nac. Agron. [Colombia]*, 5 (1942), No. 19, pp. 594-633).—Special consideration is given to diseases of apple and peach and their control, including listings of varieties found resistant.

**An apple rot fungus morphologically related to a human pathogen**, L. P. MCCOLLOCH. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 12, pp. 1094-

1095).—The author's study of the apple-rotting fungus *Sporotrichum malorum* resulted in its transfer to *Phialophora malorum*. *S. carpogonium* is considered synonymous with *P. malorum* and treated as a strain of that species. The apple-rotting fungus aligns itself with the form-genus *Phialophora*, strictly in a morphological sense.

**Boron deficiency in pear trees**, J. R. KIENHOLZ (*Phytopathology*, 32 (1942), No. 12, pp. 1082-1086, fig. 1).—Boron applications to the soil around pear trees corrected a condition characterized by fruit pitting, especially near the calyx end, and by superficial cankers on younger branches. Without treatment, dieback of twigs follows and the trees gradually die. On fruit the symptoms resemble those of the virus-induced stony pit. It is suggested that the pear disease variously termed "crinkle," "bitter pit," and "internal cork" in Australasia is the same as stony pit. Black end of the fruits, attributed to stock and scion relations, was not corrected by boron.

**Peach twig blight hits orchards hard**, O. T. McWHORTER. (Oreg. State Col.). (*Better Fruit*, 37 (1942), No. 4, p. 3).—A note on the epidemic proportions of twig blight and brown rot in unsprayed orchards (1942), with production of clean fruit where recommended precautions were carried out.

**The effect of certain added materials on bordeaux mixture in the control of peach blight and leaf curl**, E. E. WILSON (*Hilgardia* [California Sta.], 14 (1942), No. 9, pp. 491-515, figs. 3).—For adequate protection of peach trees against attack by *Coryneum beijerinckii* the twigs must be protected by a fungicide weather-resistant throughout the winter. Used in sufficient amounts, a dormant-type petroleum oil was found to increase the tenacity of bordeaux and its resultant control of blight. Neither bentonite nor cottonseed oil appeared to affect the tenacity of bordeaux or its control of twig infection. None of the added materials affected the efficiency of bordeaux for control of leaf curl (*Taphrina deformans*), a single fall application, with or without supplements, effectively reducing the disease.

In laboratory tests, with a constant volume of spray applied by an atomizing apparatus onto vertical surfaces of cellulose nitrate, when bordeaux and bordeaux plus 3 percent of oil emulsion were applied until the liquid showed signs of running down the surface the latter mixture deposited an average of 37 percent more Cu. With both types of bordeaux the deposit was greater at the runoff than at the drip stage. As to the length of time to produce runoff, oil-bordeaux was found to require the longer period. On coming in contact with a surface during application, the area covered by the spray droplets was largely determined by the wetting properties of the liquid. Since bordeaux wetted the surface somewhat better than oil-bordeaux, the droplets of this material occupied the larger area. As fewer were required to cover the surface, less bordeaux than oil-bordeaux was required to produce runoff and hence less was retained by the surface. When application was prolonged until liquid had drained from the surface and the retained precipitate was dried, the oil-bordeaux was found more evenly distributed than the bordeaux. An apparent explanation is given. Though inadequate to explain the different problems encountered in the field, these laboratory results contain suggestions that would account for wide variabilities in deposits between years, or among applications made by different individuals.

In laboratory comparisons of the two types of bordeaux to spores of *C. beijerinckii* and *Sclerotinia fructicola*, those at 8-8-100, with and without oil, were of such uniformly high toxicity as to be indistinguishable in this respect, but when successive dilutions were made bordeaux appeared somewhat more toxic than oil-bordeaux. Another assay method consisting in germination of the spores in elongated drops of water, placed on slides with one end of the drop resting

over a dried film of the fungicide and the other extending over clean glass, gave similar results. In artificial weathering tests 2 percent or more of oil emulsion was found to reduce the loss of Cu and sulfate from dried bordeaux films. In tests of wash water from weathered bordeaux and oil-bordeaux films more soluble Cu was found to escape from the latter, but it was determined that most of the soluble Cu was held by oil which escaped during weathering. Oil extracted from thoroughly dried oil-bordeaux films by anhydrous ether contained considerable amounts of soluble Cu, but the presence of this oil-held soluble Cu did not appear to increase markedly the toxicity of the wash water to fungus spores.

**Diseases of small fruits in Idaho**, E. C. BLODGETT (*Idaho Sta. Bul.* 246 (1942), pp. 27, figs. 20).—This is a conspectus of parasitic (including virus) and nonparasitic diseases of brambles, bush fruits, grapes, and strawberries, with control measures.

**Blueberry cane canker**, J. D. DEMAREE and M. S. WILCOX. (U. S. D. A.). (*Phytopathology*, 32 (1942), No. 12, pp. 1068-1075, figs. 3).—This disease is said to be of considerable economic importance in the southeastern United States, having been observed in cultivated plantings in Alabama, Florida, Georgia, Mississippi, and North Carolina, and in wild blueberries in Florida and North Carolina. The evidence shows the causal fungus (*Phylospora corticis* n. sp.) to be indigenous on wild blueberries in the South and to have spread from them to cultivated plantings.

**Seca dos galhos da figueira [Fig canker]**, O. A. DRUMMOND (*Ceres [Minas Geraes]*, 3 (1941), No. 15, pp. 162-164, pls. 2; *Eng. abs.*, p. 164).—This serious disease due to *Phomopsis cinerascens* found attacking fig branches in Brazil is described. This is believed to be the first report from America.

**Yeasts occurring in souring figs**, E. M. MRAK, H. J. PHIAFF, R. H. VAUGHN, and H. N. NANSSEN. (Univ. Calif.). (*Jour. Bact.*, 44 (1942), No. 4, pp. 441-450).—Of the 115 yeasts isolated from 3 varieties of souring figs most were *Saccharomyces* or *Candida* species (listed and discussed). Others included were species of *Pichia*, *Zygoichia*, *Hanseniaspora*, *Kloeckera*, *Torulopsis*, *Zygosaccharomyces*, *Hansenula*, and a new species of *Debaryomyces*. The sugar tolerance of the organisms was low, most of them growing in 40° but not in 50° Ball. fig sirup. Volatile and fixed acid production was low and insufficient to cause the spoilage termed souring. Evidence is presented to show that adaptive lactase formation occurs in organisms termed *S. fragilis*. Most of the fig souring appears to result from the associative action of yeasts and acetic acid bacteria. There are 24 references.

**A diagnose de deficiências nutritivas na oliveira pela injeção de soluções salinas [Diagnosis of nutritive deficiencies in the olive by injecting saline solutions]**, F. J. DE ALMEIDA (*Agron. Lusitana*, 3 (1941), No. 1, pp. 59-70, pl. 1, fig. 1; *Eng. abs.*, pp. 69-70).—Because of the low negative pressure of the sap, injection trials proved difficult to carry out and were limited to experimental conditions. By methods described  $KNO_3$ ,  $K_2HPO_4$ , and  $NH_4H_2PO_4$  were used, but the volume of liquid absorbed was very small. In these preliminary tests branches supplied with N in the form of ammonia yielded more normal fruits of large size and with more pulp. On the same branches a large proportion of the fruits failing to develop normally took on a rounded form and remained longer on the trees.

**Notas sobre o Gloeosporium olivarum Alm.**, R. V. DE GARCIA CABRAL (*Agron. Lusitana*, 3 (1941), No. 1, pp. 49-58, pls. 2, figs. 2; *Eng. abs.*, pp. 56-57).—*G. olivarum* causes a widespread disease of olive fruits which seriously affects the crop, in some years causing almost total failure. The disease appears on fully developed fruits or those approaching maturity and shows up as sunken areas covered by tiny orange to orange-brown acervuli; later the fruits become wrinkled

and are easily shed. Successful inoculations were made on cultivated and wild olive fruits, but not on leaves, petioles, twigs, or branches. The incubation period was shorter on mature than on unripe or green stages of the fruits. The fungus grows rapidly, its optimum temperature being 26° C. Between 22° and 27° spore production was abundant in culture.

**Phytophthora cinnamomi and wet soil in relation to the dying-back of avocado trees**, V. A. WAGER. (Coop. Calif. Citrus Expt. Sta.). (*Hilgardia* [California Sta.], 14 (1942), No. 9, pp. 519-532, figs. 3).—Dying-back or decline of avocados in southern California appears to be commonly associated with excessive moisture. The roots are frequently blackened and dead, and the larger ones may exhibit brown lesions. *P. cinnamomi* and *Pythium vexans* were commonly isolated from such roots. The first had previously been recorded from avocados only in South Africa and Puerto Rico. Inoculation tests indicated that if the plants were watered normally *Phytophthora cinnamomi* could be present in the soil for at least 6 mo. without serious effect, but if the roots and soil were flooded or submerged for 1-3 days the fungus caused root injury followed by rapid wilting and death of the plants. Controls without the fungus could withstand such flooding for as long as 9 days without subsequent harm. Results of tests with *Pythium vexans* indicated that it does not injure the roots, probably growing only in weakened or dead tissues or in those already attacked by *Phytophthora cinnamomi*.

**Enfermedades del banano** [Banana diseases], J. R. JOHNSTON (*Rev. Agr. y Com.* [Panama], 2 (1942), No. 8, pp. 15-16).—A brief note on banana wilt (*Fusarium cubense*) and other diseases.

**Witches' broom disease investigations.**—II, Notes on the susceptibility of of I. C. S. selections at River Estate to witches' broom disease of cacao, R. E. D. BAKER and S. H. CROWDY (*Trop. Agr.* [Trinidad], 19 (1942), No. 11, pp. 207-209).—A continuation (E. S. R., 86, p. 203). The observations here reported were obtained from young trees and no account was taken of pod resistance.

**Early diagnosis of magnesium deficiency in Florida citrus**, B. R. FUDGE. (Fla. Expt. Sta.). (*Citrus Indus.*, 23 (1942), No. 9, pp. 1, 4-5, 14, figs. 4).—When the first visible symptoms of Mg deficiency appear in grapefruit foliage it is too late to apply Mg fertilizers to trees for prevention of further development of severe deficiency conditions. The experimental data presented definitely indicate that it is possible to determine by chemical analysis of the new spring foliage the probability of the occurrence of Mg deficiency 4-5 mo. later, and it should be possible by amending any deficiency indicated by the spring analysis to prevent the impending development of further symptoms. The practical use of this information is limited by the lack of a reliable quick method for Mg determination. Probably the most important practical point contained in the results relates to the incorporation of Mg in mixed fertilizer on a unit basis in what may be considered a maintenance program that will control Mg deficiency in the tree.

**Tizon gomoso de las ramitas de los citrus** [Brown rot gummosis of citrus], H. A. SPERONI ([Argentina] *Min. Agr., Dir. Propag. y Pubs., Pub. Misc. No. 114* (1942), pp. 4, pls. 2).—This is a brief account of the disease as it occurs in Argentina on citrus fruits and branches (illustrated in color), with suggested control measures. *Phytophthora citrophthora* and *P. parasitica* were the principal fungi encountered.

**Phytophthora root rot of citrus**, L. FRASER (*Jour. Austral. Inst. Agr. Sci.*, 8 (1942), No. 3, pp. 101-105, figs. 3).—Following a brief historical account of gummosis and foot rot of citrus, the author discusses *P. citrophthora*-induced collar rot, foot rot, and root rot in New South Wales and varietal reactions to the pathogen.

**Pythiaceous fungi on citrus**, V. A. WAGNER. (Coop. Calif. Citrus Expt. Sta.). (*Hilgardia* [California Sta.], 14 (1942), No. 9, pp. 535-548, figs. 2).—Cultures from fibrous dead roots of orange and lemon trees in various southern California localities exhibiting a dying-back or decline yielded *Pythium ultimum*, *P. debaryanum*, *P. vexans*, *P. rostratum*, *Phytophthora citrophthora*, and *P. parasitica*, the first being most frequent and the last very infrequent as compared with *Fusarium solani*, which was found on almost every root. Inoculations on orange and lemon fruits with the *Pythium* species listed, with *P. irregulare*, and with all the *Phytophthora* species that have been isolated from citrus (*P. citrophthora*, *P. parasitica*, *P. palmivora*, *P. syringae*, *P. cactorum*, *P. cinnamomi*, and *P. megasperma*) are reported upon. The distribution of the *Phytophthora* species and descriptions of the morphological characters of the *Phytophthora* and *Pythium* species which have been recorded on citrus are given.

**Infeções perenais da *Tranzschelia pruni-spinosae* Pers. na *Anemone coronaria*** [Perennial infection of *A. coronaria* with *T. pruni-spinosae*], B. D'OLIVEIRA and M. DE L. V. BORGES (*Agron. Lusitana*, 3 (1941), No. 1, pp. 71-77; *Eng. abs.*, p. 76).—Infected corms planted early in the fall gave rise to a large number of leaves during winter, but the rust did not appear until late in March. The first signs were the appearance of pycnia on the lower margins of the leaves; aecia developed only on later formed leaves. The mycelium infecting the corms was always uninucleated, the binucleated condition occurring only on the green parts. By breaking the corms into small pieces, each with one bud, it was possible to obtain plants infected with one sex only. Kept free of insects, these infections developed pycnia and sterile aecia. By inoculating such plants with spermatia from different sources of sterile rust it became possible to induce fertilization, thus showing that the rust is heterothallic. Temperature apparently controls development of the rust, 34° C. for 4 days providing sufficient to kill the fungus without harming the host plant.

**Bulb rot diseases of lilies**, E. P. IMLE. (Cornell Univ. et al.). (*Amer. Lily Yearbook*, 1942, pp. 30-41, figs. 10).—A brief conspectus of diseases of bulbs while developing in the soil, including control.

**Um vírus das Liliáceas em Portugal** [A virus of the Liliaceae in Portugal], M. DE L. D'OLIVEIRA (*Agron. Lusitana*, 3 (1941), No. 2, pp. 115-120, pl. 1; *Eng. abs.*, p. 119).—A virus disease of onions is reported to have occurred in the vicinity of Lisbon since 1939, the symptoms being those of the American "yellow dwarf" and the German "Gelbstreifigkeit." Using the carborundum-leaf rubbing method, the disease was transmitted to a low percentage of inoculated plants. Other local spontaneous hosts included *Muscari comosum* and *Narcissus tazetta*. In view of the methods of onion culture prevailing, it is not believed that the disease will become widespread in Portugal.

**Severity of narcissus basal rot increased by the use of synthetic hormones and bases**, N. W. STUART and W. D. MCCLELLAN. (U. S. D. A.). (*Science*, 97 (1943), No. 2505, p. 15).—A preliminary report on increased severity of bulb infection and stimulation of growth of the fungus *Fusarium oxysporum narcissi* in culture by various growth substances and nitrogen bases.

**Insect transmission of the virus causing narcissus mosaic**, F. S. BLANTON and F. A. HAASIS. (U. S. D. A. and [N. Y.] Cornell Expt. Sta.). (*Jour. Agr. Res.* [U. S.], 65 (1942), No. 9, pp. 413-419).—Among all the insects collected from field-grown narcissus plants and tested experimentally, the following aphids transmitted the narcissus mosaic virus: *Macrosiphum solanifolii*, *M. rosae*, *M. pisi*, *Aphis rumicis*, *Myzus convolvuli*, *M. cerasi*, and *Anuraphis roseus*. These aphids transmitted the virus to 904 of 1,558 plants of the varieties Sir Watkin, King Alfred, Minister Talmu, Spring Glory, and Victoria. Miscellaneous

insects and mites, including five species of leafhoppers, two of thrips, one of springtails, and two of mites gave negative results. There are 14 references.

**The aerosol-hypochlorite technique for the sterilization of orchid seeds,** H. CASTLE and L. G. NICKELL (*Amer. Orchid Soc. Bul.*, 11 (1942), No. 6, pp. 200-201).—Although this note deals primarily with the detailed technic of sterilizing and sowing orchid seeds, a suggestion regarding choice of culture medium is included. The method as described was developed in connection with studies on the germination of orchid seeds, but it is believed it could be applied with success in the sterilization of spores and other minute resting reproductive bodies.

**Phytomonas poinsettiae n. sp., the cause of a bacterial disease of poinsettia,** M. P. STARR and P. P. PIRONE. (N. J. Expt. Stas. et al.). (*Phytopathology*, 32 (1942), No. 12, pp. 1076-1081).—The authors describe a serious disease of *Euphorbia pulcherrima*, proved due to *P. poinsettiae* n. sp. It is recommended that this species be included in the *Corynebacterium* group of phytopathogenic bacteria.

**Hybrid rose understock resistant to nematode** (*Amer. Nurseryman*, 76 (1942), No. 8, p. 21).—A note on the resistant understock *Rosa multiflora* × *R. blanda* developed by the Iowa Experiment Station and its performance in Texas.

**Damage to catalpa due to recreational use,** D. J. WEDDELL. (Univ. Ga.). (*Jour. Forestry*, 40 (1942), No. 10, p. 807, fig. 1).—A note on cankers associated with the catalpa worm (*Ceratonia catalpae*) and the fungus *Hypoxyylon rubiginosum*, arising from bark injuries.

**The effects of various concentrations of boron on the growth of pine seedlings in water culture,** W. V. LUBBROOK (*Jour. Austral. Inst. Agr. Sci.*, 8 (1942), No. 3, pp. 112-114).—The growth rate of *Pinus radiata* seedlings in water culture increased with the concentration of B in nutrient solution up to a concentration of 0.05 p. p. m. of added B, but concentrations of 0.5 p. p. m. and over gave no further increases. Marked deficiency symptoms developed at 0.005 p. p. m. of added B and very slight symptoms at 0.01 p. p. m., but none occurred in solutions containing 0.05 p. p. m. or over. Toxicity symptoms developed in older seedlings grown in solutions containing 10 p. p. m. or over, but not in those containing 5 p. p. m. or less. Needles of B-deficient seedlings tended to contain less starch than those receiving adequate supplies, but there was no obvious difference in chlorophyll content.

**White pine blister rust control policies in New York State,** H. L. MCINTYRE. (U. S. D. A. et al.). (*Jour. Forestry*, 40 (1942), No. 10, pp. 782-785).

**Blister rust control in Washington State** (*Jour. Forestry*, 40 (1942), No. 10, pp. 806-807).

**Fused needle disease of pines,** W. NELSON-JONES (*Empire Forestry Jour.* [London], 20 (1942), No. 2, pp. 151-161, pls. 2).—The occurrence of fused needle disease is reported in England on Corsican pine, Mountain pine, and Scots pine, species not hitherto recorded as susceptible. Observations and experiments indicated that recovery occurs immediately by providing conditions favoring short root production and establishment of a normal mycorrhizal system, that the incidence of the disease is associated with the arrest of short root development and mycorrhiza formation rather than with consistent poverty of mycorrhizas, that it is not transmitted by grafting nor is it due to Zn or B deficiency, and that the degree of incidence is reduced by phosphatic dressings, probably as a result of direct stimulation of fungus activity. A new hypothesis is presented in which appearance of the disease is ascribed to a sudden water shortage at the time the leaves are beginning to expand, the deficiency arising from greatly reduced root absorption owing to failure of the root system to provide functional

short roots and mycorrhizas at this critical period of the life cycle. Careful studies of the distinct phases of growth associated with root and shoot activity in different pine species and the effect of disturbance of normal correlations in this respect are called for to determine how far the arrest of short root development and mycorrhiza formation observable in all pine trees showing symptoms of fused needle is responsible for the development of such symptoms. The work of others is discussed (14 references).

**Willow blight in West Virginia**, J. A. RUPERT and J. G. LEACH. (W. Va. Expt. Sta.). (*Phytopathology*, 32 (1942), No. 12, pp. 1095-1096).—It is shown by inoculation that this disease, apparently spreading from infected ornamental plantings to native willows, is due primarily to *Phylospora miyabeana*. *Fusicladium saliciperduum*, though universally present in young lesions, appeared to be of secondary importance only. Old lesions were sometimes invaded by *Macrophoma* sp., considered a secondary saprophyte.

**Fungi associated with typical truewood decays observed in Victorian forest trees**, G. PARKIN (*Austral. Forestry*, 6 (1942), No. 2, pp. 82-86).—In this study the fungi causing decay in 23 different specimens of wood were established and the results are tabulated and discussed, with the conclusion that a particular type of decay may be caused by any one of the several fungi associated and, vice versa, that one fungus does not necessarily produce only one type of decay.

**Longevity of the spores of some wood-destroying Hymenomycetes**, C. H. HARRISON (*Phytopathology*, 32, (1942), No. 12, pp. 1096-1097). The spore longevity of six fungi was determined by suspending the spores in sterile water, streaking on agar slants, and observing for growth with a 10 × hand lens.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

**Biology handbook** (U. S. Dept. Agr., Soil Conserv. Serv., 1942, [Region 5], pp. [6]+73, [pls. 12]).—This handbook is intended as an aid in the production of wildlife on 33 million acres of wasteland, so called because it cannot be more intensively used without waste and is properly designated wildlife land. It takes up the objectives and planning procedures (pp. 1-4), importance of animal life to agriculture (pp. 5-14), essential requirements of wildlife (pp. 15-16), wildlife conservation practices (pp. 17-12), establishment of conservation practices (pp. 43-60), and control of wildlife damage (pp. 61-68). A list of co-operating State and Federal agencies and of 50 references to the literature cited and a subject index are included.

**The mole, its life-history, habits, and economic importance**, R. S. MACDOUGALL (*Highland and Agr. Soc. Scot. Trans.*, 5. ser., 54 (1942), pp. 80-107, figs. 8).

**Rabbit raising**, G. S. TEMPLETON, F. G. ASHBROOK, and C. E. KELLOGG (U. S. Dept. Int., Fish and Wildlife Serv., Conserv. Bul. 25 (1942), pp. II+63, figs. 35).—This supersedes Farmers' Bulletin 1730 (E. S. R., 72, p. 375).

**The animal parasites of the fox squirrel (*Sciurus niger rufiventer*) and the gray squirrel (*Sciurus carolinensis carolinensis*)**, J. UHRICH and E. GRAHAM (*Anat. Rec.*, 81 (1941), No. 4, Sup., p. 65).—Examination of 100 fox squirrels from southeastern Kansas resulted in the finding of the following parasites: *Eimeria* sp. in 65 percent; an unidentified sporozoan 1; an unidentified amoeba 1; *Catenotaenia* sp. 2; cysts of *Taenia pisiformis* 1; *Heligmodendrium hassalli* 15; *Trichostrongylus calcaratus* 7; *Rictularia* sp. 1; *Ascaris* sp. 1; *Hoplopyllus affinis* and *Orchopeas wickhami* 63; *Neohaematopinus sciurinus* 47;

*Dermacentor variabilis* 7; an itch mite, family Sarcoptidae, 1; and *Trombicula* sp. and *Atricholaelaps glasgowi* in 15 percent.

A survey of the endoparasites of the digestive and respiratory tracts of the Hungarian partridge (*Perdix perdix perdix* Linn.) in Whitman County, Washington, L. BRUGGER. (Wash. State Col.). (*Anat. Rec.*, 81 (1941), No. 4, Sup., p. 134).—The examination of 104 partridges collected between October 1940 and September 1941 revealed an incidence of 3.9 percent of *Heterakis gallinae*. Protozoan parasites were not found. Check specimens of Chinese pheasants (*Phasianus colchicus torquatus*) and bobwhite quail (*Colinus virginianus texanus*) showed both *H. gallinae* and species of *Eimeria*.

Breeding woodcock populations, A. T. STUDHOLME and R. T. NORRIS. (Pa. Expt. Sta. et al.). (*Auk*, 59 (1942), No. 2, pp. 229-233).

Food of toads in Oklahoma, C. C. SMITH and A. N. BRAGO (*Anat. Rec.*, 81 (1941), No. 4, Sup., p. 111).—Report is made of the findings in the stomach contents of several hundred toads representing *Bufo americanus americanus*, *B. cognatus*, *B. compactilis*, and *B. woodhousii woodhousii*.

The fauna of forest-humus layers in New York, T. H. EATON, JR., and R. F. CHANDLER, JR. ([New York] Cornell Sta. Mem. 247 (1942), pp. 26, figs. 2).—The primary mechanical factors in converting forest litter to the organic portion of humus layers are apparently arthropods and earthworms. Fine mull and the mor humus layers consist largely of fecal material, while coarse mull in northeastern second-growth hardwood forests consists largely of mixed organic and mineral matter which has passed through earthworms or associated arthropods. There appeared to be no distinct faunal differences between fine mull, matted mor, granular mor, and greasy mor, and earthworms are normally absent from these, but the arthropod population is large. Arthropods are most active in the surface of humus layers and present in declining numbers through all horizons containing organic matter.

Index VI to the literature of American economic entomology, January 1, 1935, to December 31, 1939, compiled by M. COLCORD, edited by E. P. FELT and S. W. BROMLEY (College Park, Md.: Amer. Assoc. Econ. Ent., 1942, pp. [10]+815).—A continuation of this index (E. S. R., 80, p. 222).

An apparatus for obtaining interval collections of insects, W. R. HORSFALL and A. V. TULLER. (Ark. Expt. Sta.). (*Ent. News*, 53 (1942), No. 9, pp. 253-258, figs. 5).

On the preparation and preservation of insects, with particular reference to Coleoptera, J. M. VALENTINE. (U. S. D. A.). (*Smithsn. Misc. Collect.*, 103 (1942), No. 6, pp. [1]+16, figs. 5).

[Notes on economic insects and their control] (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 673, 701, 780-794, figs. 2).—Contributions presented (E. S. R., 88, p. 361) are: *Ixodes dentatus* From Iowa, by C. R. Joyce and G. W. Eddy (p. 673) (Iowa State Col.); A Further Note on Wood-Boring by the Drugstore Beetle [Weevil], by E. G. Linsley (p. 701) (Univ. Calif.) (E. S. R., 88, p. 72); Control of Flea Beetles on Potatoes at New Church, Virginia, in 1941, by L. D. Anderson and H. G. Walker (pp. 780-781) (Va. Truck Expt. Sta.); Toxicity of Certain Acid Amides and Their N-Substituted Derivatives to Codling Moth Larvae, by E. H. Stegler and C. V. Bowen (pp. 781-784); Toxicity of Sulfanilamide and Related Compounds to the Codling Moth Larvae, by E. H. Stegler and H. L. Haller (p. 784); Refrigeration Test of Transforming Codling Moth Larvae, by F. W. Carlson (p. 787); Effect of Certain Larvicides on the Overwintering Larvae of the Clear Lake Gnat, by C. C. Deonier and A. W. Lindquist (pp. 788-789); Mixing Poisoned Bait for the Tobacco Budworm, by F. S. Chamberlin and A. H. Madden (pp. 789-790); Two Activators for Pyrethrins in Fly Sprays, by E. R.

McGovran and W. N. Sullivan (p. 792), and The Nature of "Cobalt" Once Recommended for Control of the Tobacco Hornworm, by R. H. Carter (pp. 792-793) (all U. S. D. A.); The Present Status of *Parlatoria chinensis* Marlatt in St. Louis, by J. A. Denning (pp. 784-785); A Continuation of the Studies of the Relative Effects on Insect Metabolism of Temperature Derived From Constant and Varied Sources, by T. J. Headlee (pp. 785-786) (N. J. Stas.) (E. S. R., 85, p. 500); The Introduction and Recovery of *Trissolcus murgantiae* Ashm. in California, by P. De Bach (p. 787), and The Resistance of Citrus Thrips to Tartar Emetic-Sucrose Treatment, by A. M. Boyce, C. O. Persing, and C. S. Barnhart (pp. 790-791) (both Calif. Citrus Sta.); A Killing and Preserving Fluid for Immature Insects, by J. M. Hutzler and A. Peterson (p. 788) (Ohio State Univ.); *Brassica campestris* L. and *Raphanus raphanistrum* L. as Breeding Hosts of the Green Peach Aphid, by W. A. Shands, T. E. Bronson, and G. W. Simpson (pp. 791-792) (U. S. D. A. coop. Maine Sta.); The Median Lethal Dose of Calcium Arsenate for the Honeybee, by O. H. Graham (pp. 793-794) (Tex. A. and M. Col.); and The Vetch Bruchid in Georgia, by J. L. Weimer and T. L. Bissell (p. 794) (U. S. D. A. coop. Ga. Sta.).

[Contributions to a taxonomic symposium] (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 732-761).—Contributions presented at a Taxonomy Symposium held in California in 1941 are: The Needs of Systematic Entomology, by G. F. Ferris (pp. 732-738); The Significance of Taxonomy in the General Field of Economic Entomology, by E. O. Essig (pp. 739-743), and The Present Status of Entomological Nomenclature, by E. G. Linsley (pp. 758-761) (both Univ. Calif.); The Relation of Taxonomy to Biological Control, by C. P. Clausen (pp. 744-748), and Fundamental Taxonomic Problems in Quarantine and Nursery Inspection, by C. F. W. Muesebeck (pp. 753-758) (both U. S. D. A.); and The Significance of Economic Entomology in the Field of Insect Taxonomy, by T. H. Frison (pp. 749-752) (Ill. Nat. Hist. Survey).

Connecticut State entomologist, forty-first report, 1941, R. B. FRIEND ET AL. (Partly coop. U. S. D. A. et al.). (*Connecticut [New Haven] Sta. Bul.* 461 (1942), pp. 457-548+[3], figs. 9).—A progress report (E. S. R., 86, p. 64) noting studies by M. P. Zappe, L. A. Devaux, J. T. Ashworth, H. A. Merrill, R. C. Botsford, P. Garman, W. T. Brigham, J. C. Schread, G. R. Smith, J. F. Townsend, N. Turner, R. L. Beard, J. P. Johnson, R. B. Friend, H. H. Chamberlin, P. P. Wallace, G. H. Plumb, and A. DeCaprio on control of the gypsy moth, Dutch elm disease, rodent and mosquito control, parasite work, alternate hosts of the parasites of the oriental fruit moth, apple maggot and European red mite control, nonsulfur sprays with special stickers compared with standard materials for control of apple insects, European corn borer, squash vine borer, white grubs, pales weevil injury to white pine plantings in New England, elm bark beetles, and miscellaneous insects, as well as reports on conference of Connecticut entomologists, nursery and apiary inspection, and Japanese beetle quarantine enforcement.

The tenth annual insect population summary of Kansas, 1940, R. C. SMITH and E. G. KELLY. (Kans. Expt. Sta.). (*Kans. Acad. Sci. Trans.*, 44 (1941), pp. 241-256).—A continuation of this annual summary (E. S. R., 84, p. 495).

[Entomological studies in Mississippi], C. LYLE (*Miss. Farm Res. [Mississippi Sta.]*, 5 (1942), No. 11, pp. 1, 8).—These pages include Protection of Corn From Weevils (p. 1) and Control of Cattle Grubs or Warbles (p. 8).

[Entomological investigations by the North Carolina Station] (*North Carolina Sta. Rpt.* 1941, pp. 40, 41, 45-46, 49).—A progress report (E. S. R., 86, p. 65) which contains notes on the influence of warm spring evenings on codling

moth activity; the woolly apple aphid; dusting for control of cherry mites; the blueberry mite, a new pest of blueberries; and control of pickleworms by dusting.

**Proceedings of the Entomological Society of British Columbia** (*Ent. Soc. Brit. Columbia Proc.* 39 (1942), pp. 35).—Contributions presented (E. S. R., 87, p. 90) include: Biology of the Klamath Midge *Chironomus utahensis* (Diptera: Chironomidae), by D. E. Bonnell and D. C. Mote (pp. 3-7) (Oreg. Expt. Sta.); The Black Witch Moth *Erebus odora* (L.) in British Columbia (pp. 7-9) and Notes on Some Wood-Boring Beetles of Saanich, Vancouver Island, B. C. (Coleoptera: Cerambycidae and Buprestidae) (pp. 9-13), both by G. A. Hardy; The Apple Sawfly *Hoplocampa testudinca* Klug. on Vancouver Island, British Columbia, by W. Downes and H. Andison (pp. 13-16); The Advance of the Codling Moth in British Columbia, by B. Hoy (pp. 16-19); Effect of Lime and Lime-Sulphur on the Larvicidal Value of Cryolite, by J. Marshall (pp. 19-20); A Note on *Laelius* sp., a Parasite of the Carpet Beetle (*Anthrenus scrophulariae* (L.) (Hymenoptera: Bethyridae)) (pp. 21-22) and Insects and Other Arthropods in Buildings in British Columbia (pp. 23-29), both by G. J. Spencer; The Results of Further Work Done on the Control of Grain Mites in British Columbia, by H. F. Olds (pp. 29-32); and Notes on the Laboratory Rearing of Some Canadian Ticks (Acarina), by J. D. Gregson (pp. 32-35).

**Insect and other pests of 1941**, A. E. CAMERON (*Highland and Agr. Soc. Scot. Trans.*, 5. ser., 54 (1942), pp. 108-136, figs. 28).—This annual review (E. S. R., 86, p. 353) considers the status of insects and other pests affecting stored products.

**Recent quarantine adjustments giving increased consideration to biological findings**, T. L. AAMODT and A. G. RUGGLES (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 765-770).

**The requirements of parasites for more than hosts**, G. N. WOLCOTT. (P. R. Univ. Expt. Sta.). (*Science*, 96 (1942), No. 2492, pp. 317-318).

**Synthetic organic compounds as potential insecticides**, L. E. SMITH. (U. S. D. A.). (*Indus. and Engin. Chem.*, 34 (1942), No. 4, pp. 499-501).—Attention is called to some of the synthetic organic compounds that have been tested and found to possess sufficient insecticidal value to warrant more extensive trial.

**Insecticidal properties of 1,3-Indandiones—effect of acyl groups**, I. B. KILGORE, J. H. FORD, and W. C. WOLFE (*Indus. and Engin. Chem.*, 34 (1942), No. 4, pp. 494-497, fig. 1).—The acylated 1,3-indandiones have been found to be very toxic to houseflies when tested according to the Peet-Grady insecticide bio-assay method. The profound effect of the various acylations upon the insecticidal properties of this series of new compounds provides an opportunity to study the relation between organic chemical structure and insect toxicity. The insect toxicity of the acylated indandiones was increased as the number of carbon atoms in the acyl radical was increased from 2 to 5. Thereafter the activity toward flies decreased. The isomeric valeryl-1,3-indandiones exhibited powerful insecticidal action approaching that of the pyrethrins, but their action is not sufficiently rapid for use alone in contact fly sprays. Accordingly, their applications appear to be as a substitute for the major portion of pyrethrum extractives, especially in the more concentrated insecticides. The laboratory preparation of these new compounds is described, as well as the details of the biological evaluation against houseflies.

**Free nicotine in arsenical and cryolite dust mixtures**, E. H. FLOYD, I. J. BECNEL, and C. O. EDDY. (La. Expt. Sta.). (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 620-623).—Experiments with concentrated nicotine dust mixed with various diluents and insecticides are reported. A combination with cryolite and basic

copper sulfate gave perfect control of aphids and the other insects attacking cucumbers and the yield of fruit was significantly greater than that secured from the plats treated according to the established method of control with bordeaux, lead arsenate, and nicotine sulfate spray. The yield of squash was nearly doubled where this form of nicotine was used in a dust treatment which consisted of cryolite, basic copper sulfate, nicotine, and Pyrax, as compared to the same treatment where 95 percent free nicotine was used or where no nicotine was used in the dusts. It was the most effective aphicide used in calcium arsenate mixtures in controlling the cotton aphid in field experiments, and it was as effective as nicotine sulfate in calcium arsenate for reducing the aphid population. In laboratory experiments it was compatible with and effective in killing cotton aphids when tested with 10 different diluents.

**The influence of insecticides added to soils on growth and yield of certain plants,** D. B. SCOTT, JR., and E. H. KARR (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 702-708, figs. 4).—Report is made of observations on high concentrations of lead arsenate, natural cryolite, and calcium arsenate in sandy loam and clay loam soils and their effect upon the growth and yield of bush lima beans and bell peppers grown in treated soils. "Lead arsenate and calcium arsenate at all concentrations employed in the soil resulted in a considerable reduction of the plant growth, yields, and root development. Natural cryolite in the soil, however, had little effect upon the plants other than slight reductions in the length of the tap root in the 3,000 lb. per foot-acre concentrations in sandy loam. Soluble fluorine in the soil, derived from the addition of natural cryolite, was noticeably reduced after the experiment as revealed by the soil analyses at the beginning and at the end of the experiment. Determinations of the soluble arsenic in the soils support previous reports by other investigators that arsenic remains in the soluble toxic form in certain types of soil for a number of years."

**Insecticides to control bollworm, boll weevil, cotton aphid, and cotton flea hopper,** K. P. EWING and R. W. MORELAND. (U. S. D. A.). (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 626-629).—In the experiments reported, basic copper arsenate mixed with sulfur or lime produced higher yields of cotton than calcium arsenate, lead arsenate, or cryolite for the control of the bollworm and the boll weevil and higher yields than sulfur or sulfur-arsenical mixtures for the control of the cotton flea hopper. The increase in aphids following dusting with basic copper arsenate and sulfur was less than half as great as that following dusting with calcium arsenate or zinc-safened calcium arsenate. On cotton dusted with calcium arsenate there were 3.6 times as many aphids when 0.5 percent of rotenone was added as when 1 percent of nicotine was added. Calcium arsenate containing zinc sulfate did not show much promise in holding down aphids.

**The control of pillbugs and sowbugs,** R. M. BOHART and A. MALLIS. (Univ. Calif.). (*Jour. Econ. Ent.*, 35 (1942), No. 5, pp. 654-658).—Laboratory experiments were conducted with 26 different materials with a view to determining their relative toxicity to *Armadillidium vulgare* (Latr.) and sowbugs (*Porcellio* spp.). At a concentration of 5 lb. to 1,000 sq. ft. the materials found ineffective were basic lead arsenate, tartar emetic, sodium fluoride, natural cryolite, dicyclohexylamine dinitro-*o*-cyclohexylphenate, nicotine bentonite (5 percent nicotine), nicotine sulfate dust (10 percent nicotine sulfate), derris dust (two mixtures), phenothiazine, sulfur dust, and hydrated lime. Partially effective (64 to 83 percent mortality after 3 weeks) were acid lead arsenate, copper carbonate, sodium fluosilicate, and pyrethrum dust (0.2 percent pyrethrins). Highly lethal at 5 lb. to 1,000 sq. ft. and arranged in descending order of toxicity based on lower dosages were mercuric chloride, sodium arsenite, paris green, mercurous chloride, sodium arsenate, manganese arsenate, calcium arsenate, copper cyanide, and white arsenic. Of
